***Abstract*— Ultrasound imaging is the most accessible technique to study morphology and assess the condition of the neuromuscular system. Deep learning systems have already been developed and successfully applied in several tasks related to ultrasounds. Despite that, all automatic algorithms struggle in dealing with scarcity of data or underrepresented classes in bigger datasets. This study has the purpose of describing a complete pipeline from dataset creation to model validation to reliably generate B-mode ultrasound images. This pipeline is described presenting an application for the semantic guided generation of images of the gastrocnemius medialis muscle. To achieve this goal SPADE (SPatially-Adaptive (DE)normalization) algorithm [1] was applied. 480 images (400 train, 80 test) with a wide range of echogenicity levels in the cross-sectional area of the muscle were used to train and test this approach. On the test set, a PSNR (mean ± st.dev.) of 20.16 ± 0.67 dB and an SSIM of 0.38 ± 0.02 were achieved when giving to the model the original style-label pair as the one in the real dataset. The generated images from the test set were also used as input to a pretrained segmentation model. The resulting output showed a Dice score of 0.862 ± 0.147, closely matching the results using the real images that was 0.867 ± 0.154. In this work, a generic pipeline for applying a semantic guided method for image generation is presented. The developed framework could benefit both automated algorithms for augmenting the datasets and filling the gap in underrepresented classes, as well as clinicians to have a tool for assessing how a certain structure could look with a different texture representation or as a customizable teaching system.**

***Keywords*— GAN, image synthesis, ultrasound, SPADE.**

I. Introduction

Medical imaging has an important role in the assessment of subject conditions. Ultrasound (US) is the most easily accessible method when investigating several body districts such as the neuromuscular system, inner organs, breasts, and many others. In B-mode acquisitions, the echogenicity level is a clear indicator of the condition of the scanned organ. Some examples might be the echogenicity of the Cross-Sectional Area (CSA) of the muscle [2], nodule echogenicity in Thyroid assessment [3], or breast lesion echogenicity [4].

Organs that present an echogenicity or other image features that are correlated with a pathological condition, are a minority in the spectrum of clinical acquisitions and present a challenge for automatic algorithms due to their lower numerosity and reduced contrast with surrounding structures [5]. Having a way to produce synthetic images with controllable texture features could aid the training of down-stream deep learning systems for segmentation and classification by oversampling and better representing the minority classes. The intuition behind the possibility to oversample the minority class without adding redundancy to the dataset derives from the manifold hypothesis for generative models [6][7]. If the model learns a manifold in the solution space where the minority class is represented, we can traverse that manifold to generate realistic looking and semantically correct new samples.

Moreover, generating an image tuning only the texture features maintaining a fixed semantic content, can provide an image of how the same organ would look with a different texture. This possibility can help the physician to envision the possible evolution of the subject condition in time or can support the classification decision providing examples of the same structure at different pathology levels.

In the last years, generative models such as Generative Adversarial Networks (GAN) and more recently Diffusion models have gained importance in the medical field, being applied in several tasks such as super-resolution, conditional generation, image inpainting, and many others [8][9]. One particular model is the SPatially-Adaptive (DE)normalization (SPADE) model [10], a GAN that uses a conditional normalization block to preserve semantic information during the upsampling phase of the generation process. This model was one of the first solutions for semantic guided image synthesis. Other modes that perform the same task adopting similar solutions have been described in [11]-[14]. In medical imaging, this model was already applied in [15] and other examples of semantic guided image synthesis can be found in [16]-[18].

In this work, a generic pipeline for applying a semantic guided method for image generation is presented, and the main contribution is to test the SPADE model in a specific setting, proposing a validation method based on the comparison of the distribution of image features to have a quantitative assessment of model performance on domain specific indicators and performing a task-based validation centered on the automatic segmentation of the CSA.

To test the proposed pipeline, the SPADE model was applied to generate transverse B-mode ultrasound images of the gastrocnemius medialis muscle with controllable echogenicity level in the CSA, and the quality of the generated image was validated using texture features distributions and task-based methods. The final motivation of this work is to develop a tool which could be useful for developing teaching instruments for training physicians and systems to support clinical decisions.

II. Materials and Methods

A. Dataset

The dataset that was used in this work is a subset of the data presented in [1]. The images were acquired since 2003 at the

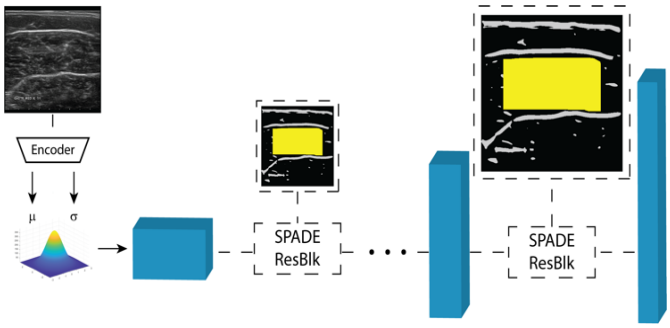

Fig. 1 Architecture of the SPADE generator.

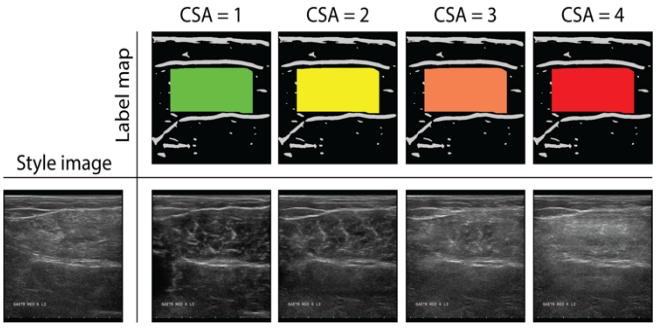

Fig. 2 Model output giving as input the same style image and changing the echogenicity level encoded in the CSA. In the label: background in black, CSA color coded, Frangi mask in light gray.

Radboud University Medical center with a fixed protocol and a convenience sample of 2.5 years of clinical results was taken. Acquisitions and annotations were performed by neurodiagnostic technicians with 5 to 10+ years of experience adopting an Esaote® MyLab Twice (Esaote SpA, Genoa, Italy) device. The probe was a 3–13 MHz linear broadband transducer, acquisition settings were the following: gain 50%, fixed depth of 40 or 60 mm depending on the muscle type, general mid-frequency setting, depth of focus at 40mm, image enhancers off. Data were anonymized so no further approval was requested from the regulatory board.

The semantic map that was fed to SPADE has 6 different labels: 0 for background, 1 to 4 to encode the gray level (i.e., the echogenicity) in the manually defined CSA, and 5 to label highly echogenic structures and especially the aponeuroses when visible. For the latter, these areas were automatically detected by applying the Frangi filter and thresholding its output at 0.4 (range 0-1) after increasing the contrast of the image. For the Frangi filter, the following parameters were used: Scale Range 6 to 9 pixels, Scale Ratio = 0.5, Beta1 = 2, Beta2 = 20. To encode the gray level of the CSA, label 1 was assigned to muscles with a mean gray level below 0.2 (range 0-1), label 2 from 0.2 up to 0.3, label 3 from 0.3 up to 0.4, and label 4 above 0.4. Image labeling can be visualized in Figure 2. We encoded the CSA to have control of its echogenicity level during inference while maintaining the same semantic structure of the image.

The dataset in [1] was sampled to have only images from the GM muscle. 100 images were randomly chosen for each CSA class in the Training set, and 20 images for each class in the Test set, for a total of 480 images. The choice not to use all the available GM images was made to have a balanced dataset, so the overall numerosity was limited by the number of images in the lowest represented class.

B. SPADE model

The official implementation of the SPADE model is available at https://github.com/NVlabs/SPADE under a CC BY-NC-SA 4.0 license. This model has the same Generator-Discriminator architecture usually seen in GANs. It takes two different inputs to decouple the style and the semantic information that it is fed to the generator. The latter takes as input a random vector of length 256 that is then passed through 5 residual SPADE blocks (SPADE ResBlks) up to a resolution of 512x512 pixels. Each ResBlks is a Resnet block, with nearest neighbor upsampling. At each block, the semantic information is input to the network via the SPADE block at the corresponding feature map resolution. This block modulates the activations of the previous layer at a pixel level depending on the label map. The Discriminator is similar to the one in the Pix2PixHD architecture and terminates with a Conv layer as in the Patch-GAN [19].

The Auto-Encoder version of the SPADE model was implemented for this study, hence using an image encoder to produce the noise input to the generator. A visualization of the SPADE generator is available in Fig. 1. More information about the architecture is available in the original paper [10].

The model was trained for 100 epochs, using a batch size of 3 and the Adam optimizer (beta1 = 0.0, beta2=0.9). The learning rate was set to constant to 0.0002 for the first 80 epochs and it decreased linearly to 0 up to epoch 100. Hinge loss and feature matching loss were used as loss functions. Training time was about 8h using a workstation with an RTX 3090 with 24Gb of VRAM.

C. Validation method

Metrics calculation for the validation of the results was performed using Matlab r2020b. To evaluate the quality of the synthetic images, all the images in the training set and the test set were generated every 5 epochs, giving as input the style image and the associated label map. As image quality metrics the 5th percentile for both the subsets for the *Peak Signal to Noise Ratio* (PSNR) and the *Structural Similarity Index Measure* (SSIM) [20] was calculated for each image. Moreover, the Frechet Inception Distance (FID) [21] of the generated training and test set were also calculated.

To validate if the network was able to reproduce a similar texture pattern as in the real dataset, all the first-order images features and four second-order Haralick features (*Contrast, Correlation, Energy, Homogeneity,* averaged for four angles 0°, 45°, 90°, 135°) were calculated. A paired T-test between each feature distribution calculated on the real and the synthetic image was made. Finally, the *Jansen-Shannon divergence* (JS) [22] was computed between the distribution of each feature in the real images and the one in the generated images to have a quantitative assessment of the distance between the real and the generated images.

The Unet model trained in [1] was applied to the Test set images both for the real images, as well for the generated ones. The original label-image pair, so with the CSA label describing the actual echogenicity of the CSA in the real image, was used generate the synthetic images. The results were compared in terms of *Dice* score between the manually defined annotations with the Unet output, using as input both the real images and the generated ones.

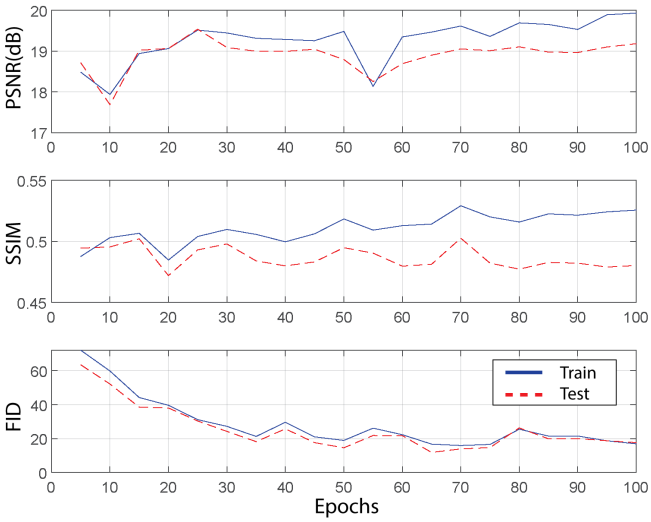

Fig. 3 Image quality indexes of generated images calculated on train (solid blue line) e test (dashed red line) set every 5 epochs. PSNR and SSIM are represented at the 5th percentile.

Finally, to qualitatively test the ability of the network to decouple the *Style* and the *Semantic* information, the ultrasound images were generated fixing the *Style* image and changing the CSA label to encode different echogenicity levels other than the one present in the *Style* image. The generated images with the corresponding inputs are presented in Fig. 2.

III. Results

Image quality assessment results are available in Fig. 3. The graph shows the progress of the 5th percentile of the metrics during training to promote the epochs. Epoch 100 presented the best mean PSNR and SSIM values, and the fourth-best FID, hence it was chosen for the following analysis.

PSNR and SSIM (mean ± st.dev.) on the test set were respectively equal to 20.16 ± 0.67 dB and 0.38 ± 0.02. Comparing FID scores across epochs on the test set shows a pattern like the one on the training set going from a value of 63.49 at epoch 5, to a value of 17.59 at epoch 100.

Table 1 summarizes the results of the JS calculation on the selected epoch (#100) of the train and test sets, along with the mean and standard deviation of every feature both in the real and in the synthesized set of images. Features with no statistical differences in the T-test are displayed in bold.

In the segmentation task, the pretrained Unet was able to adequately segment 100% of the images of the test set. Comparing network output to manual segmentations, the network achieved a Dice of 0.867 ± 0.154 on the real images. Using as input the synthesized images the Dice was 0.862 ± 0.147. To test statistical differences in segmentation performance using the two datasets, we performed a Wilcoxon paired test between the Dice metrics. P-value was 0.11 showing no statistical difference in segmentation performance using real or synthetic images.

IV. Discussion

In this work, a state-of-the-art model for image generation guided by semantic information was applied to muscle ultrasound images. The real images showed a large variability in terms of echogenicity in the CSA and the SPADE model was able to reproduce this reliably considering the whole distribution. Despite that, the difference between the same feature calculated on the real and the synthetic image is still significant for most of the features.

The comparison of feature distribution gives us the information that the SPADE model can reproduce more easily the mean value of a feature but lacks some variability of the real dataset.

Texture features analysis should be one aspect of real to simulated image comparison. The integration of human feedback and comparison of deep-learning generated feature spaces like outputs from a VGG net can give a more complete understanding of the quality and realism of simulated images.

The limitations can be addressed in future work in two main ways. The first is to add a Loss term that penalizes a narrow distribution of image features during training. The second is working on the training data both augmenting the input images or adding some noise in the label definition.
An important result can be visualized in Fig. 2. By changing the label map, the SPADE model can produce images with the same semantic content but with different levels of echogenicity while maintaining image quality across different setups. The semantic segmentation task was successful using the generated images. This result is promising especially when considering SPADE as a tool to improve existing datasets in their overall numerosity where data is scarce, and especially in the underrepresented classes that are often the ones with the worst performance indicators.

There are some limitations to this study. First of all, the choice of the best epoch during training needs to be improved. Our results in Fig.3 show a clear stabilization of the training process in the last epochs, that gives us positive feedback towards the stabilization of the GAN's training process, but there is a clear overfitting of the network. Moreover, we need to validate quantitatively the decoupling of Style and Semantic information and the reproduction of the different echogenicity levels in the CSA and more generally of the texture feature that is discriminant for the subject condition we want to simulate.

V. Conclusion

In this study, we showed a framework to implement and validate a semantic guided image generation method. We tested this pipeline using SPADE algorithm for synthesizing transverse B-mode ultrasound images of Gastrocnemius medialis. We proposed a validation method to quantify the performances of the generative model that incorporates standard image quality metrics used for natural images with domain specific metrics for medical imaging.

As future work, this framework will be tested with more modern models and different datasets comprising different organs and image modalities to investigate the performance in a wider set of tasks. It will also be necessary to improve the quality and variability of generated images and have more control over the objects in the image and their characteristics.

The final goal is to apply the described framework to develop teaching instruments for training physicians and systems to support clinical decisions. The first would be achievable generating new images from scratch, using those as a mean to evaluate the skill of the operator. The latter would be implemented as a smart tool to provide the operator with a spectrum of labelled images given the morphology of the

		Train			Test

***Abstract*— We can monitor the progression of demyelination by quantifying parameters sensitive to myelin *in vivo* using magnetic resonance imaging (MRI). g-ratio is an index used to monitor the myelin damage; here we developed a method to calculate g-ratio maps from different myelin-sensitive imaging techniques, i.e., quantitative magnetization transfer (qMT), considered as gold standard, and the T1W/T2W ratio. We compared the clinical sensitivity of the two methods, in a cohort of multiple sclerosis (MS) patients. Both approaches showed a similar trend of myelin damage in pathological subjects.**

***Keywords*—myelin, g-ratio, multiple sclerosis.**

I. Introduction

MYELIN is a lamellar structure wrapped around the axons of neurons. Since the presence of myelin significantly increases the conduction speed of the signal along the axon, myelin in essential for the transmission of the neuronal signals [1].

Multiple magnetic resonance imaging (MRI) techniques sensitive to the distribution of myelin and its quantity have been developed over time to analyze myelin *in vivo*. Among these techniques, myelin water imaging (MWI) [2] and magnetization transfer (MT) imaging [3] can be considered the most popular approaches, showing also a high correlation with myelin histological measures [4]. In this study, quantitative magnetization transfer (qMT) [5] and the T1W/T2W ratio [6] were used. Indeed, qMT estimates the magnetization transfer properties of liquid and semisolid components of tissues while T1W/T2W are semi-quantitative myelin-enhanced contrast maps.

g-ratio is an index used to quantify the state of myelin and the signal conduction speed. g-ratio estimates the thickness of the myelin for a certain axon diameter and it is calculated as the ratio between the internal and the external diameter of the myelin sheath.

Myelin thickness is influenced by demyelination and remyelination processes, which impact on the g-ratio values too. In demyelinating diseases such as multiple sclerosis (MS), g-ratio could be used to monitor the evolution of the disease.

In this study we developed an algorithm to obtain g-ratio maps from different imaging techniques and we compared their sensitivity to pathological changes in a cohort of MS patients.

II. Methods

A. MRI acquisition

Data were acquired using a Philips Ingenia 3T scanner. The protocol included: a diffusion weighted (DW) scan using an EPI spin-echo sequence (TR/TE = 6287/96 ms, resolution 2x2x2 mm^3, 3/20/20/36 DW images with b-value = 0/1000/2000/2800 s/mm^2), a high-resolution anatomical T1W 3D scan (TR/TE/TI = 6.9/3.1/810 ms, resolution 1x1x1 mm^3, flip angle = 8°) and a qMT sequence (TR/TE = 7626/59 ms, resolution 2x2x2 mm^3, 10 MT weighted and 2 reference images).

B. Subjects

59 subjects were analyzed, of which 17 healthy controls (HC; 13 females, 57±8 years), 3 relapsing-remitting MS (RRMS; 1 female, 64±3 years), 7 primary progressive MS (PPMS; 2 females, 61±4 years) and 32 secondary progressive MS (SPMS; 21 females, 56±6 years).

C. Images processing

To compute g-ratio maps both magnetization transfer and microstructural data were combined, therefore two different models were applied to different MRI images.

We pre-processed the acquired images to reduce noise and remove artefacts. Then, we processed qMT images using a two-compartment model of white matter (WM), where the hydrogen nuclei can be modeled as bounded to macromolecules or as free water protons. We obtained from these images the bound pool fraction (BPF) maps calculated as the fraction of hydrogen nuclei bounded to macromolecules [7].

Further to achieve microstructural features, the Neurite Orientation Dispersion and Density Imaging (NODDI) model was applied to obtain the isotropic volume fraction (v_{iso}) and intra-cellular volume fraction (v_{ic}) maps (Dmipy, https://nbviewer.jupyter.org/github/AthenaEPI/dmipy/) [8]. The NODDI model is a three-compartment model where each compartment (i.e., intracellular, extracellular and CSF) is associated with a different diffusion model and it is used to

estimate *in vivo* the microstructure of neurons [9].

D. g-ratio calculation from qMT

MRI-derived metrics, such as the Myelin Volume Fraction (MVF) and the Fiber Volume Fraction (FVF) [10], can be used to calculate the g-ratio *in vivo*.

$$\text{g-ratio} = \sqrt{1 - \frac{MVF}{FVF}} \qquad (1)$$

where $FVF = MVF + (1 - MVF)(1 - v_{iso})v_{ic}$ [11].

The MVF was calculated from the BPF maps and we assumed the g-ratio maps calculated from qMT as the gold standard.

$$MVF = k\,BPF \qquad (2)$$

The constant of proportionality k was estimated from the specific dataset by setting the mean g-ratio value in the forceps major to be equal to 0.7 [12] for 5 HC. The obtained k value was applied to all subjects to calculate g-ratio maps from qMT, called gratio_qMT (Figure 1).

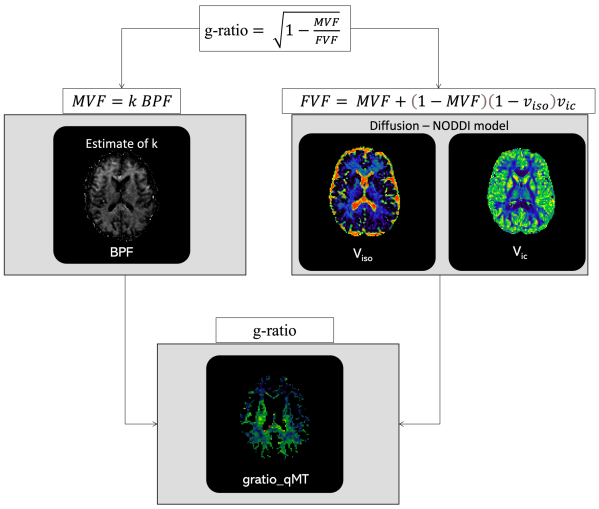

Fig. 1: pipeline for the g-ratio calculation from quantitative magnetization transfer (qMT). To calculate the Myelin Volume Fraction (MVF), the constant k for the Bound Pool Fraction (BPF) is estimated. The Fiber Volume Fraction (FVF) is calculated from v_{iso} and v_{ic} of the Neurite Orientation Dispersion and Density Imaging (NODDI) model. g-ratio maps are then obtained from MVF and FVF.

E. g-ratio calculation from T1W/T2W

We developed an innovative way to calculate the MVF, and consequently the g-ratio, from the T1W/T2W ratio. The Ganzetti method (MRtool, [6][13]) was used to obtain the T1W/T2W maps. The DW volume with b-value=0 was used as T2W input.

The existence of a significant relationship between the T1W/T2W ratio and BPF was examined in all the voxel belonging to the corpus callosum (CC). After checking for the presence of a linear relationship between T1W/T2W and BPF, parameters α and β were obtained from a linear regression model. MVF was calculated from the Eq. (3) (Figure 2).

$$MVF = \alpha \frac{T1W}{T2W} - \beta \qquad (3)$$

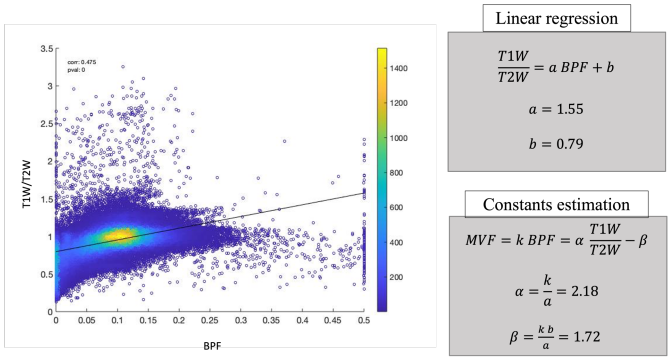

Fig. 2: on the left the linear regression line plotted on all BPF and T1W/T2W data in the corpus callosum. On the right the steps to obtain the constants α and β and the formula to calculate the Myelin Volume Fraction (MVF).

It was thus possible to calculate the map of the g-ratio, called gratio_t1wt2w (Figure 3).

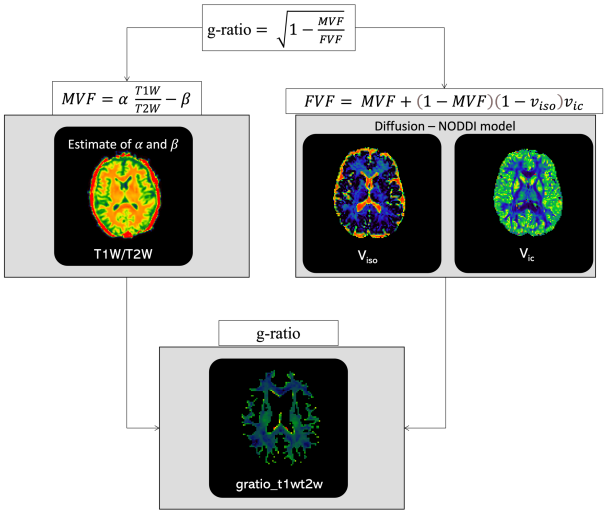

Fig. 3: pipeline for the g-ratio calculation from T1W/T2W ratio. To calculate the Myelin Volume Fraction (MVF), the constants α and β for the T1W/T2W are estimated. The Fiber Volume Fraction (FVF) is calculated from v_{iso} and v_{ic} of the Neurite Orientation Dispersion and Density Imaging (NODDI) model. g-ratio maps are then obtained from MVF and FVF.

F. Statistics

The g-ratio maps obtained with the two different approaches were compared within-subject for each of the 59 subjects. Since the non-normality of the data was verified, a Mann-Whitney U-test was performed to compare the g-ratio values of all voxels belonging to the CC.

The clinical sensitivity of the two g-ratio maps was evaluated performing a Mann-Whitney U-test between groups (i.e. HC, PPMS and SPMS). Due to the small sample size, the RRMS patients were not taken into consideration. The statistical evaluation was performed using mean values of the g-ratio in the following regions: WM, CC, and left and right optic radiations (OR_L, OR_R).

Since the small size of the groups, all of these test were performed without corrections for multiple comparisons.

III. Results

The mean value of k resulted 3.39, while α and β were respectively 2.18 and 1.72.

Figure 4 shows voxel-wise maps of the mean g-ratio in white matter obtained with the two methods across all HC subjects.

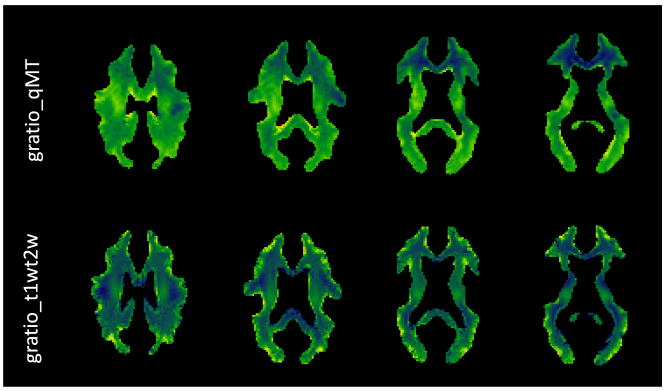

Fig. 4: Multiple axial slices (from head-to-feet) of the mean g-ratio in white matter across all HC subjects. The first row shows the g-ratio obtained from quantitative magnetization transfer (qMT), the second from T1W/T2W ratio.

From figure 4 gratio_qMT and gratio_t1wt2w maps seem to be different. According to this qualitative evaluation, Mann-Whitney U-test demonstrated that gratio_qMT and gratio_t1wt2w were statistically different ($p<0.05$).

Only the gratio_qMT showed significant differences ($p<0.05$) between groups in all the regions of interest (Figure 5).

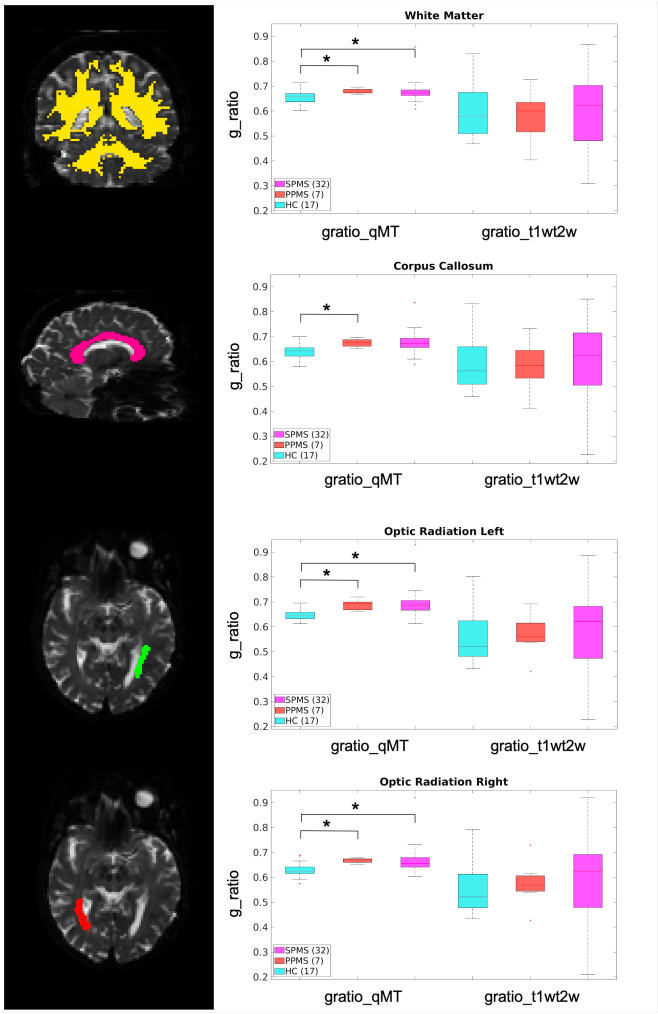

Fig. 5: boxplot of the mean g-ratio for the three groups investigated; the groups and the number of subjects per group are indicated in the legend (Healthy Controls: HC, Primary Progressive Multiple Sclerosis: PPMS, Secondary Progressive Multiple Sclerosis: SPMS). For each group, the mean value of the g-ratio is calculated in the following regions: white matter, corpus callosum, left and right optic radiations. The segmented regions are represented on the left. The asterisk indicates significant differences.

IV. Discussion and Conclusion

According to our findings, there was a difference between the values of gratio_qMT and gratio_t1wt2w. The main cause could be intrinsic to the nature of T1W/T2W images: indeed, T1W/T2W are semi-quantitative maps that are sensitive not only to the state of myelin but also to other pathological conditions, like edema and inflammation. The use of sub-optimal T2W images is another limitation of the gratio_t1wt2w maps.

Moreover, the gratio_qMT maps showed significant differences between HC and MS subjects, which were not replicated by gratio_t1wt2w - the gratio_t1wt2w maintained a similar trend of medians between groups but with a very large standard deviation of values that compromised statistical power (Figure 5). Overall, calculating a g-ratio map with the best available method could help detecting myelin damage in pathological subjects, highlighting progressive demyelination in patients with advancing MS. Therefore, g-ratio mapping might provide an additional tool to investigate the progression of demyelinating diseases and to evaluate pharmacological approaches to promote remyelination.

In this study we estimated the constant of proportionality k to obtain g-ratio maps from qMT; furthermore we developed a method to calculate g-ratio maps from T1W/T2W, starting from clinical images such as T1W and T2W. Future works can investigate the improvement of this method by using optimal T1W and T2W maps (<1 mm) in particular to see whether the large standard deviation is attributed to the sub-optimal T2W images used here. Finally, gratio_qMT displays a visible difference between the g-ratio of the frontal lobe and the occipital lobe, not seen in gratio_t1wt2w (Figure 4). Given recent publications on the whole brain connectivity, it remains to be determined whether this is biologically plausible and related to a different fiber density in different hemispheres.

***Abstract*— In this study we evaluate the performance of a fully automated analytical framework for FDOPA PET neuroimaging data, and its sensitivity to demographic and experimental variables.**

An instance of XNAT imaging platform was used to store the King's College London institutional brain FDOPA PET imaging archive, alongside individual demographics and clinical information. By re-engineering the historical Matlab-based scripts for FDOPA PET analysis, a fully automated analysis pipeline for imaging processing and data quantification was implemented in Python and integrated in XNAT.

We found good reproducibility of the data analysis by the automated pipeline (for the controls ICC=0.71, for the psychotic patients ICC=0.88). From the demographic and experimental variables assessed, gender was found to most influence striatal dopamine synthesis capacity ($F=10.7$, $p<0.001$), with women showing greater dopamine synthesis capacity than men.

Our automated analysis pipeline represents a valid recourse for standardized and robust quantification of dopamine synthesis capacity using FDOPA PET data. Combining information from different neuroimaging studies has allowed us to test it comprehensively and to validate its replicability and reproducibility performances on a large sample size.

***Keywords* — FDOPA PET, data analysis pipeline, neuroimaging biomarker, big data repository.**

I. Introduction

POSITRON emission tomography (PET), in combination with the 6-[18F]fluoro-L-dopa (FDOPA) radiolabelled tracer, has been extensively used to image the dopamine system in vivo in living human brain [1].

The tracer was introduced in 1983 [2] to quantify the integrity of the nigrostriatal dopamine and it found immediate application in subclinical models of dopamine neuronal damage and in Parkinson's Disease (PD) studies [3], [4]. Besides PD and dopaminergic neurodegeneration, FDOPA PET has proved to be valuable in other medical specialties. In psychiatry, FDOPA PET has been extensively used to quantify the dopamine system in the pathophysiology of psychotic and other symptoms across conditions, including schizophrenia [5], [6]. Several lines of evidence have linked FDOPA PET to treatment response in psychosis [7]–[10] suggesting that it might be used as a neurochemical basis to discriminate between patients likely to respond and those unlikely to respond to first-line antipsychotic drugs [11].

However, to reach clinical translation, FDOPA PET would require further validation on larger clinical datasets, aiming to support future individualized treatment and patient stratification across the different brain diseases, together with a suitable data infrastructure and robust analytical protocols to ensure high quality of the data, accurate quantification, and replicable results.

This study aims to present and validate a new infrastructure for automated analysis of FDOPA PET neuroimaging, designed with the aspiration to provide a robust benchmark for the analysis of PET data acquired with this radiotracer, facilitating FDOPA PET imaging implementation across sites and research institutions. The project takes advantage of a large FDOPA PET data repository available at the Institute of Psychiatry Psychology and Neuroscience (IoPPN) at King's College London that has been exploited to test analysis pipeline replicability and reproducibility, as well as its sensitivity to experimental and demographic covariates.

II. Methods

A. FDOPA PET data acquisition

All FDOPA PET imaging sessions in the database were acquired with a continuous dynamic acquisition (no blood sampling), with scanning beginning with the tracer injection and lasting for 90-95 minutes. All participants received carbidopa (150 mg) and entacapone (400 mg) orally ~1 hour before imaging. The FDOPA tracer (injected dose ranging from 86.4 to 414.4 MBq) was administered by intravenous bolus injection after the acquisition of a brain CT or MRI for attenuation correction, depending on the scanner availability at each imaging site. PET data reconstruction varied across imaging sites and scanner types, but all included correction for random noise, scatter, and tissue attenuation.

All the research protocols for data acquisitions were approved by local ethics committees and institutional revision boards. Informed written consent was obtained for all the participants and the studies were conducted following the Declaration of Helsinki and Good Clinical Practice.

B. Data management infrastructure

A bespoken installation of XNAT imaging technology platform [12] was deployed using the Neuroimaging Analysis Network at the Centre for Neuroimaging Sciences (King's College London) to store for each subject's demographic,

clinical information and FDOPA PET imaging data. Representational State Transfer (REST) Application-Program Interface (API) was used to upload data. Prior to storage in XNAT, the data were anonymized, harmonized in neurological convention, and corrected for radioisotope decay to ensure consistency across the data.
Analytical pipelines were integrated in XNAT, allowing their automatic execution directly on the stored data and the storage of the outcomes at scan level.

C. Automated analysis pipeline

The analysis pipeline was developed to align with our previous FDOPA imaging studies published by the Psychiatric Imaging Group (King's College London) over the last two decades [13]–[19]. The analysis of FDOPA PET imaging data was performed in MATLAB (Mathworks) and it can be described as follows. First, dynamically non-attenuated and attenuated FDOPA PET images are inputted into the pipeline. The non-attenuated dynamic images are motion corrected frame-to-frame to a single reference frame with a linear transformation using Statistical Parametric Mapping (SPM) realign function [20]. The motion information is then used to realign the attenuated dynamic images, which are then summed together to create a motion-corrected individual static PET image. A tracer-specific template and atlas defining the striatum and cerebellum are co-registered to each individual motion-correct static PET image, using SPM 12 (https://www.fil.ion.ucl.ac.uk/spm/). The Gjedde-Patlak Graphical approach [21], [22], with the cerebellum as reference region, is applied region-wise and voxel-wise to quantify Ki^{cer} (unit 1/min), a kinetic parameter used as a proxy of dopamine synthesis capacity [23]. The parametric image for each scan is finally normalised into MNI standard coordinates using the participant's PET summation image to calculate the image transformation field (non-linear transformation). The Standardized Uptake Value Ratio (SUVr) is also calculated as ratio of the tracer activity to that in the reference region. The interval 60-75 min after the injection of the radiotracer is used for this analysis, since in this time window the Gjedde-Patlak plot is linear and used to derive Ki^{cer} [11], [23].

Starting from the available MATLAB code, a fully automated version of this analysis pipeline was written in Python and integrated in XNAT.

D. Validation of the automated data analysis pipeline for FDOPA PET quantification

All the historical FDOPA scans were automatically re-analyzed using the XNAT-based pipeline. A total sample of 521 scans was used to evaluate agreement between XNAT-based and the already available MATLAB-based results, using the same analysis settings.

Data from two independent different datasets were used to test XNAT-based pipeline reproducibility. The first dataset comprised FDOPA PET test-retest imaging data from 7 healthy controls, dynamically acquired using an ECAT/EXACT3D: Siemens/CTI (Knoxville, Tennessee) PET tomograph. Full details of the research protocol and subject inclusion criteria are reported in the original reference [17].

The second dataset comprised FDOPA PET imaging data from 7 patients with psychosis before and after placebo, dynamically acquired using a Siemens Hi-Rez Biograph 6 PET scanner (Siemens, Erlangen, Germany) in 3D mode.

E. Identification of experimental and demographical covariates for FDOPA PET imaging

To investigate the presence of potential confounding factors to account in statistical analysis of FDOPA PET imaging data, the baseline scans (no pre-scan intervention) of healthy controls were selected from the database together with their experimental and demographic information. The final sample included 115 scans acquired from 3 different PET tomographs (Siemens Biograph 6 Hi-Rez, Siemens Biograph 6TruePoint, ECAT/EXACT3D) with an injected radioactivity below 200 MBq and acquisition time of 95 minutes. The experimental variables included tomograph type and radiochemistry measures (i.e. injected radioactivity, injected cold mass, specific activity) and the demographic variables included participant gender, age and weight at the time of scanning. A similar analysis was then repeated on a subsample (N=103 scans), where the data were acquired using the Biograph PET tomographs (Siemens Biograph 6 Hi-Rez, Siemens Biograph 6 TruePoint) only.

F. Statistical methods

For statistical analysis, GraphPad Prism v9 for Mac (GraphPad Software, La Jolla, CA) and SPSS (Version 27) were used. The Ki^{cer} estimates obtained from the XNAT and MATLAB analysis pipelines were compared using the Bland-Altman plot with 95% limits of agreement [24]. Correlation and mean absolute percentage difference between the two pipelines were also calculated for the following six regions of interest (ROIs): whole striatum, right striatum, left striatum, whole sensorimotor subdivision, whole limbic subdivision, and whole associative subdivision. These ROIs are commonly the primary areas of analysis in PET imaging dopamine studies [25], [26]. For both XNAT and MATLAB pipelines, test-retest reliability was estimated with the Intraclass Correlation coefficient (ICC) using a 2-way mixed-model in SPSS (version 27, IBM®), while the within-subject variation was calculated as the absolute percentage test-retest difference [17]. A p-value < 0.05 was considered statistically significant.

To investigate the effect of demographic and experimental variables on dopamine measures, a multi-linear regression model analysis was run with the K_i^{cer} and SUVr of the whole striatum as dependent variable and both experimental and demographic variables as covariates.

III. RESULTS

A. Database

The infrastructure included 892 FDOPA PET scans from 23 different studies. After removing commercials studies for which we did not have permission for data reuse, the infrastructure consisted of 792 FDOPA PET scans from 666

individuals (female 33.9%, healthy controls 29.1%) collected from four different imaging sites between 2004-2021.

The Ki^{cer} distributions across the brain are presented in Figure 1. Among the ROIs, the highest estimates were reported in the whole striatum *(Ki^{cer} mean±SD: 0.0137±0.0015 min^{-1}; min-max: 0.0102-0.0246 min^{-1} // SUVr mean±SD: 2.30±0.22; min-max: 1.71-4.11)*. Outside the basal ganglia, the substantia nigra showed the highest signal *(Ki^{cer} mean±SD: 0.0072±0.0012 min^{-1}; min-max: -0.0019-0.0122 min^{-1} // SUVr mean±SD: 1.53±0.15; min-max: 0.82-2.49)* followed by the pallidum, the amygdala, the thalamus and the prefrontal cortex. The occipital lobe, which is sometimes used as reference region for FDOPA PET quantification instead of the cerebellum [27], showed the lowest estimates in ratio to the cerebellum *(Ki^{cer} mean±SD: 0.0005±0.0004 min^{-1}; min-max: -0.0009-0.0041 min^{-1} // SUVr mean±SD: 0.97±0.06; min-max: 0.79-1.72)*.

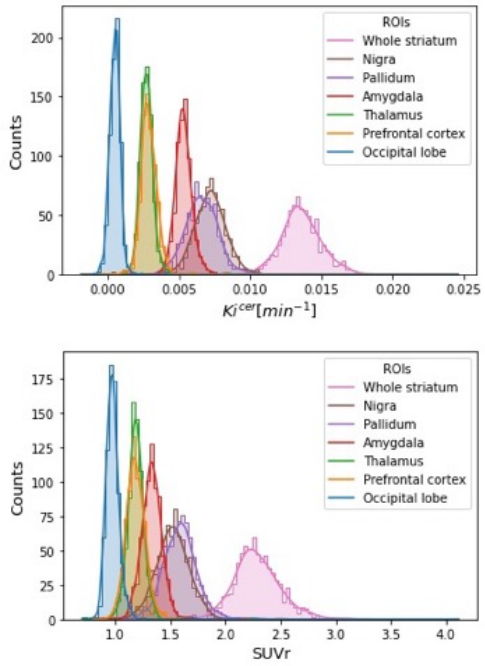

Fig. 1: Distribution of Ki^{cer} (top) and SUVr (bottom) of the main regions of interest.

B. *Validation of the automated data analysis pipeline for FDOPA PET quantification*

There was consistency between the XNAT and MATLAB pipeline, with a Ki^{cer} mean relative difference of 3.0±5.5% and a Pearson's correlation of 0.86. About 71% of the scans reported Ki^{cer} relative differences less than 5%.

In the test-retest datasets, the Bland-Altman plot confirmed good agreement between the XNAT and MATLAB pipelines for all the parameters, levels of analysis, datasets, and regions of interest. In the whole striatum, both XNAT-based Ki^{cer} and SUVr estimates are higher than the corresponding MATLAB ones within 5% mean relative difference (Figure 2). Consistently with the Bland-Altman analysis, XNAT-MATLAB Pearson's correlation ranges from 0.64 to 0.99 for Ki^{cer}, and from 0.79 to 1.00 for SUVr, with the lowest values for the limbic subdivision and the highest for the whole striatum/associative subdivision.

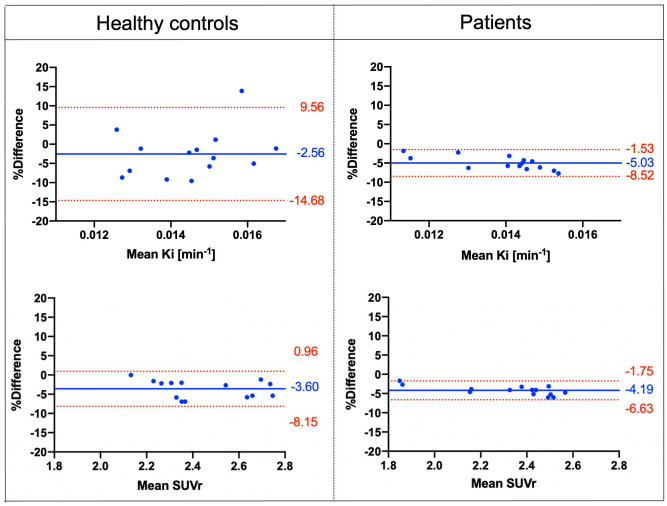

Fig. 2: Bland-Altman plots comparing Ki^{cer} and SUVr estimates of the whole striatum with XNAT-based and Python-based pipelines, both for healthy controls and patients.

In terms of test-retest reliability and within-subject variation, the automated pipeline provided reproducibility and reliability of FDOPA PET in the striatum and its subdivisions comparable to the ones previously described [17]. Averaging the results from healthy controls and patients, the ICC for the Ki^{cer} estimates ranged from 0.421 for the limbic subdivision to 0.810 for the associative subdivision. The %VAR for the Ki^{cer} estimates ranged from 6.1 for the right striatum to 12.3 for the limbic subdivision. For the SUVr, the ICC ranged from 0.865 for the limbic subdivision to 0.965 for the right striatum, while %VAR ranged from 3.0 for the right striatum to 5.1 for the whole limbic subdivision.

C. *Identification of demographical and experimental covariates for FDOPA PET imaging*

There was a significant relationship between gender and striatal Ki^{cer} estimates *($F(1,109)=10.7$, $p<0.001$)*, with dopamine synthesis capacity being higher in women than men (marginal means, women Ki^{cer}: 0.01353±0.00147 min^{-1}, men Ki^{cer}: 0.01270±0.00131 min^{-1}, effect size = 2.056E-5). Age, weight, injected radioactivity, injected cold mass, specific activity and tomograph were not significantly associated with striatal Ki^{cer}. A similar association between FDOPA PET and gender was also found when considering the subsample of scans (N=103) acquired only using the Siemens Biograph tomograph only *($F(1,98)=10$, $p=0.002$,* women Ki^{cer}: 0.01354±0.00145 min^{-1}, men Ki^{cer}: 0.01268±0.00130 min^{-1}). In contrast, none of the experimental and demographic variables were significantly associated with SUVr.

IV. Conclusion

In this study we characterized a standardized infrastructure for FDOPA PET neuroimaging to quantify brain dopamine function in living human brains. The platform was built from a harmonized FDOPA repository, integrating clinical and demographic information, together with FDOPA PET data. To our knowledge, this is the largest dataset of this type to date, including hundreds of scans with a very comparable acquisition protocol. The automated analysis framework for

FDOPA PET quantification, directly embedded in the platform, ensured full control on the analytical process and replicable results on the stored data, confirming the good replicability and reproducibility of the FDOPA PET measures in the striatum and its subdivisions. The proposed robust analytical framework aims to facilitate FDOPA PET imaging implementation across sites and research institutions and to boost the use of FDOPA PET as a clinical biomarker in psychosis and other mental disorders.

ACKNOWLEDGEMENT

This study was funded by Wellcome Trust Digital Award (no. 215747/Z/19/Z) and supported by the National Institute for Health Research Biomedical Research Centre at South London and Maudsley National Health Service Foundation Trust and King's College London. We thank all the members of the FDOPA PET imaging working group for contributing to the data collection: Sameer Jauhar, Rogdaki Maria, Robert McCutcheon, Stephen Kaar, Luke Vano, Grazia Rutigliano, Ilinca Angelescu, Faith Borgan, Enrico D'Ambrosio, Tarik Dahoun, Euitae Kim, Seoyoung Kim, Micheal Bloomfield, Alice Egerton, Arsime Demjaha, Ilaria Bonoldi, Chiara Nosarti, James Maccabe, Philip McGuire, Julian Matthews, Peter S Talbot.

***Abstract*—Quantitative microwave imaging represents an interesting complementary/alternative non-invasive diagnostic modality in the medical imaging framework. This approach provides *quantitative* images of the electric properties of target tissues located in the region of interest. In the framework of quantitative medical imaging, this work proposes a multi-step microwave imaging approach for the quantitative retrieval of human-forearm-tissue permittivity and conductivity maps. The proposed method was tested on experimental data collected at the Electromagnetic Imaging Laboratory of the University of Manitoba.**

***Keywords*—Quantitative microwave imaging, biomedical imaging, multistatic systems, experimental medical imaging.**

I. INTRODUCTION

In the framework of medical imaging, the three most common modalities are ultrasound, X-rays and magnetic resonance imaging (MRI). Ultrasound is cheap and safe since it exploits mechanical waves to perform the imaging, allowing continuous screening but with scarce resolution and difficulties in distinguishing among soft tissues. X-ray-based medical imaging generates good-resolution images with good soft-tissue contrast but at the expense of using ionising radiation which are harmful for patient health. Conversely, MRI is safe since uses static magnetic field and radio frequencies, offers excellent soft tissue contrast but still is very expensive and bulky.

Microwave imaging (MWI) represents an interesting non-invasive diagnostic modality in alternative to other conventional techniques. By virtue of its frequency spectrum (300 MHz - 300 GHz), it allows a safer and cheaper imaging which is suitable especially in the biomedical field [1]. This technique presents several advantages compared to other more established imaging modalities, such as X-ray, ultrasound, or magnetic resonance imaging (MRI) [2]. Some of the main advantages include the relatively low cost, the use of non-ionising radiation and the capability to deliver *quantitative* imaging by providing an estimate of the dielectric permittivity and conductivity maps of the investigated area without the use of contrast agents [3].

Microwave imaging has been adopted for the noninvasive exploration of several body areas, especially for breast cancer [4], [5], but also other body districts such as extremities (arm and leg) [6], brain [7], neck [8] and bones [9]. Despite its advantages, MWI is characterised by a worse resolution if compared with conventional X-ray and/or MRI, but its synergy with other imaging modalities, such as MRI or ultrasound imaging [10], further to its complementary information regarding the investigated region, can strongly impact on the medical diagnostic performance in a positive fashion.

Due to its interesting capabilities and complementarity with regard to other imaging modalities, MWI technology has good chances to become a viable modality for medical examinations. Several studies have been proposed in the last years by the scientific community involving up to hundreds of volunteers, but still this solution has not been used yet in clinical practise outside research laboratories [1]. To support this process, further initial testing requires imaging experiments of live tissues and not only phantom-based or ex-vivo situations. Certainly, this last case is more challenging compared to the laboratory-controlled ones due to movement artifacts, variations in size and the presence of more complex tissues.

Furthermore, quantitative evaluation of the electromagnetic properties (EPs) of biological tissues is paramount for various biomedical applications [11]. Several databases exist in the scientific literature which collect the EPs of biological tissues, but most of this work is related to measurements performed on ex-vivo tissue samples [12]. Nevertheless, according to some studies there is a considerable difference in values between ex-vivo and in-vivo EPs [13], which can reach the 25-30%. Thus, the estimation of in-vivo EPs in a non-invasive way is paramount for proper diagnostics.

In this work the Authors propose a quantitative MWI procedure for the estimation of the EPs of human forearm. To this aim, the approach exploits a-priori information derived from qualitative processing, which provides fundamental information to carry out the quantitative inversion. The proposed approach was tested by adopting the experimental

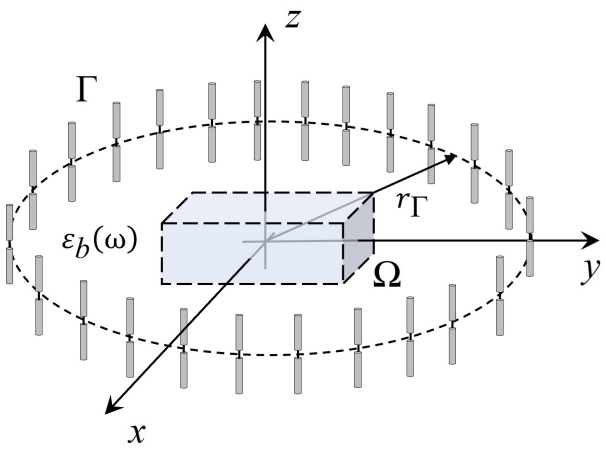

Fig. 1: Simplified sketch of the imaging system. The dipole antennas are aligned along the vertical z axis and located on a measurement circle Γ at a radius r_Γ. The imaging domain Ω is a parallelepiped and is immersed in a matching medium whose electric features are described by $\varepsilon_b(\omega)$.

data collected by the microwave tomography system developed at University of Manitoba [14]. Further details regarding the experimental imaging setup adopted for the data collection are reported in [15].

The remainder of the paper is as follows: Section II provides a brief overview of the mathematics related to the imaging problem at hand, while Section III illustrated the proposed methodology in terms of experimental data set and inversion procedure. Then, some experimental results and conclusions are reported in Sections IV and V, respectively.

II. Problem statement

A sketch of the considered geometry is shown in Fig. 1. The scenario under test Ω is assumed to include nonmagnetic, isotropic targets whose electric characteristics are described by the complex permittivity:

$$\varepsilon_x(\boldsymbol{r},\omega) = \varepsilon'_x(\boldsymbol{r}) - j\frac{\sigma_x(\boldsymbol{r})}{\omega\varepsilon_0}, \quad \boldsymbol{r}\in\Omega, \tag{1}$$

in which $\omega = 2\pi f$, f is the frequency [Hz], $\varepsilon_0 = 8.854\cdot 10^{-12}$ [F/m], and $\varepsilon'_x(\boldsymbol{r}), \sigma_x(\boldsymbol{r})$ are the relative permittivity and electrical conductivity maps of the investigated area Ω, respectively.

By assuming known (and everywhere constant) the complex permittivity of the background (matching) medium $\varepsilon_b(\omega) = \varepsilon'_b - j\frac{\sigma_b}{\omega\varepsilon_0}$, the contrast function which encodes targets properties can be defined as:

$$\chi(\boldsymbol{r},\omega) = \frac{\varepsilon_x(\boldsymbol{r},\omega) - \varepsilon_b(\omega)}{\varepsilon_b(\omega)}, \quad \boldsymbol{r}\in\Omega. \tag{2}$$

In this framework, the aim of the proposed analysis consists in retrieving the unknown contrast function, and thus the relative permittivity and conductivity maps of the targets located in the imaging domain Ω. For a fixed frequency and assuming known the "incident field", i.e. the electric field inside the imaging domain when there is no target, the scattering phenomena can be properly described by the following equations (after discretization):

$$\boldsymbol{e}_t = \boldsymbol{e}_i + \boldsymbol{\mathcal{A}}_i(\boldsymbol{x}\odot\boldsymbol{e}_t), \tag{3}$$

$$\boldsymbol{e}_s = \boldsymbol{\mathcal{A}}_e(\boldsymbol{x}\odot\boldsymbol{e}_t), \tag{4}$$

in which $\boldsymbol{x}$ is the discrete version of the unknown contrast function $\chi(\boldsymbol{r},\omega)$; $\boldsymbol{e}_t, \boldsymbol{e}_i$ are the discrete total and incident electric fields evaluated in the imaging domain Ω, $\boldsymbol{e}_s$ is the scattered electric field measured at receivers locations Γ per each illumination. The operators $\boldsymbol{\mathcal{A}}_i$ and $\boldsymbol{\mathcal{A}}_e$ are the discrete versions of the internal and external scattering operators, respectively. The symbol $\odot$ refers to the point-by-point product (i.e., Hadamard product).

At each time instant, only one transmitter is active and the remaining antennas are adopted as receivers. This scheme is repeated until all the antennas have illuminated the imaging area Ω, performing the data acquisition via a multiview-multistatic configuration.

Unfortunately, finding a reliable solution to the problem described by equations (3)-(4) is not trivial since it is nonlinear and ill-posed, and thus requires regularization strategies to reach a more stable solution. In this framework, the proposed approach strongly exploit the a-priori information derived from qualitative inversions to perform quantitative recoveries of the electric characteristics of human forearm biological tissues.

III. Methodology

A. Experimental data set

The experimental data set consists in the acquisition of five adults' forearms at microwave frequencies (0.4-2 GHz with a step of 100 MHz). The acquisitions were carried out at the Electromagnetic Imaging Laboratory at the University of Manitoba by means of an in-house microwave prototype [14]. The adopted MWI system is composed of 24 dipole antennas with a quarter-wavelength balun surrounding the investigation area Ω. The antennas are equally spaced on a circle of radius $r_\Gamma = 9.4$ cm and located at a mid-height of the hosting metallic cylinder.

Each acquisition consists of 23×24 single-frequency data points (S-parameter measurements) without considering the monostatic contribution. Due to direct coupling issues, the number of data points that can be used in practise for imaging purposes is further reduced to 19×24. The measurement procedure is repeated twice: with and without the human forearm in the imaging domain. Finally, a third measure with a 3.5-inch-diameter metallic cylinder is performed for the calibration.

B. Inversion procedure

Overall, the inversion approach consists of three steps. The first one exploits qualitative inversion methods to extract as much a-priori information as possible, while the second step consists in an enumeration analysis for the estimation of a suitable initial guess in order to ease the final quantitative

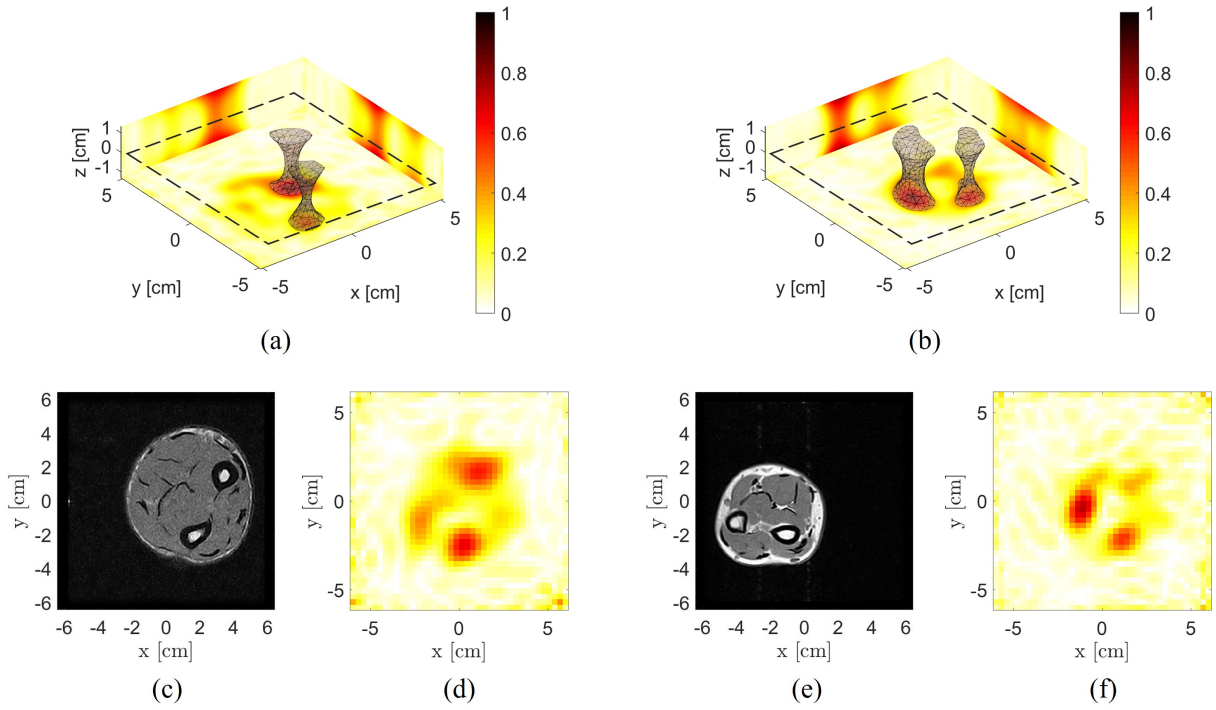

Fig. 2: (a)-(b): Qualitative three-dimensional (3D) recoveries obtained via BA for two volunteers of the Manitoba data set. (c)-(f): slices comparison between the retrieved support information obtained via 3D-BA (d, f) and corresponding MRI slices (c, e). It is worth noting that the two imaging modalities are not coregistered, even though they share the same axes.

recovery procedure (final step). More in detail, no hypothesis is assumed regarding the target location in the imaging domain and its size, which are estimated by the qualitative recoveries.

1) Step I - qualitative inversion: Among qualitative methods, the Linear Sampling Method (LSM) and the Born/distorted Born approximation (BA/dBA) are probably some of the most popular. For instance, the former one achieves the support information in a simple and effective way by solving, for a fixed frequency and point of the imaging grid, the well-known far-field equation. This method provides a map for the target support estimation (i.e., LSM indicator) which allows the generation of suitable initial guesses for successive quantitative inversions. Furthermore, the BA/dBA belong to the approximated methods and solve the inverse scattering problem by means of a convenient linearization of the discretized data equation (4). Also in these cases, the problem is still ill-posed and requires the use of proper regularization strategies.

2) Step II - enumeration analysis for suitable initial guess definition: Starting from the normalised LSM map, a pair of variable thresholds is adopted to generate a first raw approximation of the human forearm, i.e. one threshold is adopted for the forearm size definition and another one for the subcutaneous adipose tissue characterisation. More in detail, per each combination of the two thresholds, a raw estimate (i.e., without bones) of the human forearm is produced. Then, per each generated raw profile, the dBA is adopted to retrieve some spatial information regarding the bones location (a further third threshold is used to this aim). Finally, an estimate of the whole forearm morphology is derived.

Then, this estimate is assigned realistic electric tissues properties generating two quantitative maps (permittivity and conductivity). This estimated information is used to run a forward solver to calculate the electric scattered field at the receivers on Γ to be compared with the experimental data described in Subsection III-A. Lastly, the profile associated to the minimum mean square error among the simulated and experimentally-measured data is chosen as initial guess for the quantitative retrieval of the human forearm under consideration.

3) Step III - quantitative EPs refinement: The choice of the proper initial guess considered in the previous steps can be exploited for local minimization strategies to obtain reliable estimates of the dielectric in-vivo features of biological tissues. As a matter of fact, these properties are paramount for diagnostic and/or therapeutic treatments. To this aim, a multi-frequency distorted Born iterative method was adopted to perform the quantitative EPs estimation of human forearm tissues.

More details regarding the proposed approach will be provided at the conference.

IV. Results

Figure 2 reports some preliminary qualitative recoveries obtained via BA for the retrieval of some a-priori information (e.g., bones support) for two volunteers of the Manitoba data

set. More in detail, the operative frequency band adopted in the inversion procedure is $[0.8, 1.2]$ GHz with a frequency step of 100 MHz. With regard to the corresponding quantitative recoveries, they are not shown here due to space limitations and will be presented at the conference.

To provide a baseline as reference for the anatomy of the considered volunteers, the related MRI images are shown in Fig. 2(c, e) obtained with a 0.2 T Esaote E-scan XQ (T1 gradien echo protocol). Fig. 2(a, b) reports some qualitative three-dimensional (3D) inversions via BA of two volunteers of the Manitoba data set, while Fig. 2(d, f) illustrates the 2D slices at mid height with corresponding MRI reference slices in Fig. 2(c, e).

It is worth noting that the MRI and MWI images are not coregistered, even though the axes are the same. The accuracy of the coregistration is limited since the volunteer's arm and body positions were different in the MRI and MWI systems. In the former, the volunteer was supine and arm held horizontally, while in the latter the arm was held vertically with the hand clenched in a fist resting on a pad at the bottom of the chamber.

V. Conclusion

In this paper a multi-step quantitative MWI approach for the EPs retrieval of biological tissues was proposed. The methodology exploits a-priori information derived from qualitative inversion steps with the aim of providing a suitable initial guess for quantitative imaging via local minimisation procedures. As case study, the Authors considered the microwave data of human forearms collected by the group of the Electromagnetic Imaging Laboratory at the University of Manitoba.

Future work includes the testing of the proposed approach with other volunteers and the improvement of the refinement strategy with better performing quantitative inversions.

***Abstract*—Neural changes due to Alzheimer's Disease (AD) appear much earlier than objective cognitive decline symptoms. Subjective cognitive decline (SCD) is the first pre-clinical stage at which future development of the disease may be intercepted, possibly followed by mild cognitive impairment (MCI), the first step of clinical cognitive decline. Recent studies suggest that resting EEG analysis tools describing whole-brain activity, such as microstates and brain areas functional connectivity, might support a characterization of SCD and MCI conditions, but notwithstanding their clinical relevance, the cortical underpinnings of these AD prodromic states are far from being untangled. Here we verify whether the EEG activity modeled as a sequence of microstates is a better marker than simple spectral analyses in discriminating between SCD (n = 57), MCI (n = 45) and healthy controls (n = 17). While no significant differences were found in the spectral activity of our cohort, we identified effective markers of the prodromic changes of the disease in the reconstructed microstates dynamics. Specifically, cognitive decline alters the average duration, the coverage and the transition probabilities of several microstates, with the most prominent differences found for the canonical microstate C. Overall, this work advances the search for non-invasive EEG biomarkers charaterizing pre-symptomatic stages of AD, that may be used to automatically diagnose the future development of the disease.**

***Keywords*—Subjective cognitive decline, Mild Cognitive Impairment, EEG, microstates**

I. INTRODUCTION

Alzheimer's Disease (AD) is currently seen as a continuum, with changes in the structure and function of the brain occurring even decades earlier than the first symptoms' appearance, but going unnoticed. Thus, it is fundamental to identify novel, non-invasive markers that are able to predict in advance patients who are most likely to develop the disease. This would allow to improve early intervention and coordinated care plans and to limit the later burden of the dementia[1]. In this context, subjective cognitive decline (SCD) patients have gained attention as possible optimal target population for early AD detection. SCD is the self-concerned experience of reduced cognitive function, not mirrored by an objective abnormal score in standardized clinical tests[2]. SCD is a heterogeneous condition: patients belonging to it may progress to objective forms of dementias or may remain stable during their lifetime. However, this population has an overall higher chance of developing the dementia compared to the healthy population[2]. For this reason, it may be the ideal target for disease-modifying therapies to preserve cognitive function. Conversely, the first clinical sign of possible AD is mild cognitive impairment (MCI), defined as a state of objective cognitive decline that is not impairing the activities of daily living[2]. Since SCD and MCI conditions represent the two nearest points in the AD continuum, separating clinical cognitive decline from pre-clinical decline, it is imperative to find inexpensive and non-invasive markers that can distinguish between these two stages. This would allow to scale the early diagnosis of AD to larger cohorts and make it clinically feasible.

EEG may be an optimal tool in this context, as it provides a relatively cheap, quick to setup and widely available tool to functionally image the brain. A large number of studies proposed EEG biomarkers to diagnose the AD and MCI populations[3]. In the spectral domain, most of the studies identified a slowing in the resting EEG oscillations towards the delta and theta bands. A lower degree of functional connectivity patterns was also identified, related to the decrease in the small-world properties of the whole-brain network. Moreover, EEG displays a reduced signal complexity in AD and MCI when compared to the healthy population. However, only few studies explored the use of resting-state EEG activity to characterize the SCD population[4][5][6]. Thus, in the present work, we aimed at further exploring the pool of EEG markers in the SCD condition, by comparing both spectral and microstate markers on the same cohort of patients. Moreover, we explored whether microstate transition probabilities is a

hallmark of the cognitive decline.

II. METHODS

A. Participants

Patients self-referring to the Careggi University Hospital in Florence where recruited in the study, after a comprehensive neuro-psychological assessment. Patients were included in the study if they satisfied the following inclusion criteria: complaint of cognitive decline with a duration of > 6 months; Mini Mental State Examination (MMSE) score greater than 24. Exclusion criteria were: comorbidities and diagnosis of other pathologies that may affect their EEG and their cognitive status (e.g. depression). A total of 103 subjects met the inclusion criteria. They were classified as 58 SCD, according to Subjective Cognitive Decline Initiative (SCD-I) Working Group criteria[2], and 45 MCI based on NIA-AA criteria[7]. Additionally, 17 healthy control subjects (H), aged 55 to 75 years, were recruited to compare their resting-state EEG. All subjects were recruited in accordance with the Declaration of Helsinki and the study was approved by the local Institutional Review Board. All participants in this study signed an informed consent.

Resting-state EEG data was collected from patients meeting inclusion criteria at the IRCCS Don Gnocchi (Florence, Italy). EEG was collected from patients resting on a chair in a comfortable position, using the 64-channels Galileo-NT system (E.B. Neuro S.p.a.), using the extended 10/20 channels location, and a sampling rate of 512 Hz. Approximately 15 minutes of eyes-closed EEG recording were collected from each participant (Fig. 1A). EEG data was offline pre-processed to remove physiological and non-physiological artifacts. A semi-automatic pipeline was developed to this aim, combining the use of the PREP pipeline and ICA artifact removal[8](Fig. 1B).

B. Spectral markers

The power spectral density of each EEG signal was computed by means of the Welch's method (5 s non-overlapping windows). The spectrum was divided in four canonical frequency bands: delta (1-4 Hz), theta (4-8Hz), alpha (8-13 Hz) and beta (13-30 Hz)[9]. The relative power in each band was obtained by normalizing it with respect to the total power in the bandwidth 1-48 Hz. From each channel relative power, an average scalp power is computed by averaging all channels activities. Moreover a region of interest (ROI) power is obtained by averaging over channels belonging to six different areas of the scalp as in [10]: frontal right, frontal left, central right, central left, occipital right and occipital left.

C. Microstates extraction

EEG microstates are quasi-stable topographies in the EEG time domain, lasting approximately 80 to 120 ms[11]. As reported in previous studies, the typical number of microstates appearing at rest is four and they have stereotypical topographies. Hence, to obtain a microstate representation of the input EEG signals, we applied the modified k-means clustering algorithm separately for each subject, setting the number of clusters to four[11]. The input to the modified k-means were the $30 * 10^4$ topographies having the highest global field power (GFP) on the entire EEG signal. To avoid obtaining sub-optimal clusters due to local minima, the algorithm was restarted 50 times for each EEG signal, and the solution minimizing intra-cluster distance was selected. Once four single-subject microstate topographies (the clusters' centroids) were obtained, we performed a second pass on the k-means clustering, now having as inputs the entire set of average single-subject topographies. We imposed that each topography coming from the same subject should belong to a different grand-average map. These grand-average maps were matched by visual similarity with the canonical maps observed in previous works and named A, B, C and D. Single-subjects maps were matched with the canonical grand-average maps. Group-level maps were also obtained as the centroids of the maps belonging to each diagnostic group. The temporal sequence of EEG microstates was then reconstructed by back-fitting the grand-average maps to each subject's signal with a winner-takes-all procedure: only the microstate topography with the lowest Euclidean distance from the topography at each time-point was considered active at that time-point. Segments with microstate duration less than 30 ms were rejected and reassigned to the subsequent most similar map.

Microstates were both tested for topographical and temporal differences among groups. We used TANOVA (topographical analysis of variance) to check for differences among SCD, MCI and H subjects in their average microstate maps. Regarding microstate dynamics, from the back-fitted microstate signals, we obtained a discrete sequence of microstates by only retaining transitions among different canonical microstates. We then computed the average microstate duration for each subject and we extracted each microstate's coverage, i.e. the percentage of time a given microstate remains active over the total recording time. We finally computed microstate transition probabilities. Transition probabilities p_{ij} were defined as the probability of passing to microstate j at time $t + 1$, given the current state at time t is microstate i.

For both domains of variables (spectral and microstates), we first assessed the normality of the sample by Shapiro-Wilk test. When the domain displayed normal behavior in most variables, we used one-way ANOVA to compare the three groups, followed by t-test post-hoc tests for pairwise comparisons. Otherwise, we used the Kruskal-Wallis test to compare the three groups, followed by Wilcoxon rank sum post-hoc tests. All post-hoc comparisons were corrected with the Bonferroni method.

III. RESULTS

First, we addressed the spectral differences among groups. Delta and alpha relative power displayed only a trend toward difference due to the large inter-subject variability (delta band: ANOVA F-statistic = 2.19, p = 0.065, η^2 =0.046; alpha band: ANOVA F-statistic = 1.92, p = 0.151, η^2 = 0.032). The highest effect size was found in the occipital areas for the delta band

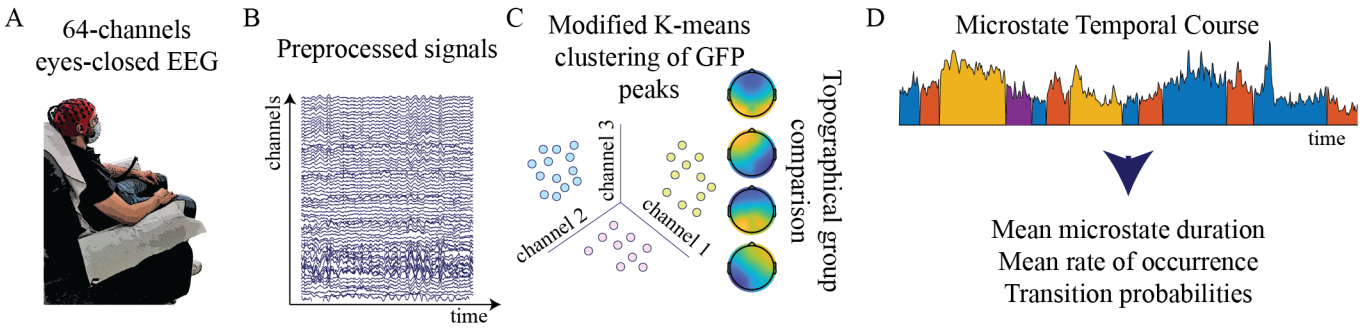

Fig. 1: Microstates extraction. (A) EEG is recroded in the eyes closed condition. (B) The signal is preprocessed to remove artifacts. (C) The clean signals is fed into the modified K-means algorithm and the single-subjects topographies are obtained. Mean topographies among groups are compared using TANOVA. (D) The gran-mean topographies are back-fitted into single-subject EEG signals and temporal metrics are computed it.

(left: ANOVA F-statistic = 2.95, p = 0.056, η^2 = 0.048; right: ANOVA F-statistic = 2.66, p = 0.074, η^2 = 0.043). In alpha, the left frontal area was the one with largest differences among groups (ANOVA F-statistic = 2.67, p = 0.073, η^2 = 0.043)

Regarding microstate topographies, the TANOVA test did not highlight any difference among groups (multi-group TANOVA average dissimilarity: microstate A d = 0.316, p = 0.79; microstate B d = 0.583, p = 0.32; microstate C d = 0.353, p = 0.71; microstate D d = 0.459, p = 0.40).

Conversely, several significant differences resulted in the microstates temporal sequence. Regarding duration (Fig. 2A) and coverage (Fig. 2B) of each microstate, we found significant differences in both measures for microstate C (duration: Kruskal-Wallis H-statistic = 9.68, p = 0.008; coverage: Kruskal-Wallis H-statistic = 7.92, p = 0.019). Additionally, the coverage of microstate B was altered in MCI subjects when compared to H controls (Kruskal-Wallis H-statistic = 9.68, p = 0.008). Also microstates transitions were altered (Fig. 2C), coherently with changes in the duration of each state. Prominently, transitions to the canonical microstate C were less likely in MCI, both compared to SCD and H. Transitions from microstate D to microstate B were more likely in MCI conditon compared to the SCD condition.

IV. DISCUSSION

In this work we concurrently analyzed possible spectral and microstate markers of prodromal stages of AD (SCD and MCI) and healthy controls, hence allowing for direct comparison on the power of these markers in detecting the progression of cognitive decline. We found that microstate dynamics markers, rather than their topographical representation, are able to discriminate between SCD and MCI, and are a better and more robust marker than the spectral ones.

While we did not find any significant difference in the spectral domain, we observed trends that were similar to the ones described in previous literature, both for AD and SCD[3][5]. Specifically, our results are consistent with the ones describing a slowing in the oscillations as the cognitive decline progresses, as depicted by an increase in delta band activity and reduced alpha peak power. However, as described in [4] microstates are relevant in characterizing cognitive decline. While we did not find any topographical difference among microstates related to the progression of cognitive decline, we additionally introduced the transition probability and identified it as a valid marker distinguishing SCD and MCI subjects. We can conclude that microstate temporal dynamics retain information regarding the progress of cognitive decline in the considered cohort. Such information is also related to functional networks in the brain[12], and hence could give insights on the pathogenesis of AD from very early pre-symptomatic stages of the disease.

There are, however, some limitations in this study that we will address in the future. First, our sample is relatively small when compared to the one previously used to study microstates in SCD[4]. We did not recruit any patient with AD, hence not having a reference on the other end of the Alzheimer's disease continuum. In future studies, we will also explore more advanced metrics of the temporal microstate dynamics, such as microstate complexity, as it has been shown to be a predictor of AD[13]. Finally, we will combine the identified resting-state EEG markers, along with other neuro-psychological, genetic and demographic factors, to better address the heterogeneity of the SCD population. We will use these features to build a machine learning classifier able to optimally discriminate between different levels of cognitive decline, with the ultimate goal of testing it in a longitudinal study.

***Abstract*— Cortical control of reach-and-grasp movements is one of the key challenges of brain machine interfaces (BMI). Recent advancements enabled tetraplegic subjects to control robotic arms through this approach. However, the fine control of such movements is usually automatic rather than controlled by the patient, and this might not be the optimal solution in real life environments. Here we show that fine properties of reach-and-grasp movement can be decoded thanks to K-medoid clustering. We recorded the activity of 71 neurons from the premotor cortex of a macaque performing different reach-and-grasp movements depending on the shape and the position of the object presented. The K-medoid algorithm selected in an unsupervised way four firing patterns associated with specific clusters of neurons' activity. Describing the cortical activity during each movement through the distances from these four medoids and feeding the resulting vector into a support vector machine (SVM) algorithm enabled the identification of the specific movement performed. This decoding approach could in future support a finer control of robotic arms - or other devices – through cortical BMI.**

I. Introduction

DECODING motor intentions from neural activity is a key step for the development of neuroprostheses [1]. Neuroprostheses based on cortical recordings aim at restoring the ability of tetraplegic patients to communicate and act with the outside world. Motor intentions, indeed, can be decoded from patient's motor imagery, as demonstrated by different BMIs applications (e.g., from EEG data: [2]). Hand trajectories can be decoded from recorded motor cortical areas, as it is done in [3], [4]. However, the intention/planning of a movement can be decoded also from premotor cortex [5] to predict goals and expected targets, leaving the specific kinematic to be defined at the low level by the actuator.

Here, we focus on decoding what we reckon are three important features for defining any reach-and-grasp movement: extension, laterality, and type of grasp.

First, we compared two different behavioural tasks, in which the monkey is asked to grasp with any hand either some food or a carabiner. This choice of objects grants two different grasping techniques: pinch and palmar, respectively.

Second, we focused on pinch grasp only, since, according to the experimental protocol, the food could be presented in both reachable and non-reachable areas.

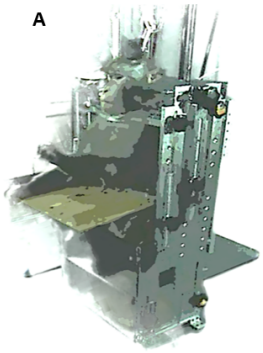
For both analyses, we computed pairwise distances among raw spike-trains, rather than work on a pre-processed representation of the neuronal response.

II. Methods

A. Implant and Data Acquisition

Electrode arrays were chronically implanted in the ventral premotor cortex of a monkey (*Macaca mulatta*). The implant site was defined choosing as landmarks the inferior and superior arcuate sulci, and the central sulcus.

The neuronal activity was then recorded by means of customized 32-channels floating microelectrode arrays (FMAs, Microprobes for Life Science, Gaithersburg, MD, USA). These arrays are relatively small and can be easily implanted in separate locations, thus allowing the simultaneous coverage of different areas of the cortex. Moreover, the electrodes can be designed to reach different depths intracortically.



Four FMAs with alternating depths (2.5 mm and 4 mm) were implanted, for a total of 128 recording channels.

The collected data was wirelessly logged using a system (Deuteron technologies, RatLog-128) that allows to band-pass filter (2-7000 Hz) at a conversion rate of 32000 Hz. Thus, both local field potentials' and single/multi units' activity were available for analysis.

B. Experimental Protocol

The monkey was trained to sit on a primate chair and to respond to specific stimuli. Specifically, the behavioral tasks involved different reaching-grasping and mouth actions. In this study, the monkey was asked to grasp either food (*Pinch Grasp*) or a carabiner (*Palmar Grasp*). In both cases, the monkey was free to choose the hand for performing the task (*Right* or *Left Hand*). Furthermore, in case of pinch grasping, the food could be presented either in reachable or non-reachable areas (*Near* and *Far Presentation*).

A

PALMAR vs PINCH Grasps		
CLASS	# successful trials	
Palmar Right	15	Palmar: 25
Palmar Left	10	
Pinch Right	20	Pinch: 42
Pinch Left	22	
TOT	67	Right: 35 Left: 32

PINCH GRASP for FOOD		
CLASS	# successful trials	
Far Right	9	Far: 18
Far Left	9	
Near Right	11	Near: 22
Near Left	11	
TOT	40	Right: 20 Left: 20

B

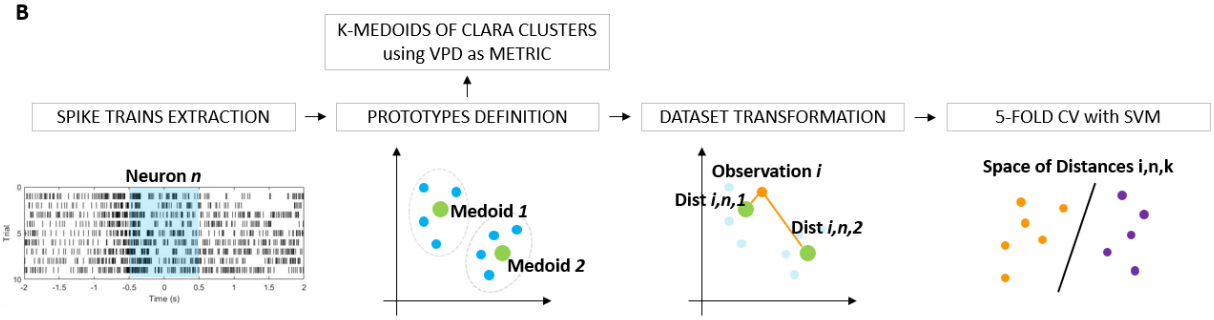


Fig. 1: Schematic of methods. A) Left: Monkey performing reach-grasp from a primate chair. Right: Tables with number of successful trials for each type of behavioral task. B) Flowchart of implemented pipeline. First, all the spike trains from the behavioral tasks under analysis are extracted. Then, the CLARA algorithm looks for the K medoids of the K clusters that best separate the training dataset. Each instance is then re-represented using its VPD with respect to all the medoids. Finally, a 5-fold CV with SVM and feature selection is performed to decode specific aspects of the movement from the transformed neuronal data.

The monkey was filmed while performing the behavioral tasks with an 8-high resolution camera system, and ethological scoring of the videos was performed to obtain the timestamps of the events. The list of successful trials for each type of grasp is reported in Fig.1A.

C. Data Processing for Classification

The neuronal recordings were first processed using a fully automated spike sorting algorithm (MountainSort4.0 [6]) and 71 single units were extracted. The features selected for the decoding process were the pairwise spike-train distances. Thus, based on the type of classification performed, specific windows of spike-trains were extracted from each sorted unit.

To reduce the number of spike-trains to be stored and the number of pairwise spike-train distances to be computed for training and testing the classifier, we defined representatives that best divided the training dataset. If the spiking pattern of a neuron is repeatable over different trials of the same task, and there is a high inter-task distance, then the dataset is likely to have well-defined clusters.

We used these clusters' centres to redefine the whole dataset: each spiking pattern of a neuron was represented by the Victor-Purpura distance (VPD) [7], [8] from the all the K representative spiking-patterns of the same neuron. The VPD is computed as the cost to transform one spike-train into another via spike removal/addition and spike shifting. The VPD depends on the parameter q_cost, which attributes different importance to temporal scales/jittering. In fact, it is good practice to test different values of this parameter to identify the one that gives the best discriminative performances. For our analysis, the q_cost search was performed on a logarithmic grid ($[1, 3, 5, 7]$ x $[1, 0.1, 0.01, 0.001]\ ms^{-1}$).

D. Clusters' Centres Definition

In order to keep the temporal structure of the activity without using a vector-space embedding [9], the *centre* of a cluster can be generated using random spiking patterns. However, a wiser choice is to select *medoids*, representative objects belonging to the same dataset.

For this purpose, we used *K-medoid*, a clustering algorithm that selects K medoids, so that the sum of distances between each medoid and any other instance belonging to the same cluster is minimized. In other words, the medoids are the most centrally located objects in the clusters. Indeed, K-medoid is generally considered more robust to outliers than K-means [10], which can select as *centre* elements placed outside the cloud of points.

We employed the CLARA (Clustering LARge Applications) algorithm [11] for performing the search of medoids. As K-means, this method requires the user to specify the number of clusters. We selected preliminarily K = 4. Moreover, we used VPD as metric for computing the clusters' dissimilarities. The CLARA algorithm was then repeated for each single unit.

E. Grasp Type and Laterality Decoding

In the first analysis we performed, we kept both food and carabiner grasping trials. Each repetition of the tasks was labeled as a combination of *{Pinch, Palmar} x {Right, Left}* features.

For each observation, the neurons' spike trains were extracted in a 500 ms window before the grasping event. For this type of classification, we considered only 38 out of 71 single units, basing our choice on neurons showing a discriminative distance matrix for *{Pinch, Palmar} x {Right, Left}* classes. The number of features amounted to 152 ($\#\ medoids * \#\ neurons$).

A 5-fold Cross-Validation (CV) was performed to train and evaluate the performances of a Support Vector Machine (SVM) in three different classification problems:

- *{Pinch, Palmar} x {Right, Left}*;
- *{Pinch, Palmar}*;
- *{Right, Left}*.

We refer to the first case as *multiclass* classification problem, whereas the last two are defined *binary* classification problems.

Optionally, inside the CV loop, a feature selection step can be performed. Only the training set is fed to the feature selection algorithm, in order to prevent data leakage and positively biased performances [12]. We chose the minimum-Redundancy-Maximum-Relevance (mRMR, MATLAB-fscmrmr [13]) feature selection algorithm, which is mainly based on mutual information between features and classes. Given the ratio between observations and predictors, we tested two different thresholds for feature selection to avoid overfitting: 4 and 16.

F. Presentation Proximity and Grasp Laterality Decoding

In a second set of analysis, we considered only the food grasping trials, as they added another level of classification. Even though, the reach-and-grasp movements were performed similarly across trials, the food could be presented either in reachable or non-reachable areas. In both situations, the monkey was trained to wait for the food to get closer to initiate the reaching movement.

Thus, each repetition of the food grasping task was labeled as a combination of *{Far, Near} x {Right, Left}* features.

Contrary to what done before, where only one timepoint was relevant for the study (*G*, grasping), here we explored the evolution of the spiking activity across all the different phases of food grasping. Thus, we identified three timestamps (*F*, food presentation; *G*, grasping; *M*, food touching the mouth) and we extracted the spike trains of the following windows: $(F, F + 500\ ms)$; $(G - 500\ ms, G)$; $(G, G + 500\ ms)$; $(M - 500\ ms, M)$. Each phase was treated as an independent dataset to be fed to the decoding algorithm.

Also in this case, we considered only the neurons showing, qualitatively, a discriminative distance matrix for *{Far, Near} x {Right, Left}*. Hence, 26 out of 71 single units were selected, creating a vector of 104 features.

In a similar fashion, a 5-fold CV was performed to train and test an SVM in three different classification problems:

- *{Far, Near} x {Right, Left}*;
- *{Far, Near}*;
- *{Right, Left}*.

Optionally, inside the CV loop, a feature selection step could be performed with thresholds 4 and 16.

III. RESULTS

A. {Pinch, Palmar} x {Right, Left}

First, we compared two different behavioural tasks, namely food and carabiner grasping. The aim was to capture and amplify the differences in neuronal response during the planning phase for two types of objects handling. We used a CV loop to train and test an SVM for the prediction of type of grasp (*{Pinch, Palmar}*) and hand chosen (*{Right, Left}*). We tested the predictions for both *multiclass* and *binary* classification problems. The performances (reported in Table I) were assessed in terms of mean accuracy over the 5 folds of the validation loop.

As Table I shows, the SVM classifier with no feature selection implemented (total of 152 features) reached 82.1% when trying to predict simultaneously both the type of grasp and the lateralization. For this *multiclass* problem, other two SVM models with 4 and 16 features were tested as well. The respective decoding performances were 62.6% and 77%.

As one would expect, the performances further improved in the two *binary* classification problems. For the prediction of type of grasp only (*{Pinch, Palmar}*), the classifier reached 88%, 94%, 95.5% with 4, 16, 152 features respectively. On the other hand, for laterality decoding, the classifier got 86.6%, 89.6%, 88% with 4, 16, 152 features respectively.

Table I also reports the values of q_cost for which the best performances were achieved. For the *multiclass* problem the values were generally lower than those used in the binary problems. The more the cost increases, the more the VPD is transformed from a rate distance to a temporal distance.

TABLE I: MEAN ACCURACY [%] (q_cost_VPD [$1/ms$])

	SVM_4	*SVM_16*	*SVM_152*
{Pinch, Palmar} x {Right, Left}	62.6 (0)	77 (0)	82.1 (7e-3)
{Pinch, Palmar}	88 (0.7)	94 (7e-3)	95.5 (0.3)
{Right, Left}	86.6 (0.03)	89.6 (0)	88 (0.5)

Mean accuracies over 5-fold CV. In brackets, the q_cost for which the accuracy associated was achieved.

B. {Far, Near} x {Right, Left} for each Phase

For the second analysis, we limited the study to food grasps only. Here, we wanted to observe the neuronal evolution through different phases of planning a food grasping movement. For this purpose, we independently trained and tested the four previously defined phases of grasping.

For each phase, we decoded the proximity of food presentation (*{Far, Near}*) and, again, the laterality (*{Right, Left}*). We tested for both *multiclass* and *binary* classification problems. The performances (reported in Table II) were assessed in terms of mean accuracy over the 5 folds of the validation loop.

Similarly to what done before, we created SVM models with different numbers of features (i.e., 4, 16, and 104), and we trained and tested them for all the possible combinations.

As Table II shows, the classifier for the *multiclass* problem reaches higher accuracies over the moment when the hand touches the food (72.5% with 16 feat). Whereas, for *{Far, Near}* higher performances can be found at the very beginning, when the food has just been presented (87.5% with 16 feat). Finally, for *{Right, Left}*, the best performances were again achieved over the actual grasp (95%-97.5% with 16 feat).

Table II also reports the values of q_cost for which the best performances were achieved.

TABLE II: MEAN ACCURACY [%] (q_cost_VPD [$1/ms$])

	Phase	*SVM_4*	*SVM_16*	*SVM_104*
{Far, Near} x {Right, Left}	1	50 (0.7)	60 (1e-3)	52.5 (0.3)
	2	70 (0.3)	72.5 (0.3)	67.5 (7e-3)
	3	52.5 (0.03)	72.5 (3e-3)	57.5 (0.3)
	4	52.5 (0.03)	52.5 (7e-3)	65 (0.01)
{Far, Near}	1	90 (0.1)	87.5 (0.01)	80 (0.1)
	2	65 (0.1)	65 (0.1)	77.5 (0.3)
	3	67.5 (0.7)	70 (3e-3)	65 (0.3)
	4	62.5 (0)	60 (0.07)	70 (0.3)
{Right, Left}	1	77.5 (3e-3)	87.5 (0.3)	62.5 (0.3)
	2	97.5 (0.01)	95 (0.05)	100 (0.3)
	3	92.5 (0.7)	97.5 (1e-3)	100 (0.1)
	4	80 (0.7)	87.5 (0.05)	95 (3e-3)

Mean accuracies over 5-fold CV. In brackets, the q_cost for which the accuracy associated was achieved.

IV. DISCUSSION

We explored the possibility of decoding three key features of grasp from clustering analysis of intracortical recordings in the ventral premotor cortex. We developed a cross-validated machine learning algorithm that can successfully predict the desired type of grasp and laterality, and that can decode the proximity of the food presented.

In both analyses, the algorithm reaches good accuracies in the *multiclass* problems, but its performances can be further improved in the *binary* classification problems. This suggests the possibility of using hierarchical decoding techniques for elevating the accuracies in case of simultaneous decoding of different features of grasping.

Moreover, in the second analysis, we observed an interesting response to food presentation. Even though the distinction between far and near is not reflected in a reaching movement, we are still able to differentiate between them. Since the electrodes are positioned in the premotor cortex, and, thus, the response cannot be vision-based, we speculate that a planning phase takes place even though the monkey does not perform a far or near grasp. Similarly to *motor imagery*, we are thus decoding an action possibility [14]. Then, as soon as the food gets closer, the planning is remodulated, and the option of choosing either right or left hand arises.

The processing pipeline that we suggest implementing is the one with 16 features selected. Indeed, the number of total features decreases by almost one order of magnitude (*e.g.*, 16 instead of 152) and, hence, there are less pairwise VPDs to be computed and less representative spike-trains (i.e., medoids) to be stored. This allows for virtually online computations without losing significantly in terms of performances.

This study is currently limited to a small set of grasp characteristics, but we intend to include other types of objects for defining a complete set of hand pre-shaping in the premotor cortex, and we also want to include the execution of different extensions of the arm during reaching phase. We also believe that an approach based on multi-units' activity, rather than single-units', might prove useful for online implementation of the algorithm, without losing sensitively in accuracy.

Finally, we want to complete the second analysis performed with a *phases-mix*. This means that we want to implement a classifier trained and tested simultaneously on all phases, in order to observe its ability of capturing the grasp phase as well.

***Abstract*— The Choroid Plexus (ChP) is a brain vascular tissue involved in regulatory processes. ChP Volume (ChPV) modifications are related to neurodegenerative disorders. Therefore, ChPV, that can be obtained from manual segmentation of brain MRI, is an imaging biomarker candidate to monitor disease evolution. This work proposes a method for the automatic segmentation of ChP based on hyperparameters optimization of Deep Neural Networks (DNNs). Twenty-Seven hyperparameters and architectures combinations were trained on T1-w MRI with two different selection strategies: select the best models using the routinely used Dice Coefficient and combining it to the Absolute Percentage Volume Difference. The selection of the ten best models was made on bias and variance of Absolute Percentage Volume Difference and best DNNs were ensembled by majority voting for both selection strategies. The proposed ensemble models outperform single DNNs (Dice Coefficient for both ensembles: 0.81±0.07; Percentage Volume Difference - ensemble Dice: 0.41±10.75%; ensemble Dice&Volume: -0.05±10.49%). Ensemble segmentations obtained using the combination of Dice and Absolute Percentage Volume Difference are preferable since the variance obtained in the testing phase is slightly lower than the commonly used Dice metric. Therefore, the proposed ensemble of DNNs, selected exploiting both Dice and Absolute Percentage Volume Difference, is a promising tool to obtain automatic quantification of the ChPV.**

***Keywords*—Choroid Plexus, Deep Neural Networks, Semantic Segmentation, Multiple Sclerosis.**

I. Introduction

The Choroid Plexus (ChP) is a vascular tissue located inside the brain ventricles. The ChP is present in all four ventricles, and it is part of the Blood-CSF-Barrier (BCSFB) [1]. The main role of the ChP is the production of relevant portion of the CSF, therefore it can be considered part of the glymphatic system [2]. Moreover, the ChP is involved in further features: active and passive transport of substances between BCSFB and Blood-Brain-Barrier (BBB); intercellular communication through gap junctions; maintenance of brain homeostasis; clearance pathways in the brain for drugs, proteins, and waste products; immunological function implicated in inflammatory processes [1], [3], [4]. Recent studies [5], [6] have shown the relation between functional and anatomical modifications of the ChP and several neurological and neurodegenerative disorders or worse symptoms in psychosis, like schizophrenia or depression. The ChP volume (ChPV) has been observed to be altered in presence of inflammatory states in Multiple Sclerosis and Alzheimer's disease [7], [8]. Therefore, the ChPV is a promising candidate to become a biomarker to improve the understanding and monitoring of neurological disorders [9]. Consequently, the need to robustly delineate ChP to obtain ChPV is gaining interest. The gold-standard technique to depict this anatomical region is the manual segmentation on T1-w MR images (here considered as ground-truth (GT)). However, this method is time-consuming, and it is affected by inter- and intra-operator variability due to the size, tortuosity, and low contrast between the ChP and the ventricles [10]. It has just been demonstrated the lack of accuracy of the freely available methods (FreeSurfer, Gaussian Mixture Model) to automatically segment the ChP [11].

The aim of this work is to propose a method for the automatic segmentation of the ChP based on Deep Neural Networks (DNNs). Dice Coefficient [12] is the metric broadly used in semantic segmentation task with DNNs to select the best model configuration during the validation phase. However, the final goal is having both a good ChP delineation and robust ChPV estimates. Our purpose is to firstly compare the performances of selected configurations using the Dice Coefficient or combining it to the Absolute Percentage Volume Difference. Secondly, we investigate whether the ensemble of the best ten DNNs obtained with both approaches improves the ChP segmentation in terms of ChPV estimate. The DNN performance will be compared to the GT performed by trained neuroradiologists with ITK-SNAP [13].

II. Materials and methods

A. Materials

The dataset was provided by the Multiple Sclerosis Centre of the University Hospital of Verona. The dataset is composed by 128 subjects (age 36.7±10.1 years): 24 healthy controls (HC) and 104 Relapsing-Remitting Multiple Sclerosis (RRMS). Images were acquired with two different Philips 3T MRI scanners: 67 subjects on a Philips Achieva TX with 8-channels head coil (Software version R3.2.3.2) (Scanne r1) and 61 subjects on a Philips Elition S with 32-channels head coil (Software version R5.7.2.1) (Scanner 2). Parameters of 3D T1-w MPRAGE sequences for Scanner 1 were: resolution 1x1x1 mm; SENSE acceleration factor: 2.5; TE/TR: 3.7/8.4 ms; FA: 9°; total acquisition time: 4min 50s. MPRAGE

sequence parameters for Scanner 2: 1x1x1 mm; compressed SENSE acceleration factor: 4; TE/TR: 3.7/8.4 ms; FA: 8°; total acquisition time: 3min 20s. On each T1-w MRI, the ChP in the two lateral ventricles were segmented by consensus of two neuroradiologists. We randomly divided the population into a training set (64 subjects: 12 HC/20 RRMS Scanner 1, 32 RRMS Scanner 2), a validation set (28 subjects: 5 HC/9 RRMS Scanner 1, 14 RRMS Scanner 2) and a testing set (36 subjects: 7 HC/14 RRMS Scanner 1, 15 RRMS Scanner 2).

B. Methods: DNNs training and performance

The first step of this work was the training of the DNNs using the Dice Coefficient or the combination of Dice Coefficient and Absolute Percentage Volume Difference to select the best model parameters. We tested twice twenty-seven combinations of architectures and hyperparameters. DNNs were implemented in MONAI version 0.8 [14]. We had selected three DNNs architectures: 3D U-Net [15]; DynUNET, MONAI implementation of nnU-Net [16]; UNETR [17]. We had considered as DNNs hyperparameters: the patch size (64x64x64, 96x96x96, 128x128x128), the loss function (Dice, CrossEntropy (CE), combination of Dice and CE (DiceCE)). We trained all the configurations with the application of data augmentation transforms (rotations, translations, small rotations, intensity shifts) to the training set.

We used the Adam-Weighted optimizer [18] with parameters: learning rate (1e-04), weight decay (1e-05), max iterations (4e04), batch size (1).

Goodness of each combination was assessed on the testing set. The analysed performance indices were: Dice Coefficient, Absolute Volume, Percentage Volume Difference (ΔVol%) and Absolute Percentage Volume Difference (|ΔVol%|) (Eq. (1)).

$$|\Delta Vol\%| = 100 * \frac{|Volume_{GT} - Volume_{Prediction}|}{Volume_{GT}} \ [\%] \quad (1)$$

To establish a minimum requirement in ChPV quantification, a threshold of 21.4% for |ΔVol%| was used to guarantee the ability of the DNNs in detecting Multiple Sclerosis (MS) pathological alterations based on recent findings [19]. A t-test (α=0.05%) was performed on Dice Coefficient between the two ensembles obtained and on Absolute Volume between the GT and the single ensembles. The influence of the model variance on the ChPV estimate was analysed also with Bland Altman plot.

C. Methods: DNNs selection criterion for the ensemble

We performed the ensemble for both the selection strategies employing the same selection criterion, aiming to refine the segmentation. DNNs were scored on mean |ΔVol%| and the ten best DNNs capable of keeping the bias under the pathological alteration detection threshold (21.4%) were selected. The ensemble procedure took together the results of the best networks possibly producing a more robust and more flexible output than a single network. We modified the standard ensemble method in MONAI to include the selected DNNs. Our module created the ensemble using a majority voting procedure considering the single-model predictions, averaging the ten best candidate prediction maps. A probability threshold of 50% was then used to produce the final ensembled segmentation.

III. RESULTS

For both selection strategies, all tested configurations return an estimate of ChPV that is adequately precise in detecting differences between MS and controls (|ΔVol%| < 21.4%). To be more restrictive, the ten best configurations selected for the ensemble are below this threshold considering not only the bias but also the variance (1.96SD).

Tables I and II show the most relevant performance metrics for the top ten models and for the ensembles for both selection strategies. Most of the selected configurations are equal for the two strategies.

TABLE I: PERFORMANCE METRICS – DICE ENSEMBLE

Configurations	*Dice Coefficient [0-1]*	*Absolute Volume [mm³]*	*Percentage Volume Difference [%]*

UNETR96DiceCE	0.79±0.07	2387±548	-1.23±13.93

Performance metrics of the selected models and the ensemble of them for the Dice Coefficient and Absolute Percentage Volume Difference selection strategy. The configurations are presented in form Architecture-PatchSize-LossFunction. The results are reported in the form (mean±SD). Dice Coefficient and Percentage Volume Difference metrics are calculated using GT T1-w manual segmentation as reference.

Dice Coefficient for the selected models is in range [0.77-0.81] for both selection strategy. Considering ΔVol%, the range of value for the Dice selection strategy considering |1.96SD| is (min-max) [12.77-17.54%], while that of the Dice&Volume is [12.06-18.4%].

The ensemble results of the best configurations for the two selection strategies underly equal performance in terms of

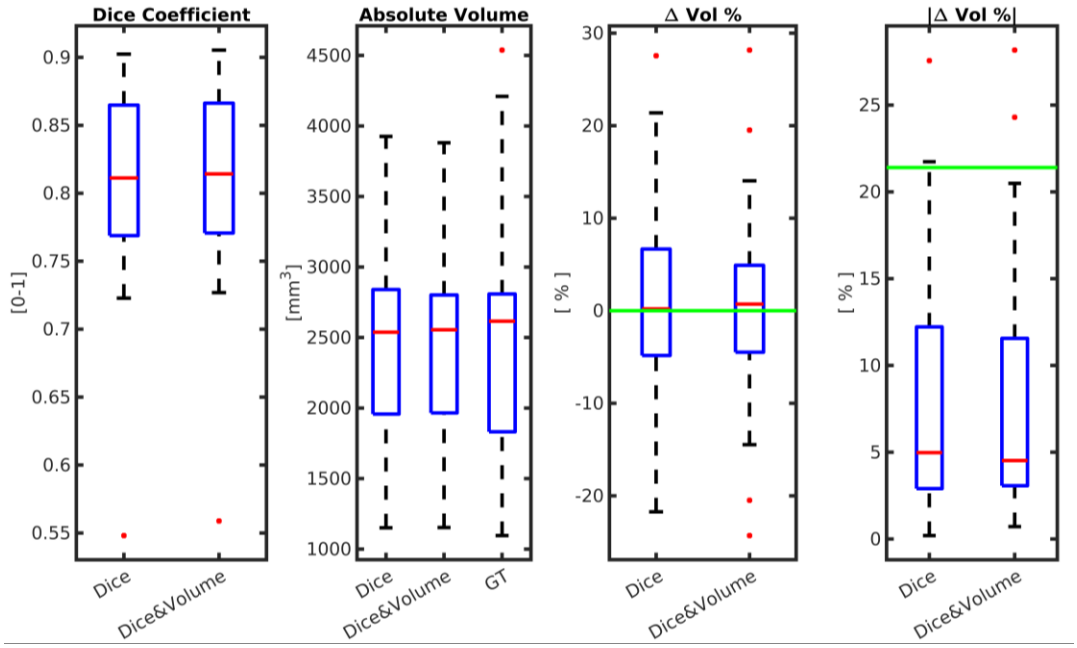

Fig. 1: Comparison between the ensemble of the ten best configurations selected considering as saving metric the Dice Coefficient (Dice) and the ensemble of the ten best configurations selected considering as saving metrics both Dice Coefficient and Absolute Percentage Volume Difference (Dice&Volume). From left to right, boxplot of: Dice Coefficient, Absolute Volume, Percentage Volume Difference (ΔVol%) and Absolute Percentage Volume Difference (|ΔVol%|) with highlighted in green the pathological alteration detection threshold for Multiple Sclerosis (21.4%). Reference: GT T1-w manual segmentation.

Dice Coefficient (0.81±0.07), while in terms of ΔVol% the ensemble Dice&Volume shows both a lower bias (-0.05%) than the other ensemble (0.41%), and slightly lower variance (SD ensemble Dice&Volume: 10.49%; SD ensemble Dice: 10.75%).

Fig. 1 shows the boxplot for the performance metrics calculated between the compared ensemble segmentations and the GT. As commented before, the Dice Coefficient is the same for both the ensemble predictions: the t-test accepts the null hypothesis. Concerning the volume metrics, by visual inspection the Absolute Volume, ΔVol% and |ΔVol%| are comparable. The t-test reveals that there are no statistically significant differences either between the two ensembles or between the single ensemble and the GT. However, the Inter Quartile Range between the 75th and the 25th percentiles for the ΔVol% metric are 9.39 for the ensemble Dice&Volume and 11.50 for the ensemble Dice, highlighting less variance when the selection method includes the |ΔVol%|.

In Fig. 2 it is shown a representative subject 3D T1-w MRI in coronal view with superimposed the ensemble segmentations and the GT manual segmentation. By visual inspection the two ensemble segmentations are comparable with GT.

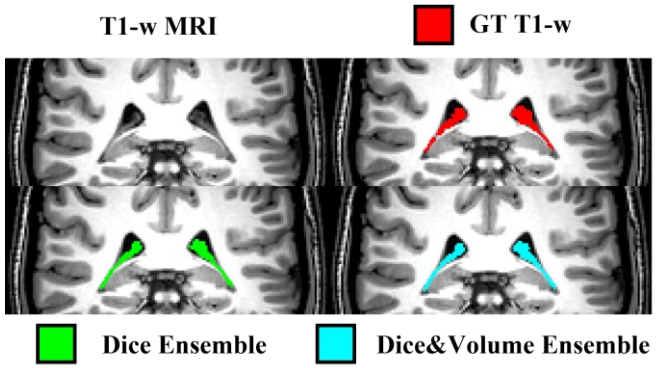

Fig. 2: Predicted segmentation results for a representative subject. 3D T1-w MRI (coronal view) with overlayed the ChP segmentations. From top left to bottom right: 3DT1-w MRI, 3D T1-w MRI with overlayed GT T1-w manual segmentation, the ensemble of the ten best configurations selected considering as saving metric the Dice Coefficient (Dice Ensemble), ensemble of the ten best configurations selected considering as saving metrics the Dice Coefficient and the Absolute Percentage Volume Difference (Dice&Volume Ensemble).

Fig. 3 shows the Bland Altman plot of the Dice Coefficient

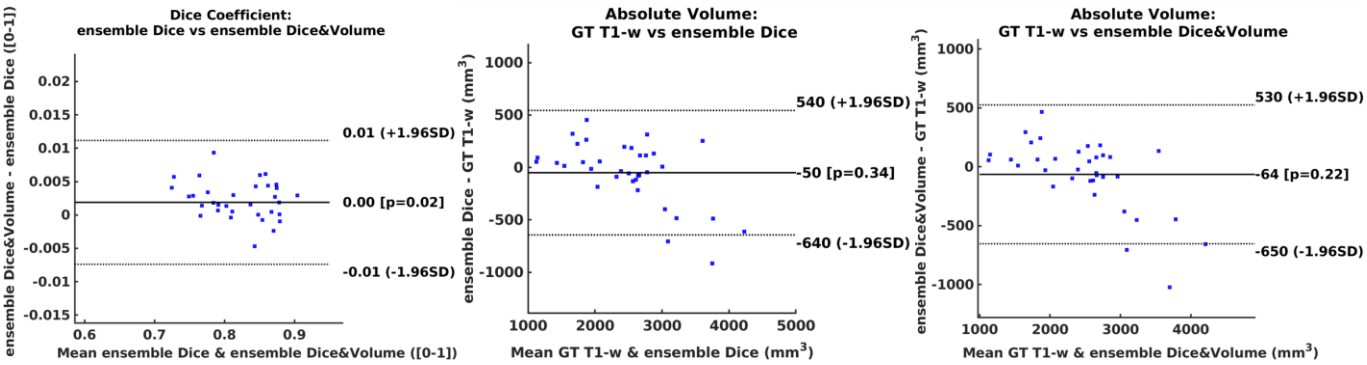

Fig. 3: Bland Altman plot for (left-right): Dice Coefficient of the two compared ensemble segmentations (Dice, Dice&Volume), Absolute Volume of GT T1-w manual segmentation and ensemble Dice and ensemble Dice&Volume.

of the two compared ensemble segmentations, Absolute Volume of GT T1-w manual segmentation and ensemble Dice and ensemble Dice&Volume. Regarding the Absolute Volume, the two ensembles behave similarly.

Taking into consideration the whole results, the addition of the volume information during the validation step gives better results in terms of less variability of ChPV.

IV. Discussion

Among the selected configurations, it is difficult to find a set of parameters that maximize the predicted segmentation performance in terms of accuracy, robustness and good ChPV estimate for both the selection strategies. The more selected loss functions are CE and DiceCE, suggesting that CE lowers the bias in ChPV estimates. The most selected patch size is 96x96x96, advising it as a good trade-off between the ChP size and the available image resolution preserving GPU memory occupancy. The more selected DNNs architectures are DynUNET and UNETR, suggesting that the use of self-configuring nets or transformers improves the results for this segmentation task. The goals of this work are to investigate if the addition of a volumetric score in the model selection during validation phase can improve the segmentation result and if the ensemble of a restricted pull of configurations exceeds the performance of a configuration taken individually.

Comparing the ensemble segmentations obtained with different selection strategies, on one hand it could be said that predictions don't differ in terms of Dice Coefficient and this result is confirmed by the visual inspection of the segmentations compared to the GT (Fig. 2), the t-test and the Bland Altman plot (Fig. 3). On the other hand, the t-test result reports they are not statistically different in terms of volume metrics. The ensemble predictions obtained with Dice selection strategy provide a higher variability in the estimates. Fig. 1 shows in the ΔVol% boxplot a lower variability in the ensemble segmentation obtained from the selection strategy that uses both Dice Coefficient and |ΔVol%| to save the models, suggesting this is the winning strategy to have the best trade-off between bias and variance in the ChPV estimate, improving the performance of the single selected DNNs.

The main limitation of this study is the small dataset, even if the studies published in this field have comparable number of samples with the GT obtained manually [20]. It should be tested the consistency of these results in a huge number of subjects varying the type of patients (e.g., Alzheimer's Disease, depression).

V. Conclusion

The ensemble of the selected DNNs provides reliable estimate of ChPV combining DNNs such as DynUNET and UNETR. In the validation phase, the use of both Dice Coefficient and Absolute Percentage Volume Difference metrics to save the best model parameters instead of just Dice Coefficient lowers the variability of the ChPV estimate, increasing the reproducibility and the robustness of the ChP segmentation.

These findings suggest that DNNs ensembles could be further used to automatically estimate ChPV in large cohort of patients; furthermore, the addition of a volume metric to select the models on which to perform the ensemble improves the performance of the segmentation task.

***Abstract*— Melanoma is the most aggressive skin cancer and its detection in the early stage is crucial for a successful medical treatment. Many algorithms have been developed to provide an objective examination, but none proved effective in clinical practice. We propose an innovative and automatic method that derives a 3D model of the patient's body from multiple macroscopic images through photogrammetry, identifies all nevi and computes diagnostic indices related to asymmetry, border, colour, dimension, and volume for each detected nevus. Good preliminary results were obtained from 15 subjects, who underwent a cutaneous biopsy for a melanoma suspicious nevus. The proposed method provides an analysis of a large portion of the body, potentially the total body, identifying the nevi with a precise location in the skin surface, and calculating useful clinical indices. The derived 3D model allows computing novel volumetric information of nevi, which can provide new insight for melanoma diagnosis. In addition, the precise localization of each nevus in the patient's body can facilitate monitoring its evolution over time. For these reasons, the proposed method could be a major advance in melanoma screening and diagnosis.**

***Keywords*— melanoma, photogrammetry, 3D reconstruction, moles mapping.**

I. Introduction

Melanoma arises from melanocytic cells and it can occur anywhere these cells reside [1]. The most frequent type of melanoma is melanoma cutaneous, which is the most aggressive skin cancer. Melanoma affects over 300,000 [2] people worldwide every year.

Important risk factors for melanoma are skin phototype (type 1 and 2 according to Fitzpatrick scale), high-dose and intermittent UV light exposure, genetics, and the presence of a great number of moles on the skin surface.

Delayed diagnosis leads to worse outcomes, thus making early diagnosis a fundamental step to improve patient survival [3]. Through secondary prevention (screening of moles), early diagnosis could provide improved outcomes, a better quality of life, and reduced economic burden for the healthcare system.

Melanoma diagnosis is based on clinical examination of pigmented skin lesions, followed by epiluminesce microcopy. In particular, to identify a suspicious mole, the ABCDE (i.e., Asymmetry, Border irregularity, Colour variation, Dimension, Evolution over time) rule was developed, which considers the shape, structure, colour, dimension of the mole, and evolution of the mole over time. The ABCDE rule assumes that asymmetrical moles, with irregular contours, multiple colours or peculiar colours such as blue or white, and a diameter larger than 6mm are significant risk factors for melanoma [4]. The most relevant and prognostic factor for melanoma is tumour thickness, linked to the proliferation of malignant melanocytes toward the subcutaneous tissue [5].

Currently, melanoma diagnosis is dependent on the dermatologist's experience and consists in the identification of all suspected moles in the body, followed by the manual acquisition of the image of a single mole, the framing of the mole with a dermatoscope and the placement of a camera in the lens; this procedure is exposed to individual judgment and reasoning. Dermatologic examination application during everyday clinical practice is crucial but it is also time and resource-consuming. Furthermore, this procedure is affected by individual reasoning and judgment.

A dermatologic examination can identify melanoma-suspicious moles, but only a biopsy and the subsequent histological examination can lead to the final diagnosis of cancer [6]. It is thus useful to find new technologies and methods able to assist clinicians in identifying suspicious moles that need a more accurate evaluation, especially when dealing with patients with hundreds of moles.

In the last two decades, many algorithms have been developed to provide an objective examination, mainly providing an image-level classification, or estimating clinical indices from an image depicting a single mole. Recent research works indicate that Machine Learning [7][8][9][10] and Deep Learning [11][12][13][14] techniques can improve diagnostic procedures for skin melanoma detection. Currently, these methods analyze an image depicting a single mole usually acquired through a dermatoscope. Most of the Literature algorithms provide an image-level classification suggesting whether the image depicts a melanoma. Instead, some recent Literature algorithms [15][16][17] provide a pixel-wise segmentation that detects the region corresponding to the mole and can be used to extract quantitative clinical indexes that can be directly provided to clinicians or used to suggest an automatic melanoma classification. Despite the significant progress made over the last few years, the Literature shows a subjective assessment and limited clinical relevance of the proposed methodologies.

The most common instrument for skin lesions examination is the dermatoscope, also known as polarized dermatoscope or epiluminescence microscope. Various models are produced and marketed by different companies. It is a hand-held visual

aid device a clinician can use to examine and diagnose each single skin lesion. This tool does not allow automatic mapping of patient moles and is rarely integrated with automatic single mole analysis software. Systems that were recently proposed for total-body mapping are based on the analysis of a single macroscopic image depicting a large portion of the patient's skin, thus not providing a 3D moles mapping. In addition, further analysis of each single skin lesion is manually performed, thus reducing the benefit of an automated system.

The device that is proposed in this Project allows a 3D mapping of the patient body, potentially the total body, combined with the automated identification and analysis of every single mole in the skin surface. Thus, it could be a major advance in melanoma screening and diagnosis.

II. Methods

Fifteen adult patients referred to the Veneto Institute if Oncology (IOV) of Padova for a cutaneous excisional biopsy of an atypical mole were included in this study. To take part in the study, after being properly informed about the aim, methods, and implications of the study, all patients must sign the informed consensus, approved by the local Ethical Committee.

12 images of the whole patient's back and suspicious lesions to be biopsied had been taken at each session. The images were acquired for each patient using a system prototype which consists of a vertical structure with a horizontal movable arm containing 12 cameras and 4 polarized led lights. All 12 cameras shoot simultaneously so that the movements of the patient did not influence the acquisition of images. This structure was developed and made based on the Italian patent n° IT 102016000132357 [18]. Fig.1 shows a sketch of the medical device which is currently in use at University of Padova.

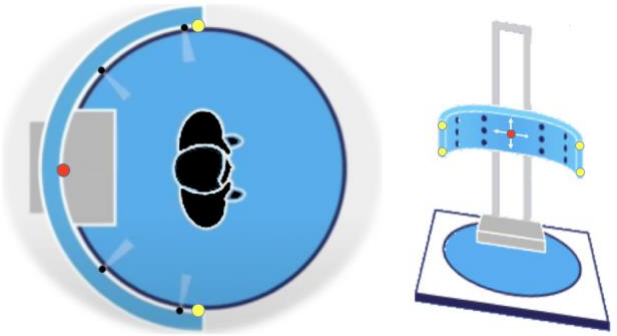

Fig. 1: Sketch of the medical device. Black dots correspond to cameras, yellow dots correspond to polarized led lights.

With the medical device, 12 pictures acquired from multiple viewpoints of the region of interest are taken a few days before the biopsy is performed.

A few weeks after the surgical biopsy, an histological exam of the excised lesion is available. This pathological report represents the gold standard for the diagnosis of cutaneous melanoma.

Photogrammetry technology may allow increasing the accuracy of clinical criteria. Moreover, depicting a large portion of the body allows for identifying the moles that differ from the others, which is one of the main clinical features indicating melanoma (the so-called ugly duckling sign) [19].

A 3D model is then reconstructed using the Structure from Motion (SfM) Photogrammetry technique. The procedure finds common key points between images, aligns the photos, creates a mesh, and then textures it. For the various parts of the obtained model, images corresponding to the best orientations for the specific part under analysis are extracted and called 2.5D images. The obtained 3D model is useful to evaluate the thickness of each mole and it could be an efficient tool for dermatologists to detect moles that are changed over time (part of the E criterion of the ABCDE rule).

A specific algorithm has been developed for the analysis of the obtained 3D model, to automatically identify and analyze every single mole.

For each 2.5D image, the HSV (Hue, Saturation, Value) colour space is considered and the positions of the moles in the skin area are identified by analyzing the intensity of channel S (Fig2.b). Channel S is indeed a relevant channel for drawing attention to the moles, which are lighter than the rest of the skin and therefore identified as local maxima. After the localization of every mole on the S channel as a local maximum of the region of interest, a cropped image of 120x120 pixels for every mole is produced from the original image. The crop is created so that each mole corresponds to an image in which approximately 30% of pixels belong to the mole. By creating the image this way, mole segmentation can easily and accurately be performed.

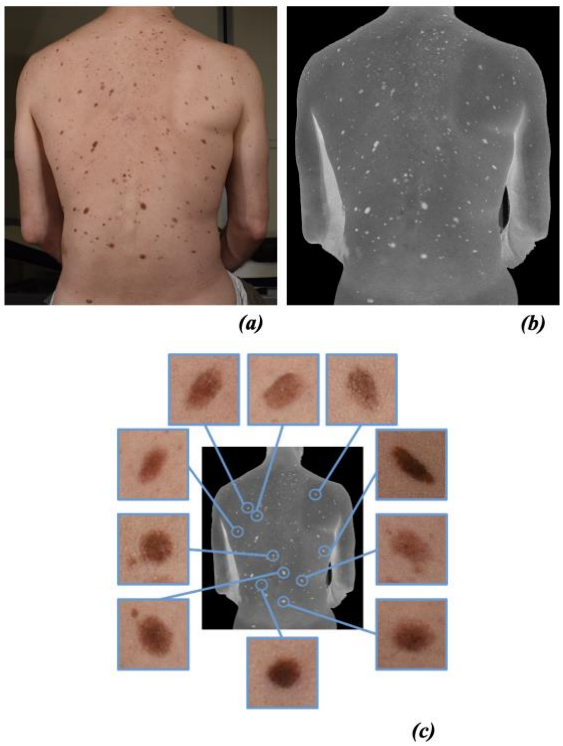

Fig. 2: (a) One of the 12 images of the back of a patient. (b) Representation with channel S. (c) Cropped images of some moles obtained by channel S representation.

Fig.2 shows one of the 12 pictures of the back of a patient (Fig2.a); its representation with channel S once the background was removed, which emphasizes the moles

(Fig2.b); an example of some cropped images with one mole on the centre, which are easily obtained thanks to the representation in channel S, that identifies all the moles as local maxima (Fig2.c).

The RGB (Red, Green, Blue) colour space of the cropped image is then considered, in particular channel blue, which is the one that allows the best identification of the border of the mole. The border is then segmented through local thresholding; active contours are then applied to refine the contour.

ABCDE characteristics are then derived. The asymmetry of the segmented area is estimated by using principal axes and calculated with the rotation matrix; the variance of the distances between the centroid and each border point is used to estimate a border index; the number of peaks in H is used to estimate information about the color; major and minor principal axes are used to compute the dimension of the mole (Fig3.a). In addition, the thickness (Fig3.b) of each individual mole is calculated on the corresponding region of the 3D model. Fig.3 shows a portion of the patient's back, focusing on one mole from which minor and major principal axes and their length are derived; moreover, Fig3.b shows the thickness of the mole which is derived from the 3D model. Fig.4 shows the histogram of the H channel of the mole in the previous figure and the histogram obtained by a mole with colour variation. The latter histogram (Fig.4b) denotes the presence of multiple distributions and peaks.

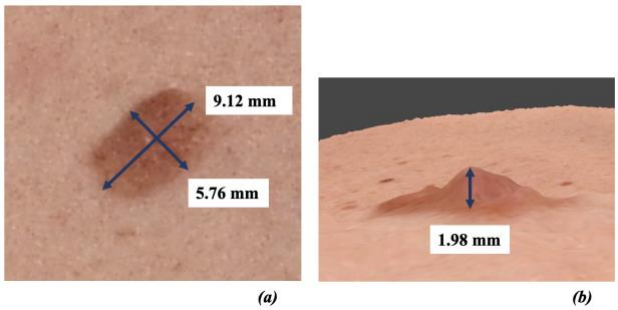

Fig. 3: (a) 2.5D crop image of nevus detected with automatic segmentation border and lengths of diameters. (b) Mole thickness was taken from the 3D model.

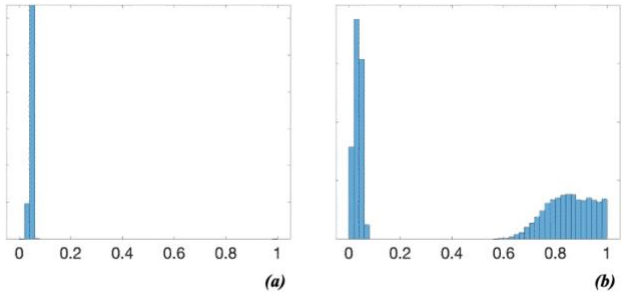

Fig. 4: (a) histogram of H channel of the mole in the previous figure. (b) histogram of H channel of a mole with variation in colour.

III. Results

Images from 15 subjects were considered. For each subject, 12 back skin images were simultaneously acquired using 12 digital cameras equipped with polarizing filters (Nikon D3500). Each subject had one mole considered suspicious by an expert dermatologist and was referred for a cutaneous excisional biopsy.

The proposed algorithm correctly identified all the main nevi in the patient's back and all suspicious moles were considered among the moles automatically identified.

For evaluating the segmentation, 30 moles were considered and analyzed both manually and automatically: for each subject, it was considered the suspicious mole, which was about to be biopsied, and another randomly selected mole. The IoU (Intersection over Union) index was therefore calculated in the 30 moles by comparing the automatic segmentation and the manual segmentation. All the segmented moles showed an IoU index of about 0.9: being this very close to 1, the result denotes a good correspondence between automatic and manual segmentation.

The automatically estimated clinical indices were used to distinguish normal moles from those with suspected melanoma. Although a global index has not yet been developed, in the considered limited dataset the suspicious moles differ in anomalous values of color variations (4 moles), asymmetry and dimension (3 moles), border irregularity (2 moles), or high values in all the derived clinical indexes (6 moles). The thickness proved to be useful for classifying as normal two moles which otherwise would have been misclassified as suspicious.

These preliminary results encourage the further development of the proposed method and the evaluation of a large number of subjects. An exhaustive investigate about accuracy, specificity and sensitivity of the proposed method for melanoma detection is also required.

IV. Conclusion

This Project aims to develop a system that can be beneficial for melanoma detection and for mole monitoring in a population screening program. Indeed, the current methodology is exposed to clinicians' experience, and subjective judgment, time consuming and attention demanding.

The medical device proposed in this Project consists of 12 cameras and 4 polarized led lights, which allow the simultaneous acquisition of 12 high resolution images of the patient cutaneous surface from different viewpoints. These images are used to build a 3D model of the patient skin surface, through photogrammetry. An algorithm has been developed to analyze the obtained 3D model, providing clinicians with a mole mapping and with visual and quantitative information automatically derived for each mole, providing a reliable map of the suspicious moles.

The proposed hardware and software system has been tested on 15 patients referring to IOV for a suspicious mole that needs to be excised. The acquired images allow obtaining a 3D model of the skin surface of each subject. The algorithm specifically developed in this Study was able to correctly identify all the main nevi depicted in the images. Consistency between manual and automatic segmentation was also obtained. Finally, the automatically derived clinical indexes (ABCD: asymmetry, border irregularity, colour variation, dimension), combined with the measurement of volume

(thickness) obtained by the 3D model, allow the correct identification of the suspicious moles among the others.

The results of the biopsies will be used to improve the specificity of the algorithm. In addition, once data will be collected from a large number of patients, images and verified labels will be used for the training of an algorithm based on Machine\Deep Learning techniques which can lead to the accurate and generalizable classification of suspicious moles.

Further developments of the proposed algorithm will include the identification of the ugly duckling sign, i.e., the mole which is different from the others because of its shape or colour. Indeed, the acquired macroscopic images depict a large portion of the skin surface in which many moles are present, and the one that looks different from the others can be easily detected and then highlighted for evaluation by clinicians.

In addition, a specific procedure for the computation of evolution over time from images acquired from the same patient at different times will be developed. Indeed, patients involved in this study took part in the follow-up session 5/6 months after the first one. The comparison and quantitative measure of the same mole imaged at different times might provide fundamental information about the evolution over time of pigmented lesions, a well-known criterion of suspicion presence of melanoma.

Although the two images of the same patients taken few months apart already show some small differences in nevi through image registration, more follow-up sessions need to be done to see relevant changes of each nevus.

Error perception in different environments: Monitor vs Augmented Reality

***Abstract*—Detection of errors results in a typical brain response, identified in the Electroencephalographic (EEG) signal called Error Potential (ErrP). The ErrP is widely used for correcting the output of external devices (e.g. autonomous driving, Brain-Computer Interfaces) and, therefore, its identification and its correct stimulation are crucial.**
In this paper, we present the analysis conducted on the EEG signal recorded from 17 subjects that underwent a protocol of error stimulation in two environments: through at a Monitor and in a Virtual Theatre. Each session consisted of three consecutive acquisitions.
The comparison of the two environments in terms of temporal characteristics of the ErrP (Grand Average and Single Trial analysis) resulted in a significantly more pronounced and faster response of the brain during the Monitor acquisition (Mann-Whitney test, with a p-value threshold of 0.05).
Moreover, it has been noticed that the amplitude of the characteristic peaks followed a decreasing trend along sessions, due to the repetitiveness of the experiments and therefore boredom of the participants.
In conclusion we were able to assess a more robust stimulation of the ErrP in the Monitor environment, reflected in a stereotypical waveform of the Evoked Potential. This may be due to the subjects not having the habit of using Augmented Reality or Virtual Reality.

***Keywords*—Signal processing, Electroencephalography, Evoked Potential, Augmented Reality.**

I. INTRODUCTION

The perception of errors by subjects is reflected in their brain activity and can be detected in the electroencephalographic signal (EEG). In particular, it results in a characteristic Evoked Potential (EP) named Error Potential (ErrP) [1]. The anterior cingulate cortex, a region located in the medial-frontal areas of the brain, is the primary location for the error-related activity [2]. Depending on the task, various types of ErrPs can be identified, one of which is elicited when there is an error in the interaction between a user and a machine. This type of ErrP exhibits a characteristic pattern, consisting of a negative peak at 250 ms post-error, a positive peak at 320 ms, and a final negative peak at 450 ms [3]. The ErrP finds major application in Brain-Computer Interfaces(BCI), systems that permit to use an external device using the interpretation of brain activity. In this field, the ErrP is mainly used to correct the erroneous output of the BCI system (i.e. the one not expected by the subject) [5].
Moreover, the detection of errors in real-time can be employed also in other sectors such as autonomous driving [6] or psychiatry. Concerning the latter case, literature has highlighted that the performance in detecting errors by subjects is strictly linked to their attention level [7].
The detection of errors during ErrPs stimulation experiments can be highly variable and dependent on the cognitive state and the engagement level of the subject during the trials. This variability can greatly impact the ability to accurately identify the presence of ErrPs in the EEG recordings. Therefore, it is essential to carefully design an engaging and effective protocol for catching user attention, as well as to use an appropriate experimental setup for stimulation, in order to obtain reliable and robust results [8].
Virtual Reality (VR) and Augmented Reality (AR) technologies have become increasingly popular in brain stimulation experiments due to their ability to enhance user engagement and involvement. However, research has shown that the performance of these technologies can be affected by the subject's level of familiarity and comfort when using them [9].
In this paper, we present a study that investigates the analysis of the ErrP signal when stimulated by video-games in two different environments: a standard monitor and a Virtual Theatre using Augmented Reality (AR) technology. The study aims to compare the ErrP signal in these two environments and to understand how the use of VR/AR technology affects the realization of the ErrP signal. The results will provide valuable information on the potential benefits and limitations of using VR/AR technology in brain stimulation experiments.

II. METHODS

A. Protocol

The analysis has been conducted on 7 females and 10 males participants (age: 21.8 $\pm$ 0.77 years). The protocol for stimulating the ErrP was created using Unity [10], and it involves a car moving along a road with randomly appearing checkpoints (represented as rings) on the left or right side of the street. The car has a 50% chance of approaching the checkpoint or going in the opposite direction. If the car misses the checkpoint, an ErrP is expected to be elicited. Each subject is presented with a total of 20 checkpoints per acquisition. The protocol is run twice for each subject, on different days at the same time. One session was taking place in a lab with the subject viewing the protocol directly on a monitor, while the other was in a Virtual Theatre, which is a room equipped with Augmented Reality technology. It consisted of a 360° round with a diameter of 7 meters and featured a projection on a curved surface of 360°. This advanced technology allowed

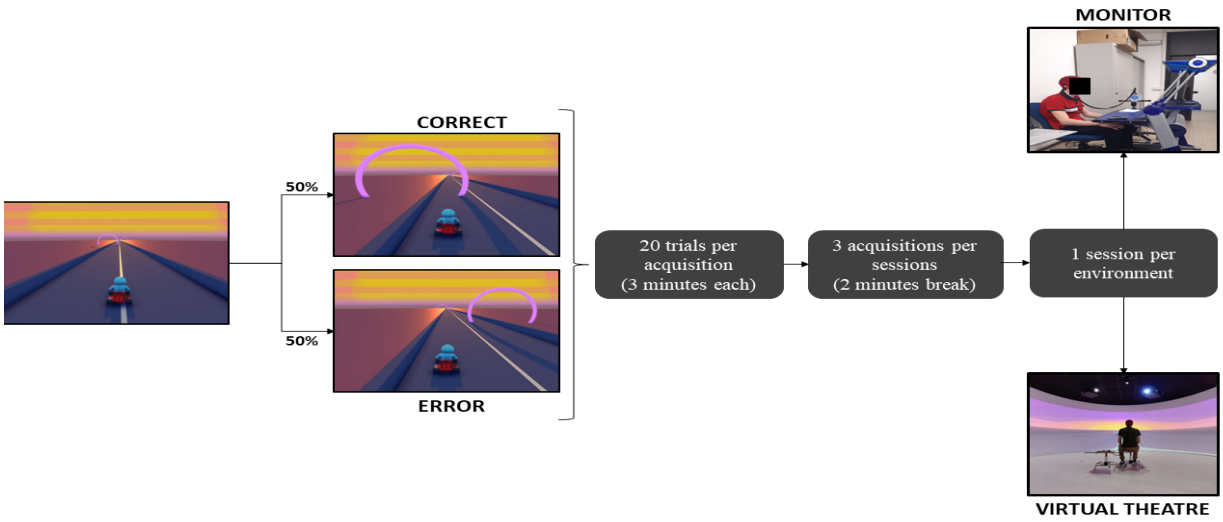

Fig. 1: Experimental protocol.

for a more immersive and interactive experience for the subjects during the feedback sessions. During each session, the participants were acquired three consecutive times with a break of 2 minutes between each acquisition. The environment of the first session was randomly chosen for each subject. The schematic of the complete protocol is reported in Fig. 1.
During the acquisition, the EEG signal was recorded with the EBNeuro BE Plust LTM amplifier with 64 electrodes placed on the scalp and with gel applied(EBNEURO, Florence, Italy). The synchronization of the EEG signal and the trigger of the event was made through software using the Lab Streaming Layer protocol.

B. EEG signal processing

The recorded EEG signal was first filtered between $1-30Hz$ to remove noise components at high frequencies. After having removed low amplitude channels (e.g. channels with flat recordings), Common Average Re-referencing was applied to attenuate the noise common to all channels. Thus, ErrP epochs of 1 second after the onset of the stimuli were extracted.
Artifacts related to eye movement (blinking and horizontal movement) were removed using Independent Component Analysis.
For each subject and for each acquisition, the Grand Average of the ErrP trials was computed together with the Single Trials estimates obtained by the subspace regularization method [11]. The subspace regularization is based on the regularized least squares scheme and needs an estimate of the background EEG to highlight the single ErrP response from the EEG.. In our work, we used the recorded EEG one second before the onset of each erroneous stimulus as an estimate of the background EEG of the corresponding Single Trial.

C. Extracted Features

We extracted the main characteristics of the ErrP both from the Single Trials and the Grand Averages. The main features extracted were: the latency and amplitudes of the positive peak between 200 and 500 ms; the latency and amplitude of the negative peak between 400 and 700 ms. The latency of the negative peak was computed with respect to the latency of the positive peak in order to avoid delay propagation.
These features were computed for the electrodes FCz and Cz since the ErrP realization is mainly localized in the fronto-cental area of the cortex.

D. Statistical analysis

The features extracted from the EEG recorded in the Monitor and Virtual Theatre environment were compared to assess any significant differences in the ErrP realization in the two different environments. In particular, we used the Mann-Whitney non-parametric test for each feature comparison and a p-value lower than 0.05 was used to assess significant differences.

III. RESULTS

In Fig.2 are reported the Grand Averages in Monitor(left) and Virtual Theatre(right) for the same subject as an example. We notice that the EP realization is closer to the characteristic waveform of the ErrP during Monitor acquisitions than during Virtual Theatre trials. In this latter case, no negative peaks are observable after the positive peaks, which also occurs with higher latency. These observations are confirmed by the distribution of the computed features reported in Tab.I. In the table are reported the medians, the 25th and the 75th quantiles of the distribution of each feature for each acquisition in Monitor and Virtual Theatre for electrodes FCz and Cz. The highlighted cells (in bold) show significant differences between the two environments ($p<0.05$; Mann Whitney test). It is worth noticing that, especially for the FCz electrode, the ErrP stimulated in the Monitor environment has more pronounced peaks (both negative and positive) and significantly lower latency for almost all acquisitions. It is also observable that

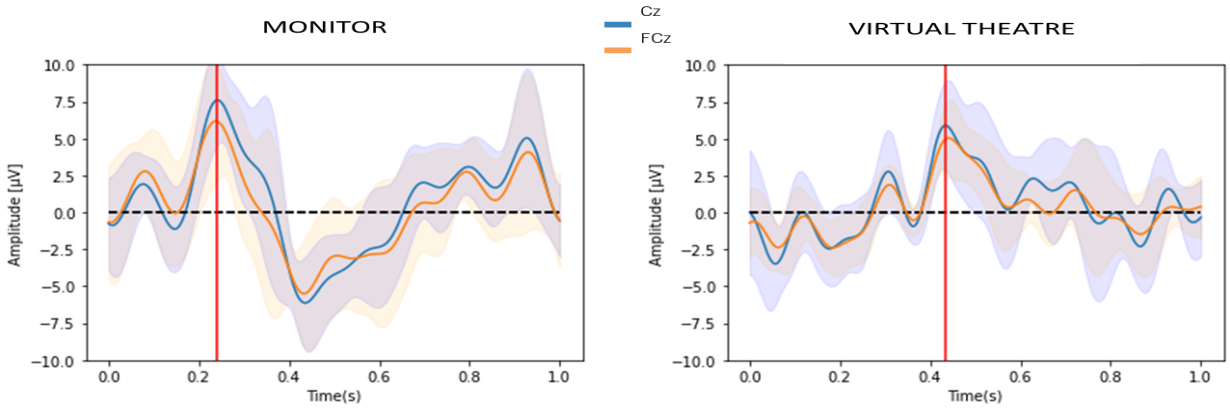

Fig. 2: Grand Average of the ErrP epochs in electrodes Cz(blue) and FCz(orange) in the investigated environments: Monitor (left) and Virtual Theatre(right). Shaded is reported as the confidence interval of the averaged epochs.

the amplitude of the peaks in absolute values tends to decrease along acquisition in both electrodes and environments. The Single Trial analysis confirms these findings. The distribution of the values of the computed features (after estimation of the single sweep with the subspace regularization method) are reported in Tab.II. Also in this type of analysis, the Monitor stimulation resulted in significantly higher amplitudes of the peaks and lower latencies, especially for electrode FCz. The amplitude of the peaks confirms the decreasing trend along the three acquisitions found in the Grand Average analysis. These differences along acquisitions have been tested with the Kruskall-Wallis non-parametric test, but no significant difference could be assessed both in the Grand Average and in the Single Trial analyses.

IV. Discussion

The presented results suggest that, in our data, the Monitor environment can better engage subjects during ErrP stimulation experiments. This is reflected in a faster and more pronounced response of the brain in the frontocentral area in presence of ErrP. Even if the characteristic waveform of the ErrP was obtained also when stimulated in the Virtual Theatre environment, the response was significantly slower and the amplitude of the peaks significantly lower. This issue can find

TABLE I: Distribution of the temporal features computed for the Grand Averages of the ErrP epochs. The values are reported with the following format: median(25th quantile,75th quantile). The latency of the negative peak was computed with respect to the latency of the positive peak. In bold are reported the values that resulted in a p-value less than 0.05 in the Mann-Whitney test.

answer in the feedback that the participants gave at the end of both sessions. Concerning the Virtual Theatre, they found the environment very distracting, not because of external factors, but due to the novelty of the environment itself. Indeed, none of the participants was used to work or play with AR or even VR.

The decreasing trend of amplitude peaks from the first to the third session may be a result of the repetition of the experiment. Additionally, a high rate of ErrP trials during acquisition may have removed the element of surprise, leading to weaker stimulation of the EP troughout the sessions.

V. Conclusions

In this paper, we presented a study on the differences in terms of temporal characteristics in stimulating brain response after an erroneous event looking at a Monitor and with AR. The Monitor provided a more robust stimulation of the ErrP mainly due to subjects being more used in interfacing with this type of technology. However, the repetition of acquisitions and the lack of interaction of subjects with the system led to the boredom of the participant. Lowering the probability of appearance of an erroneous event, integrating the presented protocol with an ErrP classifier and giving real-time correction of the position of the car, may engage more subjects' attention, resulting in a complete BCI system controlled by ErrP.

Time-frequency analysis of brain response to 3D slant texture and stereo cues

F. Peveri[1], G. Arnulfo[1], S. P. Sabatini[1] and A. Canessa[1]

***Abstract*— Visual system estimate surface slant from different visual cues, but on how and where these cues are integrated there is still much to be understood. The aim of this study is to fill the gap we identified regarding brain activity elicited by complex visual stimulation defined by different cue to slant. We used electroencephalography (EEG) and time – frequency analysis to characterize the cortical responses to monocular and binocular cues. We design slanted surfaces defined only by texture and binocular disparity, and surfaces defined by the two cues combined in a conflictual and non - conflictual configuration. The processing of these visual stimuli enhanced the same pattern of spectral modulation in all investigated ROIs but with different latencies and different patterns depending on the available visual cue.**

***Keywords*— EEG, visual cues, slant perception, texture, binocular disparity, conflictual cues**

I. Introduction

The primary aim of visual perception is to build an accurate representation of the outside world from the collection of signals impinging on the retina. One of the most difficult tasks is to estimate three-dimensional (3D) surface shape. The visual system makes use of different sources of information (cues) to accomplish it including binocular disparity, shading and lighting, and perspective / motion parallax [1]. The optimal estimation of 3D orientation of surfaces and shape recognition supports a range of behaviours, from placing and grasping objects to navigation in the environment. The 3D shape of an object at any point on a smooth surface can be closely approximated over a small neighbourhood by a plane and the most fundamental measure is local surface orientation [2]. Human adults can integrate different sensory estimations to reduce the uncertainty of the final percept (e.g., integrating stereo and texture information to judge surface slant). The optimal reduction in uncertainty is obtained by a weighted averaging of these estimates, in which each one is weighted in proportion to its relative reliability [3, 4]. We are then also able to integrate different visual cues when these are in *conflict* with each other, which means that each cue signals a different slant. Recent studies have investigated the neural mechanisms involved in processing individual visual cues [5, 6, 7] but the investigation of where and how cue combination occurs in the brain has not received the same interest, especially using electroencephalography (EEG) techniques. Two of the most prominent cues for estimating slant orientation are surface texture, that provide monocular information about the 3D structure and the binocular disparity, which results from the subtle differences between the two views of the eyes and provides a powerful cue to depth. In this work we focused on this two visual information to characterize the cortical responses to stimuli depicting slanted surfaces defined by texture and stereo cues in isolation, and the two cues combine in a conflictual and non-conflictual configuration.

II. Related work

Visual cues to slant have received a great deal of attention in the psychophysical, computational and neuroscience literature. Single cues combination is demanding for the brain, cortical activation measured with fMRI for different depth configurations are more discriminable when the other cues to depth (e.g., texture gradient) agree with disparity cues, suggesting [8, 9] a form of cooperative combination. Welchman et al [10] measured fMRI responses while observers judged the 3D slant of surface defined by binocular disparity and perspective. They compared behavioural and fMRI responses evoked by changes in one or both depth cues founding that the fMRI responses in extrastriate areas (hMT+/V5 and lateral occipital complex), rather than responses in early retinotopic areas, reflect differences in perceived 3D shape, suggesting that the cue-combination processes occur in higher visual areas. Other studies investigated the dynamic of visual processes [11] with EEG, which allows separating visual and later decisional processes in time. They combined EEG with a model-based analyses to determine at what latencies and electrode locations visual evoked potentials (VEPs) parametrically reflect visual cue reliability. Their stimuli were defined by contour and surfaces cues and the analyses shown that cue reliability effects are not systematically time-locked to response initiation or execution processes, but they observed effects at longer latencies, well after the typical latencies of visual processing mechanisms. They speculated that contour and surface cues are combined and the variations in their reliability are resolved at a relatively late stage of processing. Again, Murphy and Welchman [3] suggested that area V3B/KO is intricately involved in the integration of qualitatively dissimilar depth cues. In another recent work, Pegna et al. [12] used event-related potentials (ERPs) to study perceptual sensitivity to stereo versus mono input in a perceptual matching task. The task consisted of comparing the shape of two novel 3D objects under conditions of stereo and mono viewing. The results showed an early perceptual sensitivity to the mode of input shown by a negative amplitude modulation between 160 and 220 ms post-stimulus onset. Results also showed later modulation of ERP amplitude during an N2 component between 240 and 370 ms for stereo and mono input that was linked to the perceptual matching of shape. Moving to the time-frequency domain, some studies [13, 14, 15] have investigated, using desynchronization/synchronization (ERD, ERS) analysis, how different frequencies are modulated during visual cognitive tasks. They observed both alpha-band and beta-band ERD modulations during processing of visual cues. Gallotto at al. [20] probed alpha power modulations during directional cue

visualization, observing different modulations dependent on the type and direction of the presented stimulus.

III. Materials and Methods

Observers. Eight healthy participants with normal or corrected to normal vision from the University of Genoa. The mean age was 24 years.

Stimuli and set-up. Stimuli were grayscale stereograms of slanted textured surfaces, with slant (rotation about a central horizontal axis) defined separately by texture and binocular disparity. We generated the textures by Voronoi tessellation of a regular grid of points jittered in two dimensions [3]. We chose this type of texture in order to avoid the introduction of another cue-to-slant, the perspective. We presented the surfaces inside a circular aperture with a radius of 31.3° of visual angle and a blurred profile. We set the background color to a mid-grey. We design visual stimuli defined only by texture, only by binocular disparity and both cues combined in conflictual and non-conflictual manner.

We created stimuli and task using a 3D graphic engine, Unity3D, and exploiting Shaders, short powerful programs that render graphics data. Building incongruent visual cues to slant requires a virtual camera that renders the texture of a slanted plane and a projector, whose shader projects that texture on a plane with a different slant which is observed by two stereo cameras, see *Figure 1*. For stimuli defined only by disparity cue to slant we used random dots generated with Psychophysics Toolbox for MATLAB (PTB) [17], from there we obtained the two images for the right eye and left eye.

The set-up consists of 3D monitor (LG, 1920x1080, 42”, 100 Hz) connected to an Alienware with NVIDIA GeForce RTX 3090 Graphics card. To be able to stereoscopically see the stimulation with this apparatus, it was necessary to create the rendered visual stimulus by placing the two images (for left and right eye) side by side, halving the horizontal resolution. A photodiode was placed in the lower right corner of the monitor connected to an Arduino. This served to send trigger signals to the EEG amplifier though a Triggerbox, whenever the stimulus was displayed. For this reason, a white patch was lit for 0.1 s, on the lower right corner concurrently to the visual stimulus onset.

Procedure. We instructed subjects to wear 3D polarized glasses and sit at a viewing distance of 50 cm with the head stabilized by a chin rest. For each condition (only texture cue (condition *T*), only disparity cue (condition *D*), both cues (condition *TD*) and both cues conflictual (condition *TDc*), the task consisted of 360 total trials. As depicted in *Figure 2*, we presented the stimuli for 1.5 sec interspersed with a blank screen for 1 sec, for a total duration of each block of approximately 15 minutes. A 10-minute rest was provided between the four blocks. The slant value of the stimuli for the *T, D* and *TD* conditions were a random value in a range of 9 possible slants, from -40° to 40° with step 10°. Slant values for the *TDc* condition were chosen based on the perceptual metamers constructed by the subject. Before characterization task with EEG recording, subjects performed a perceptual matching task in order to produce a set of stimuli that were perceived to have the same slants but composed with a different combination of stereo and texture information. This was done by adjusting, with a handle-tracked board, the disparity cue of a stimulus (where the texture cue remains fixed to a random value between 15° to 45°, with a step of 5°) to match a cue-consistent reference stimulus with a slant of 30°. These 3D perceptual matches are sometimes called slant metamers: objects perceived to have the same slant but with different combinations of the available cues, the same thing that happens with the psychophysical phenomenon of color metamerism, where different spectral distributions can elicit the same perceived color [18].

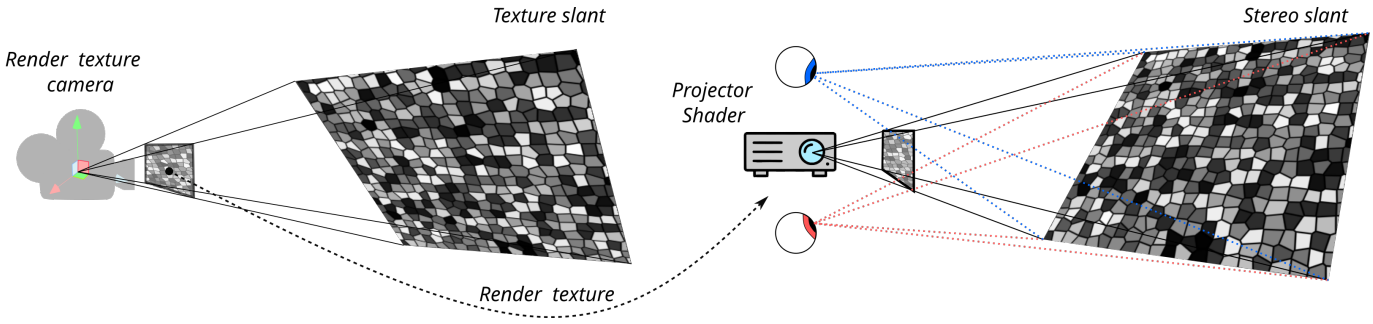

Figure 1: **Generation of cue - conflict stimuli with Unity3D.** How incongruent stimuli are generated. A textured plane object is viewed by a camera that creates a rendering texture that is passed to a projector that projects the "slanted texture" on a plane that physically has a different slant. This plane, viewed by two stereo cameras, yield the pair of images that define the final incongruent stimulus.

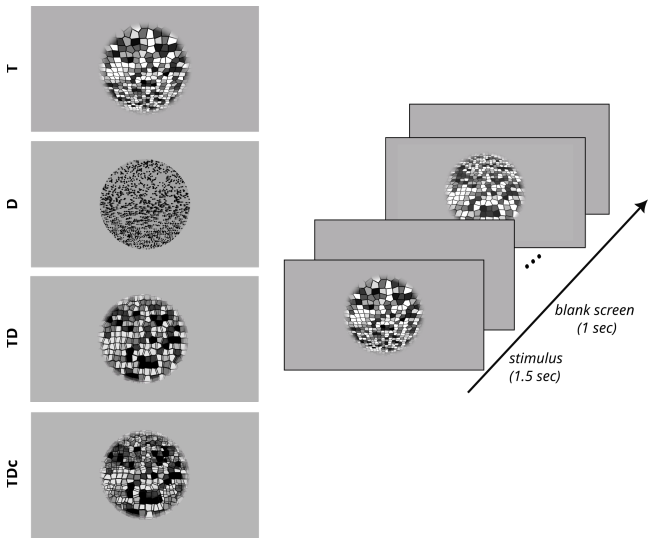

Figure 2: **Visual stimulation**. On the left, examples of displayed stimuli for all conditions. On the right, a block sequence of presentation. The task begins with a fixation cross, then the stimulus is presented for 1.5 sec follow by a blank screen for 1 sec.

EEG recordings and analysis. We recorded EEG activity using *BrainVisionRecorer* from *BrainProduct*. We used a 64-channel Ag/AgCl scalp electrodes that were referenced to the FCz. We adjusted individual electrodes until impedances were below 15 kΩ before starting and we continuously recorded EEGs at a sampling frequency of 500 Hz. Raw data underwent an off-line pre-processing artifact rejection and noisy electrodes removal. For this purpose, we used a dedicated pipeline to clean raw data. We firstly linearly detrend the data, in order to remove slow cortical activity, and applied a spectral and spatial filtering - *Zapline* filter [19] - to remove power line noise (50 Hz). Next, we removed ocular artifacts (e.g., blinks, horizontal eye movements). We decomposed the signal into physiological and artefactual components (muscle artifacts) by the use of independent component analysis (ICA method).
We carried out data processing with Brainstorm ®, an open-source software written almost entirely in MATLAB scripts that allows in-depth brain signals analysis [20] and custom scripts. Then, in order to study the behaviour of different ROI in the brain, electrodes were divided into four ROIs, based on their scalp position, representing frontal, central, parietal and occipital ROIs, summarized in table 1. ROIs signals were subsequently constructed averaging all electrodes data belonging to that group.

Time-frequency analysis and event related spectral perturbation. Time-frequency domain analysis was performed, in order to compute the event related spectral perturbation (ERSP), in each participant, for each ROI and for each condition. In order to obtain the ERSP we transformed data by means of a time-frequency decomposition using 80 Morlet wavelets in the [1;80]Hz range (central frequency = 1Hz, Full Width Half Maximum = 3s) [21]. To avoid border effect we applied the wavelet decomposition to the continuous data and then epoched the time-frequency representation around the stimulus onset with a window of 0.5 s pre-stimulus and 2.5 s post-stimulus.
To compute ERSP, firstly we performed a single trial division dividing the wavelet transform for each single trial by the power spectrum computed over the full trial interval [22]. After that, ERSPs trials data were averaged and log-transformed to better evaluate the intensity changes. Then, the magnitude of the spectrum was baseline-corrected by subtracting the mean log power spectrum computed within the pre-stimulus interval (−0.5 to 0 s).
Using ERSPs allowed us to evaluate possible synchronization and desynchronization latencies, for different stimulus conditions in the various considered ROIs. To better characterize amplitude and latencies of synchronizations and desynchronizations we computed also the Event related synchronization and desynchronization (ERD/ERS) integrating the ERSP in three specific frequency bands (theta [4-7] Hz, alpha [8-12] Hz and beta [13-30] Hz).

IV. Results

In *Figure 3* we reported the ERSP plot of each ROIs - from left to right - frontal, central, parietal and occipital, and for each stimulus condition, *T, D, TD* and *TDc* - top to bottom. Darker colour indicates stronger differences in spectral power compared to the baseline, red signals a power increment,

Table 1: ROIs electrodes table

Frontal	'Fp1','Fp2','F3','F1','Fz','F2','F4'
Central	'FC3','FC1','FC2','FC4','C3','C1','Cz','C2','C4'
Parietal	'CP3','CP1','CPZ','CP2','CP4','P3','P1','Pz','P2','P4'
Occipital	'PO7','PO3','POz','PO4','PO8','O1','Oz','O2'

which mean a synchronization, while blue signals a power decrement, which means a desynchronization. It is possible to see by eyes that there are synchronizations in theta and alpha bands and a desynchronization in beta band. More precisely it can be noted that, starting from the stimulus onset, there is a synchronization in the theta and alpha, while later these are followed by a greater desynchronization in the beta one. Regarding the duration and amplitude of these modulations, it is seen that synchronization has a higher amplitude but a shorter duration than desynchronization, which is more persistent, until the end of the stimulus presentation. Among the various ROIs, no major differences are identified, while what stands out is a difference in synchronization especially between condition *D* and the others and between *D* and *T* compared with the case in which both visual cues were presented (*TD* and *TDc*). *Figure 4* shows mean ERD/ERS values for the 4–7 Hz frequency band (first row), 8–12 Hz (second row) and 13–30 Hz (third row) as a function of time.

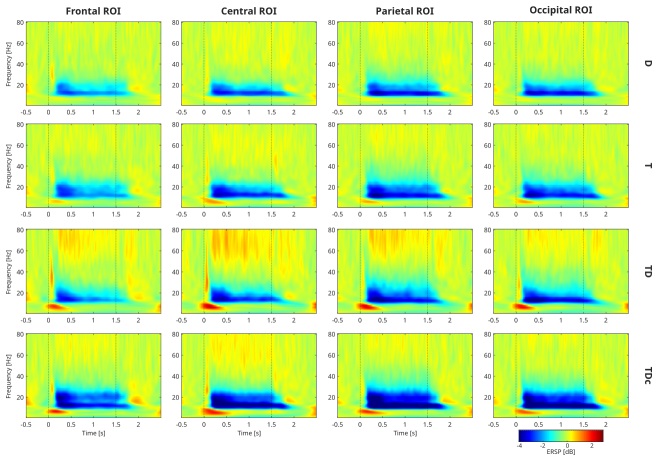

Figure 3: **ERSPs**. Mean time frequency maps representation across subjects for the four different ROIs. Each column represents a different ROIs, while each row is a different stimulus condition.

V. Conclusion

The aim of this work has been to investigate the cortical dynamics during a visual task to evaluate and highlight differences in how the brain process texture and stereo cues. We conducted EEG recordings on eight healthy participant and performed ERS/ERD analysis. We observed that slanted surfaces stimuli elicit synchronization in alpha and theta bands and a longer desynchronization in beta band. Further analysis is needed to investigate deeper the cortical activity. We did not perform a statistical analysis in this preliminary study because the number of subjects was relatively small. The next step will be to acquire a larger number of subjects in order to go looking for significant differences in cortical activity elicited by visual stimulation defined by monocular and binocular cues and defined by a conflicting combination of these.

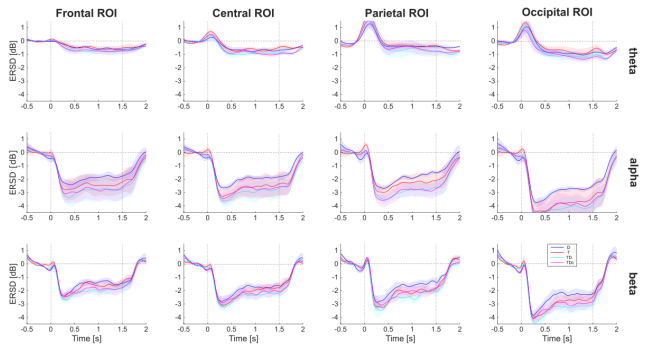

Figure 4: **Time course of ERSDs.** Mean ERSD (solid line) and SEM (shaded area, estimated using *jackknife* method) for the four different ROIs in theta, alpha and beta frequency bands, across subjects. The four colored lines in the plots represent the different conditions of the visual stimulus (*D, T, TD, TDc*).

***Abstract*—Several biomedical imaging modalities are available in the scientific literature for breast cancer diagnosis, each with its own advantages and limitations. In this framework, microwave tomography has gained a certain interest in the last years due to its capability to provide quantitative maps of tissues electric properties in a safe, non-invasive fashion. Furthermore, this imaging modality proved to be cheaper than traditional medical exams. By virtue of the great advantages that artificial intelligence, and more specifically deep learning, has delivered especially in the medical area, this paper proposes a novel procedure for breast cancer imaging by means of microwave radiation. The two-dimensional numerical results reported in this work seem promising and allow to identify and image potential malignancies in the breast.**

***Keywords*—Microwave tomography, breast cancer imaging, deep learning, multistatic systems.**

I. INTRODUCTION

Breast cancer represents one of the commonest types of cancer among women [1]. It is currently the second leading cause of death in the United States, and is expected to surpass heart diseases as the leading cause of death in the next few years. Its early detection is paramount for planning successful treatment and allowing a proper recovery for the patient.

Among the commonest medical imaging modalities adopted for its diagnosis it is worth mentioning X-ray mammography, which nowadays still represents the gold standard, the magnetic resonance imaging (MRI), ultrasound imaging and nuclear medicine [2]. Each of the previously-mentioned medical imaging technologies has its own advantages and limitations. X-ray and MRI are characterised by excellent spatial resolution, but on the other hand X-ray is harmful for patient's health due to the adoption of ionising radiations and due to breast compression, while MRI is very expensive and sometimes uncomfortable for claustrophobic patients. Furthermore, both imaging modalities are not portable, and more in detail in the MRI case, the acquisition process is slow and unsuitable for patients with metallic implanted devices.

Breast ultrasound imaging does not suffer from the X-ray and MRI limitations since it exploits mechanical waves for non-invasive diagnostics. It is used as a follow-up test for abnormalities found by mammogram and provides some guidelines for biopsy inspections. Its main limitation are related to the operator-dependent nature of this medical exam, to its poor resolution and low contrast of the image. Furthermore, complementary information regarding the molecular properties of the observed tissues can be inferred from nuclear medicine, which operates by injection of radioactive substances. This imaging modality is very expensive, uses ionising radiation and has limited resolution [3].

Due to the previously-mentioned limitations and drawbacks of the actual medical imaging technologies for breast cancer diagnosis, there has been a vivid interest from the scientific research community to explore frontier technologies and imaging approaches to perform early, reliable and less expensive diagnostics. In this framework, the use of microwave frequencies for breast cancer imaging has received significant attention in the last decades, since these radiations are safe for patient's health and can allow a better sensitivity [4], [5]. In this framework, microwave tomography (MWT) can offer several advantages over classical methods since it is inexpensive, non-ionising, and comfortable from patient's point of view [6]. By virtue of the differences in the electrical properties between normal and malignant tissues in the microwave frequency range, this technique might represents a good ally/alternative for safe, cheap, and early breast cancer diagnosis. Furthermore, it is able to provide *quantitative* information by retrieving tissues permittivity and conductivity maps [4].

In particular, MWT can provide complementary information on the investigated regions which can be merged with the one deriving from traditional exams to support medical decisions. Nevertheless, there are still some technical challenges and open topics to be solved, which involve both hardware and software [7]. Among the main drawbacks to obtain reliable quantitative images via MWT it is worth mentioning the well-known non-linearity and ill-posedness issues and their consequences affecting the mathematics of the considered inverse problem, such as the presence of local minima [8]. In this framework, fast and reliable nonlinear approaches are desirable for addressing the breast cancer imaging problem and, more in general, whatever diagnostic biomedical imaging problem. Among the most recent approaches, deep neural networks (DNNs) can represent a useful and flexible tool for quantitative imaging and, thus, for early breast cancer detection.

In this regard, the considered paper proposes a deep learning (DL) approach for breast cancer detection and imaging via MWT. The considered methodology consists of two steps: the

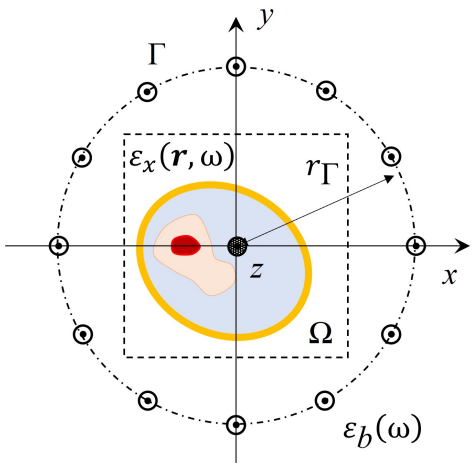

Fig. 1: Simplified 2D sketch of the imaging system. The antennas (dipoles) are located on a measurement circle Γ at a radius r_Γ, aligned along the vertical z axis. The imaging domain Ω includes the target of interest and is filled with a matching medium whose electric feature is $\epsilon_b(\omega)$.

former one adopts DL to firstly identify suspicious breasts which might be affected by malignancy, while the latter step consists of a fully-connected neural network performing the quantitative imaging for the localisation of the potential cancerous areas.

The remainder of the paper is as follows. Section II recaps the main equations ruling the scattering phenomena and describes the geometry of interest, while Section III illustrates the proposed methodology. Some results are reported in Section IV and some conclusions in Section V end the paper.

II. Problem Statement

In the following, a simplified two-dimensional (2D) geometry will be considered as shown in Fig. 1. The hosting medium is assumed to be homogeneous and non-magnetic, with complex permittivity $\epsilon_b(\omega) = \epsilon_b' - j\frac{\sigma_b}{\omega\epsilon_0}$, i.e. ϵ_b' and σ_b (S/m) being the relative permittivity and conductivity of the background medium, ω being the angular frequency and $\epsilon_0 = 8.854 \cdot 10^{-12}$ F/m.

The considered imaging system consists of a circular array of antennas located on a measurement circle Γ in a multiview-multistatic configuration, i.e. all the antennas can act as transmitter as well as receiver, but only one transmitter per time is active while all the remaining antennas work as receivers. The measurement circle Γ surrounds the imaging domain Ω in which the target breast is located immersed in the hosting medium. The targets located inside Ω are illuminated via transverse-magnetic electric field generated by z-oriented current wires located on Γ and adopted as antennas.

The scattering phenomena related to the interaction between the electric field generated by the antennas (known as *incident field*) and the target tissues depend on the contrast between the electric properties of the background medium and those of the target. By virtue of these differences, and measuring the scattered field on the measurement line Γ, it is possible to retrieve the breast tissues properties maps by solving an electromagnetic inverse scattering (EIS) problem. Thus, the electromagnetic scattering equations ruling these phenomena can be written as [8]:

$$E_s = \mathcal{A}_e(\epsilon', \sigma, E_t) + n\,, \tag{1}$$

$$E_t = E_i + \mathcal{A}_i(\epsilon', \sigma, E_t)\,, \tag{2}$$

in which the dependence on the spatial coordinates, operating frequency and background electric features has been implied. The quantities E_i and E_t represent the incident and total electric fields inside the imaging domain Ω, respectively, while E_s is the scattered field collected at receivers locations on Γ. The operators $\mathcal{A}_i$ and $\mathcal{A}_e$ are the internal and external radiating operators and n is the measurement noise which affects the data, here assumed to be additive, white and Gaussian (AWGN).

Concerning the imaging applications, the considered framework can be dealt with as an EIS problem whose aim consists in the retrieval of quantitative estimates of unknown electric permittivity ϵ' and conductivity σ functions inside Ω starting from the scattered field samples measured on Γ. As mentioned in Section I, this is here achieved by means of properly trained neural networks, allowing real-time applications with accurate, reliable reconstructions.

III. Methodology

The workflow of the proposed methodology consists of two steps: the former one which aims at identifying potentially-suspicious breasts by means of convolutional neural networks, and the latter one performing the quantitative imaging with the aim of retrieving the permittivity and conductivity maps of the tissues under consideration to identify the malignant areas through a fully-connected neural network.

To this purpose, an in-house 2D numerical realistic breast phantom repository has been considered for the training of the neural networks. More in detail, the Authors adopted the realistic breast repository described and proposed in [9], which consists of 120,000 numerically-generated 2D healthy breast phantoms organised into four classes according to their percentage of fibroglandular tissue. This data set has been further enriched with 30,000 malignant breast phantoms numerically generated by considering different shape, size, extension and location of the malignancies inside the tissues. Each breast profile, together with the corresponding "scattering matrix", represents the database for the neural networks training.

With regard to the first step, i.e. the classification of the considered breast phantom as *suspicious* or *healthy*, a ten-layer convolutional neural network (CNN) is adopted. In this case, the input of the network is the scattering matrix, i.e. the scattered field measured on Γ, while the output is a label which classifies the profile as healthy or not. Complementary to this first step, the second one adopts a different topology that is based on a three-layer fully-connected neural network. More specifically, this step is applied in those cases in which the CNN of the previous analysis has identified a suspicious

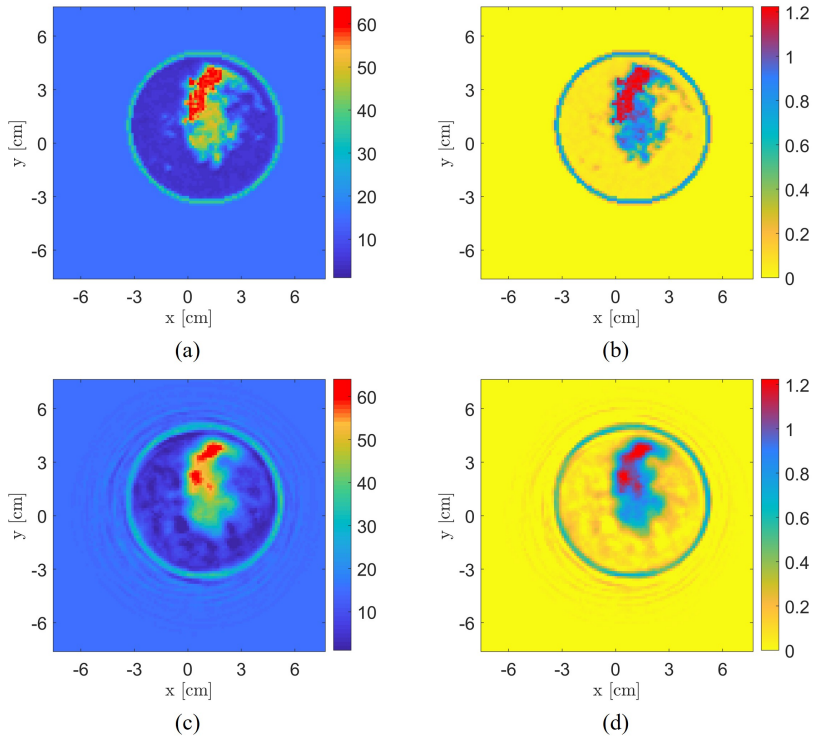

Fig. 2: Retrieved permittivity and conductivity profiles in the case of malignant tissues (light red areas). Reference permittivity (a) and conductivity (b), and corresponding recoveries (c)-(d).

breast phantom, and thus requires further investigation for the tumour spatial localisation. In this latter case, the input of the network is still the scattering matrix, while the output consists of the estimated permittivity and conductivity maps. Further details regarding this latter network architecture and training for the imaging are reported in Section 3.2 of [9]. Table I summarises all the training details and settings relatively to the adopted neural networks proposed in this paper.

IV. Results

Concerning the generation of the scattering matrix from the breast profile, a forward solver based on the method of moments (MoM) was adopted. The considered imaging system consists of 30 antennas equally-spaced in angle on a measurement circle of radius 12 cm arranged in a multiview-multistatic configuration. The transmitted signal is a line source at the fixed frequency of 1 GHz and the imaging domain has size equal to 15×15 cm^2 discretized according to Richmond's rule. In all the following simulations, the data have been corrupted by AWGN with SNR = 30 dB.

Table II shows the confusion matrix related to the classification step of the proposed approach. The reached accuracy is 99.46%. Relatively to the imaging step, it is worth noting that this analysis was performed by starting from the network trained on the healthy population (i.e., 120,000 breast profiles), as reported in Section III, and then by applying a fine-tuning strategy to re-train the network with the 30,000 malignant profiles (80% for the training and 15% for the validation with respect to the whole malignant database). As a result from the proposed approach, Fig. 2 reports the retrieved *quantitative* permittivity and conductivity maps with corresponding references (more results will be shown at the conference). It is easy to observe that the proposed imaging approach results quite accurate in retrieving the malignant areas, which are represented in light red in the figure.

Complementary to the information reported in Fig. 2, Fig. 3 illustrates the statistical 2D distribution (pdf) of the electromagnetic parameters for both healthy (subfigures (a) and (c)) and cancerous (subfigures (b) and (d)) tissues for the breast phantom reported in Fig. 2. It is worth to note that the limited overlapping of the distributions ensures good accuracy in the cancer detection task, making the tomographic microwave imaging suitable for diagnostic purposes.

V. Conclusion

In this paper, a two-step DL-based approach for breast cancer imaging via MWT has been proposed. The first step adopts a CNN to identify suspicious breasts which could be affected by cancer, while the second step exploits a fully-connected neural network to perform the imaging and identify the potentially malignant areas.

As supported by the results reported in Section IV, the proposed approach seems quite promising and able to provide accurate quantitative recoveries of the investigated regions. Furthermore, its generalisation to the more realistic three-

dimensional (3D) scenario is straightforward, even though at the expense of a higher computational burden.

Future work will focus on its application to the 3D case, to the performance improvement by adopting different NNs topologies and architectures, as well as on the study of the impact of model error and high noise on the recovery performance.

***Abstract*— Alterations in dendritic spines morphology and topology are known to be implied in several neurodegenerative diseases. However, visualizing and reconstructing the exact morphology of spine necks using conventional confocal imaging is still a challenge. In the light of this, we propose the extension of Hessian matrix eigenvalue analysis for the detection of tubular structures to the problem of 3D neck tracing. In this work we stress the relevance of the tracing procedure initialization, for the novel application of this standard approach to the specific scenario. Preliminary results on confocal microscopy images from ex-vivo human samples allowed to obtain almost 80% of necks keeping an average distance of less than one voxel from the reference segmentation and half of them fully overlapping with it. The preliminary results are promising, since they pave the way towards the development of this model-free solution to accurately trace spine neck.**

***Keywords*—Confocal microscopy, pyramidal cells, dendritic spines, tracing, neuronal reconstruction.**

I. Introduction

Dendritic spines are neuronal protrusions implied in synaptic function, supporting learning, memory and motivation [1]–[6]. Changes in spine density, size, shape and distribution have been detected in neurodegenerative diseases such as Alzheimer's, autism spectrum disorders and many others [7]–[9]. To this end, quantitatively characterizing such features would be of particular interest. However, obtaining faithful information on dendritic spine morphology is not an easy task. Indeed, spines necks have a thin and small structure which is hard to discriminate with conventional microscopy, since its size is close to the optical resolution limit of the imaging techniques [10]. On the other hand, the high density of spines makes the manual or a semi-automatic segmentation tedious and time-consuming, increasing the necessary introduction of automatic procedures.

Several approaches have been proposed for reconstructing spine necks. Some of them require a large database of images to create a library of deformable models [11] or train convolutional neural networks [12]. Models based on global approaches to segmentation might fail in detecting spine necks given the different signal-to-noise ratio (SNR) properties of small structures [13], [14]. Thus, approaches based on local intensity or morphological local characteristics were proposed [14]–[18]. One of the most adopted tools, NeuronStudio [16] exploits local geometrical models. However, this approach is optimized for head spine detection and is suboptimal for neck spine shape characterization. In [17], a curve based on Legendre functions is fitted between dendrite shafts and detached spine head in 2D microscopy images, to adapt to different possible neck geometries. Geometrical features, as those based on tubular structures exploited in [19] for vascular tree, was evaluated in [18]. Specifically, eigenvalue analysis of the Hessian matrix has been introduced to define vesselness measures in biomedical images [19]. In fact, within tubular structures, the smallest-magnitude eigenvalue of Hessian is associated with the eigenvector directed along the minimum intensity variation, i.e., the longitudinal axis of the tubular structure. In [18] the information from local Hessian matrix was used to design an adaptive filter for dendrite tracing and spine head detection. The approach proved to achieve a good performance on stimulated depletion image but was not applied to image stacks.

In this work, we present a novel neck-tracing approach that exploits the eigenvalue analysis of the Hessian matrix. Specifically, the proposed method will be applied to images where both dendrites and spine heads have already been segmented. The aim is to correctly identify and trace the spine necks. We will point out the relevance of the tracing algorithm initialization and we will propose and evaluate different strategies. We test our method on 3D stacks of confocal images of a human pyramidal cell dendrite. We validate our approach against ground truth assisted segmentation of spines performed by expert-users.

II. Material and Methods

A. Experimental data

We processed a confocal image stack of an intracellular injected layer III pyramidal neuron from the human brain cingulate cortex (freely available for the scientific community and presented in [20]). Sections were imaged with a Leica TCS 4D confocal scanning laser equipped with to a Leitz DMIRB fluorescence microscope. All the data was also provided with a reference segmentation of the dendritic branch and spines reconstructed manually using Imaris 6.4.0 (Bitplane AG, Zurich, Switzerland).

B. Neck tracing procedure

Tracing a neck consists in connecting two disconnected clusters of segmented voxels, one linked to the spine head, and one linked to the dendrite. Therefore, to test our approach, we firstly performed a binary segmentation of the intensity image leaving some spines disconnected. We created such segmentation employing Otsu's method in the Icy software [21] which defines the optimal threshold based on the observed intensity distribution of pixel values. We refer to this segmentation as Otsu segmentation, OS [22]. The proper neck tracing approach is run on the unsegmented portions of the intensity image, and it is composed of an initialization phase

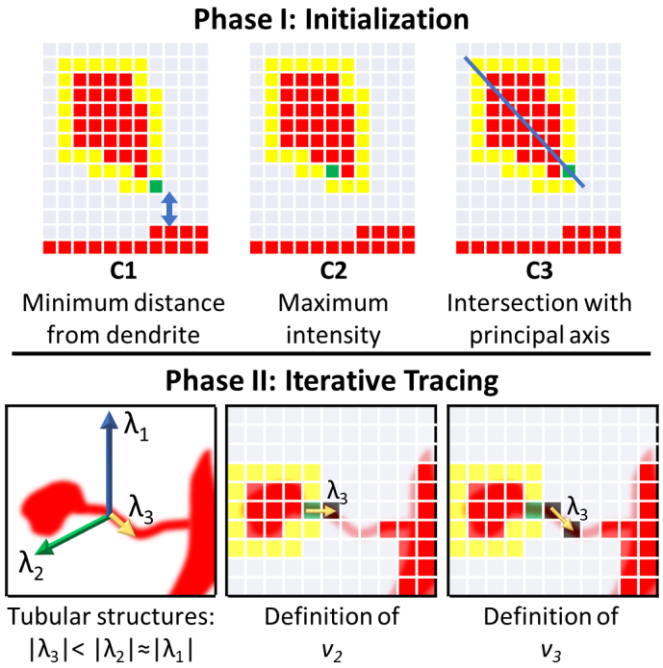

Fig. 1 *Schematization of the neck tracing approach. OS is marked in red, OB in yellow. Phase I) selection of the first voxel in the trace among those in OB, with the three tested criteria. Phase II) thanks to the properties of the Hessian matrix eigenvalues within tubular structures, the neck can be traced by 1) performing the eigenvalue analysis at voxel v_i; 2) defining v_{i+1} as the neighboring voxel intersected by the smallest eigenvector.*

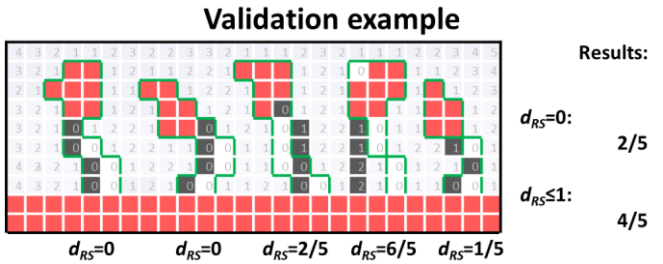

Fig. 2 *Validation example simplified in a 2D case: necks (black) connecting disconnected clusters of OS (red) are compared against RS (white with green borders) in terms of average Euclidian distances. Distance values in cells are rounded to the highest integer.*

(phase I) aiming at selecting the starting seed of the path-finding phase (phase II). The approach is sketched in Fig. 1.

Phase I defines the first voxel of the trace among those composing the outer border (OB) of the disconnected spine. We tested 3 different criteria: C1) the voxel in OB that is closest to the dendrite in terms of Euclidean distance; C2) the maximum intensity voxel within OB; C3) the voxel in OB intersected by the principal axis of the spine, placed on the side of OB that is closest to the dendrite.

Instead, phase II consists of a one-voxel step procedure starting from the first voxel and iteratively repeated to define the trace of the neck. For each voxel v_i in the trace, the Hessian matrix is defined computing the second order derivatives D_{xx}, D_{yy}, D_{zz}, D_{xy}, D_{xz}, D_{yz}. Eigenvectors and eigenvalues of the Hessian matrix are then extracted. Eigenvalues encode the information on second-order intensity variability along the axis defined by the eigenvector. Within a tubular structure, the direction parallel to the main axis is the one meeting no structure boundaries, i.e., the one along which the smallest intensity variations occur. This situation, schematized in the lower-left panel of Fig. 1, can be summarized by the formula $|\lambda_3| < |\lambda_2| \approx |\lambda_1|$. Therefore, starting from v_1 as defined in Phase I (shown in green in Fig. 1), v_2 is chosen within the 26-neighborhood of v_2 as the voxel being intersected by the eigenvector of the Hessian matrix associated to the smallest absolute eigenvalue λ_3, visualized with a golden arrow in Fig. 1. The procedure is repeated starting from v_2 to define v_3 (lower-right panel in Fig. 1), and then iterated on each v_i, to define v_{i+1}, until the trace meets the dendrite, or a given number of steps, Max_Steps, is reached. Max_Steps is identified to avoid the algorithm getting lost in a non-tubular structure or failing to reach the dendrite.

C. *Validation*

We preliminary validated our method on 350 spines included in one image stack. A gold-standard semi-automatic segmentation of these spines was published in [20] and is here labelled as Reference Segmentation, RS. This ground-truth was obtained with the software Imaris by combining spine-by-spine segmentations defining multiple ad hoc binary thresholds. Among the total number of spines, we focused only on those disconnected (26-neighbors) from the dendrite in the OS.

The tracings obtained using the three initialization strategies were evaluated, using a distance measure d_{RS} of each traced neck from the RS. Such measure is 0 when all the voxels in the neck overlap with the reference segmentation, and non-zero otherwise. The validation measure d_{RS} was estimated as it follows:

- For each voxel of the traced neck
  - we assign 0 if the voxel belongs to the RS
  - we estimate the Euclidean distance d_{RS} from the edge of the RS
- We average the obtained value across the voxels of the considered neck, to obtain the average d_{RS}

Using this approach, we can provide a quality assessment also for necks that do not fully overlap with RS.

III. Results

A. *Quantitative analysis*

Out of the 350 spines marked in RS, OS results in 88 spines disconnected from the structure core. We observed that segmented spines are separated on average by less than 10 voxels from the segmented dendrite, so we empirically set Max_Steps to 20. In Fig. 3, we report the quantitative evaluation of the three initialization criteria implemented for phase I, in terms of percentage of necks that fully overlap with RS, i.e., that show $d_{RS} = 0$, and percentage of necks showing $d_{RS} \leq 1$. C2 is the criterion providing the best results, with $d_{RS} = 0$ for the 47.7% of the 88 necks and $d_{RS} \leq 1$ for the 77.3% of them.

B. *Neck reconstructions*

In Fig. 4, we report four examples of traced necks, visualized with 3D reconstructions and overlayed on OS and RS. We observe that, with a good approximation, the majority

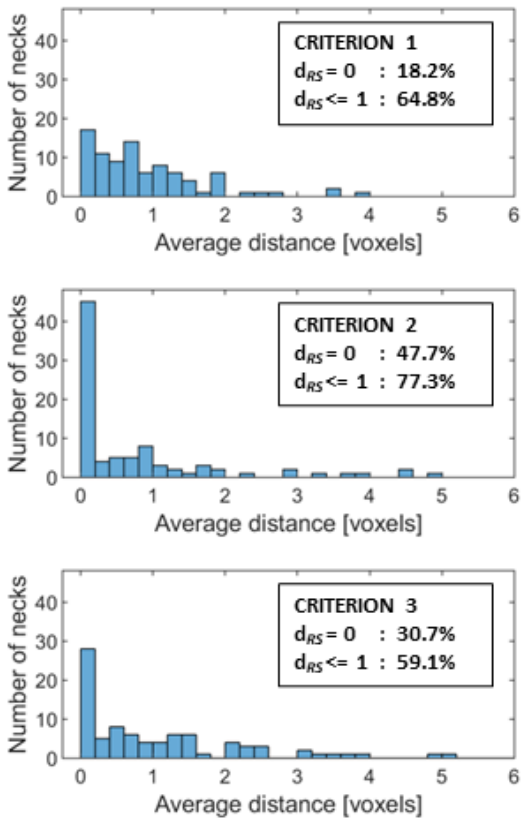

Fig. 3 Evaluation of the three initialization approaches of phase I in terms of average distance from RS for the 88 disconnected spines.

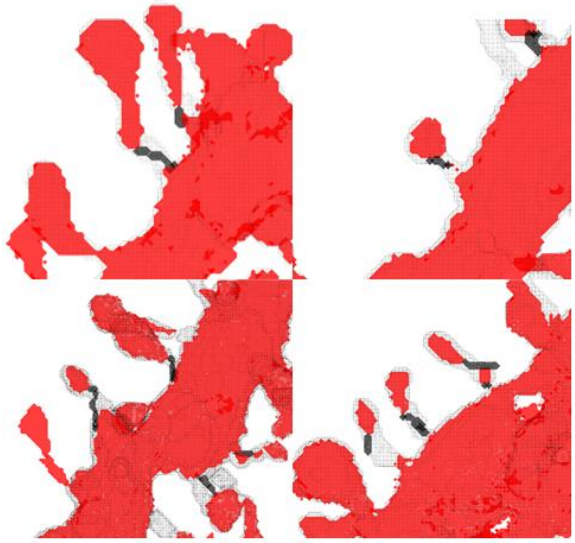

Fig. 4 Four examples of necks reconstructed by the algorithm (in black) overlaying OS (red) RS (gray).

spines have been successfully connected with the proper section of the dendrite.

IV. Discussions

In this work, we present a novel approach for spine neck reconstruction using the local information of the Hessian matrix. The geometrical information achievable by such analysis was already exploited for spatial filter design in [19] for spine head and neuron tracing. To our knowledge, the implementation for spine neck sequential tracing presented here is novel. Moreover, by testing three initialization criteria, we highlighted the relevance of this phase and assessed the maximum intensity voxel within the outer border of the spine as best starting point. With this criterion, we obtain a good percentage of tracings being in line with a published reference segmentation produced with a deep learning-based approach.

For the image used in this work, a reference segmentation RS capable of keeping spines connected to the corresponding dendrite was already available, since spine and neck identification was obtained using a manual 3D reconstruction of the same image sample performed with the software Imaris. Future tests will be required on samples on which a segmentation able to keep spines connected has not yet been achieved. This could be the case of confocal standard- or super-resolution STED images from clarified tissue. These tests will require a validation based on manual segmentation and a comparison against other available methods.

Due to the image type, which describes injected cells, and due to the bimodality of the intensity histogram, Otsu's method, that exploits a global intensity threshold, was selected as one of the simple strategies to segment this type of dataset. However, other methods employing different segmentation strategies can be used [23] and their results merged with the proposed approach when spine neck segmentation is failing.

To validate our results, we designed a strategy that estimates an average distance of the reconstructed neck from the RS. Since RS can be as thin as a single voxel, this strategy better characterizes the results with respect to a binary decision on a complete overlap between the reconstruction and the RS. We provide histograms of the average Euclidean distances between necks and RS, and we report the percentage of necks showing $d_{RS} \leq 1$, considered as satisfying reconstructions. In this work, this validation measure is also used to compare the three initialization criteria, highlighting a far better performance by C2 with respect to both C1 and C3 (Fig.3). Performance of the minimum distance criterion (C1) is impaired by the neck curvatures, which are often bent with respect to the direction normal to the dendrite surface. The performance of spine principal axis criterion (C3) is impaired by the multiple shapes that can be assumed by spine heads [24], which can present very wide caps and thus a principal axis that is aligned to the dendrite. Choosing the highest-intensity sub-threshold voxel resulted to be the best initialization criterion. In addition, on segmentations that do not rely on the sole magnitude (e.g., segmentation algorithms based on deep learning [11], [25], [26] structure enhancement filters [27], [28] or statistical modelling [29]), the use of C3 might not be optimal and should be further tested.

We have to stress that the generalizability of C2 criterion to images with lower SNR, with respect to the one here analysed, should be further tested. In fact, this solutionis likely to be sensitive to noise since it selects the maximum intensity voxel. As a result, a different criterion could better perform on a different image type.

We observed that definitions of the starting point on the wrong side of the spine produce erroneous tracings that could hardly be recovered. In this light, further research on the proper initialization of neck tracing algorithms is crucial. Future developments should focus on providing a less local definition of maximum intensity, e.g., adopting smoothing

filters in phase I prior to applying C2, or employing measures based on percentiles within a neighbourhood. Similarly, in phase II the eigenvalue analysis could be conducted with an approach that is still local, but less punctual, to be more robust to noise. A more noise-robust local eigenvalue analysis should impact the performance as well in Phase II: this could be achieved in the computation of the Hessian by weighing the contribution of a neighbourhood of voxels, e.g. using convolutions with derivatives of gaussians instead of punctual differentiation, as in [19], [30].

As our algorithm does not perform spine assignment, the presence of spines belonging to different dendrites within the same stack could lead it to the tracing of non-existing necks. To target this issue, in an interesting future development a crucial preliminary spine assignment step based on a 3D watershed transform could be integrated in the algorithm.

An application of our approach on super-resolution techniques (e.g., STED, STORM), which allow to resolve spine morphology even in clarified thick slices (500 μm), will be also explored in the future.

V. Conclusion

We present an algorithm to detect neck spines using an approach based on the Hessian matrix eigenvalue analysis applied to confocal microscopy. The centrality of initialization is addressed, assessing important changes in algorithm performance when different initialization criteria are employed. Our results suggest that a precise tracking of spine necks could be obtained using a model-free solution. An accurate reconstruction of spine necks will help to define the morphology of the synaptic transmission centre implied in neurodegenerative diseases.

***Abstract*— Group level characterization of brain networks still represents an open issue in modern neuroscience. Investigating the functional mechanisms underlying the complexity of the human brain requires an analytical way to efficiently integrate information from multiple subjects, while properly handling the intrinsic inter-subject variability. Here we investigated the potentiality of the PARAllel FACtorization (PARAFAC) algorithm for the extraction of grand average brain connectivity matrices from simulated EEG datasets. Synthetic data were parametrized according to different levels of three parameters: network dimension (NODES), number of observations (SAMP-SIZE) and noise (SWAP-CON) in order to investigate the way they affect the reconstruction of grand average networks. Robustness to noise as well as the proper modulation of informative content have here been proved empirically, revealing that the best performances in terms of FPR, FNR and AUC were achieved for great number of observations and low noise level.**

***Keywords*— EEG, PARAFAC, group analysis, connectivity estimation.**

I. Introduction

The representation of the central nervous system as a complex network made its own way in modern biomedicine, being validated at both structural and functional levels by anatomical studies and noninvasive neuroimaging techniques[1]. In modern neuroscience, group level characterization of such a complex network can be either used to investigate pathological conditions or determine the existence of a common connectivity pattern elicited by the same experimental paradigm in different subjects (i.e. the grand average). Such a challenging issue implicitly requires an effective way to integrate information from multiple subjects, as well as handling the intrinsic inter-subject variability. Many different approaches have been proposed over the years, but there is currently no consensus on a univocal analysis pipeline for the extraction of the grand average connectivity pattern.

Especially in the last decades, PARAllel FACtoriation (PARAFAC) algorithm has made its own way as a useful tool for the analysis of multidimensional biomedical data. Pester et al. proposed the use of PARAFAC algorithm to extract grand average from fMRI derived networks in a group of subjects [2]. Under the hypotheses of linearity, this kind of approach allows to split the original data matrix into a sum of rank-one tensors (i.e. factors), revealing the presence of different connectivity patterns "hidden" in the original one. Miwakeichi and colleagues decomposed a multichannel time-varying EEG spectrum into a series of distinct components, by means of a PARAFAC decomposition in space, frequency and time domain [3]. Furthermore, combining PARAFAC algorithm together with hierarchical clustering, Belyaeva et al. proposed a tensor-based approach for the extraction of developmental signatures from multi-subject MEG data [4]. In particular, they were able to extract early and late latency event-related field components, allowing to discriminate between high and low performance groups.

Here we investigated the potentiality of a PARAFAC-based approach to estimate the grand average from a synthetic dataset mimicking brain connectivity matrices of different subjects exposed to the same experimental condition.

II. Materials and Methods

A. Tensor decomposition by means of PARAFAC algorithm

PARAFAC is a decomposition technique that factorizes an N^{th} order tensor into a sum of R rank one tensors, where R is the rank of the original tensor [5]. An N^{th} order tensor is rank one if it can be rewritten as the outer product of N vectors:

$$X = a^{(1)} \otimes a^{(2)} \otimes \dots \otimes a^{(N)} \tag{1}$$

where the symbol "$\otimes$" represents the vector outer product. The PARAFAC decomposition of a rank R third order tensor $X \in R^{I \times J \times D}$ can thus be rewritten as:

$$X = \sum_{r=1}^{R} X_r + E = \sum_{r=1}^{R} a^{(r)} \otimes b^{(r)} \otimes c^{(r)} + E \tag{2}$$

Where $a \in R^I, b \in R^J, c \in R^D$ and $E \in R^{I \times J \times D}$ is a residual error term. Elementwise, Eq. (2) can be rewritten as

$$x_{ijk} = \sum_{r=1}^{R} a_i{}^{(r)} b_j{}^{(r)} c_d{}^{(r)} + e_{ijd} \tag{3}$$

Each term $a_i{}^{(r)}$, $b_j{}^{(r)}$ and $c_d{}^{(r)}$ in Eq. (3) acts as a weight expressing the contribution of the r^{th} component of a, b and c on x_{ijd}. By setting the number of required rank-one tensors to any $1 \leq f \leq R$, the original informative content of X can be split into an arbitrary (but bounded) number of factors.

By switching the error term to the left side of Eq. (2), PARAFAC algorithm finds out the best approximation $\hat{X} = X - E$ for the original tensor X. The PARAFAC decomposition of X can thus be obtained by solving the optimization problem:

$$|| X - \hat{X} || \text{ with } \hat{X} = \textstyle\sum_{r=1}^{f} a^{(r)} \otimes b^{(r)} \otimes c^{(r)} \tag{4}$$

The solution to the problem in Eq. (4) can be found by means

of the alternating least squares (ALS) method [6].

B. PARAFAC to extract the Grand Average connectivity matrix

A generic brain connectivity dataset X obtained from a population of individuals is composed by s different $K \times K$ connectivity matrices, where s is the number of individuals and K is the number of nodes of the connectivity matrix.

By properly rearranging each subject's connectivity pattern as a first order tensor $\pi^{(s)} \in R^{K^2}$ with $s = 1, 2 \dots S$, PARAFAC algorithm can then be applied to the second order tensor $X \in R^{K^2 \times S}$ obtained by stacking each $\pi^{(s)}$ side by side.

$$X = \left[\pi^{(1)}\pi^{(2)} \dots \pi^{(S)}\right] \tag{5}$$

The PARAFAC decomposition of the bidimensional data tensor X can thus be written as:

$$X = \sum_{r=1}^{f} a^{(r)} \otimes b^{(r)} + E \tag{6}$$

or, elementwise

$$x_{ij} = \sum_{r=1}^{f} a_i{}^{(r)} b_j{}^{(r)} + e_{ij} \tag{7}$$

The terms $a_i{}^{(r)}$ (respectively $b_j{}^{(r)}$) indicate the way the i^{th} element of the vector $a^{(r)}$ (respectively the j^{th} element of $b^{(r)}$) modulates x_{ij}. In this kind of scenario a_i represents the strength of a specific functional connection, while b_j are the subject-wise loadings indicating how relevant is the pattern in $a^{(r)}$ for the reconstruction of X [7].

C. Synthetic data generation

For each virtual subject, a synthetic connectivity matrix was generated as a randomly modified version of a predefined ground-truth matrix, which emulates the behavior of an EEG-derived brain connectivity matrix. Since simulated network's density was fixed to 0.1, modifications of the original ground-truth consisted in connection swaps between different positions within the original synthetic connectivity matrix.

To investigate both validity and robustness of the reconstructed patterns, synthetic data analysis has been parametrized with respect to:

- dataset sample size (SAMP-SIZE, $s \in \{10, 20, 30, 50, 100\}$), defined as the number of participants included in the simulated cohort of subjects;
- dataset dimension, defined as the number of nodes of the simulated EEG connectivity matrices (NODES, $k \in \{20, 30, 50\}$);
- percentage of swapped connections with respect to the original ground-truth network (SWAP-CON, $m \in \{0.10, 0.30, 0.50\}$), representing different levels of inter-subject variability of the connectivity matrices (noise level).

D. Testing PARAFAC algorithm on synthetic data

PARAFAC algorithm was tested on different synthetic datasets representing a set of connectivity matrices obtained from a group of participants undergoing the same experimental condition. The simulation study repeats the following steps for $T = 100$ iterations:

1. Generation of synthetic datasets composed by different connectivity matrices (one per subject).
2. Application of PARAFAC algorithm in order to factorize the data matrix X as a sum of f rank-one tensors. Here we set $f = 2$, assuming that the first rank-one tensor represents the common mode, while the second one embodies a random pattern due to inter-subject variability.
3. Selection of the rank-one tensor that better represents the grand average connectivity pattern within the whole dataset. In particular, we looked for the pattern $\tilde{a}^{(r)}$ paired with the subject-dependent loadings in $\tilde{b}^{(r)}$ with minimum variance. In fact, since $\tilde{a}^{(r)}$ is supposed to be a recurrent connectivity pattern in X it is expected to be equally expressed in a large number of individuals: this means that the corresponding subject-wise loadings in $\tilde{b}^{(r)}$ are expected to be very similar each other.
4. Evaluation of the performances by comparing the rank-one tensor chosen at the previous point with the current ground-truth. In particular, we used False Positive Rate (FPR), False Negative Rate (FNR) and the Area Under the ROC (AUC) to evaluate how far the reconstructed pattern is with respect to the ground-truth.

Three separate two-way repeated measures Analyses of Variance (ANOVA) were carried out across the 100 iterations considering SAMP-SIZE ($s \in \{10, 20, 30, 50, 100\}$) and SWAP-CON, ($m \in \{0.10, 0.30, 0.50\}$) as main within factors. FPR, FNR and AUC were separately considered as dependent variables. The same ANOVAs were then repeated for each number of nodes considered in the study (NODES, $k \in \{20, 30, 50\}$). The statistical significance level for all tests was set to 0.05 and the Tukey's post-hoc test was performed to assess differences among the levels of the within factors.

III. RESULTS

A. Performances of PARAFAC algorithm on synthetic data - FPR

ANOVA results in Table I point out that either single or combined factors have a significant effect on the FPR distribution. In Fig.1 we reported FPR distributions obtained by applying PARAFAC algorithm to synthetic $k \times k$ connectivity matrices with $k = 20$, characterized by different sample sizes (SAMP-SIZE) and different levels of noise (SWAP-CON).

As reported in Fig.1, FPR values are close to zero when the sample size is greater or at least equal to 20 subjects, regardless for the percentages of swapped connections; on the other hand, when $s < 20$ FPR is still <5%. The number of involved subjects has a mitigating effect reducing FPR values as the cohort of recruited patients increases for all the percentages of noise corruption. Similar results were found for all NODES levels ($K = 30, 50$).

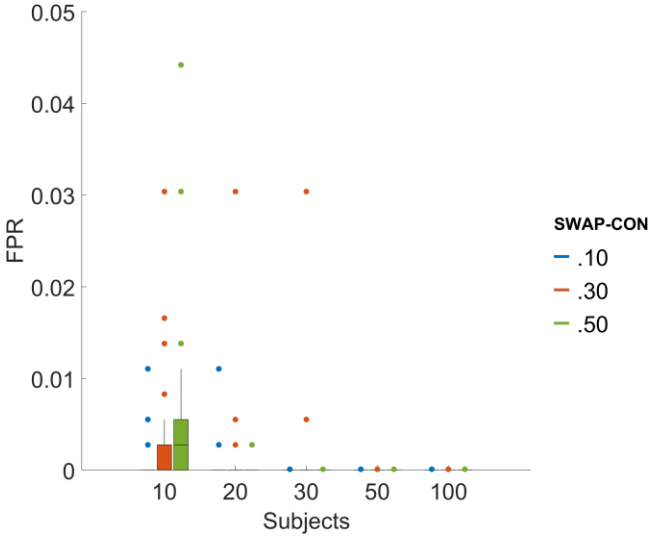

Fig.1. Boxplot diagrams reporting FPR distributions obtained applying PARAFAC algorithm on synthetic data generated using five different levels of SAMP-SIZE (along x-axis) and different levels of SWAP-CON (different colors of the bars). Results refer to synthetic datasets of dimension equal to 20 nodes.

TABLE I

Effect	DOF	F values - FPR		
		20 nodes	30 nodes	50 nodes
SWAP-CON	(2, 198)	$\mathbf{8,26}^{(*)}$	$\mathbf{8,04}^{(*)}$	$\mathbf{5,42}^{(*)}$
SAMP-SIZE	(4, 396)	$\mathbf{49,04}^{(*)}$	$\mathbf{44,20}^{(*)}$	$\mathbf{44,36}^{(*)}$
SWAP-CON* SAMP-SIZE	(8, 792)	$\mathbf{6,25}^{(*)}$	$\mathbf{7,20}^{(*)}$	$\mathbf{4,94}^{(*)}$

Results of three-way repeated measures ANOVA computed considering FPR as dependent variable, SWAP-CON and SAMP-SIZE as within main factors. The analysis was repeated for three different number of nodes (20, 30, 50). Acronym DOF is for degrees of freedom. The symbol (*) indicates significant effect of the factor ($p<0.01$).

B. Performances of PARAFAC algorithm on synthetic data - FNR

Results of the 2-way repeated measures ANOVA on FNR are summarized in Table II. As for FPR, either single or combined ANOVA factors significantly affect the FNR distribution. Boxplot in Fig.2 illustrates how the FNR distribution changes according to different levels of the generating variables (SWAP-CON and SAMP-SIZE).

TABLE II

Effect	DOF	F values - FNR		
		20 nodes	30 nodes	50 nodes
SWAP-CON	(2, 198)	$\mathbf{1208,60}^{(*)}$	$\mathbf{2554,72}^{(*)}$	$\mathbf{5548,21}^{(*)}$
SAMP-SIZE	(4, 396)	$\mathbf{118,01}^{(*)}$	$\mathbf{401,08}^{(*)}$	$\mathbf{748,47}^{(*)}$
SWAP-CON* SAMP-SIZE	(8, 792)	$\mathbf{85,36}^{(*)}$	$\mathbf{247,68}^{(*)}$	$\mathbf{480,37}^{(*)}$

Results of three-way repeated measures ANOVA computed considering FPR as dependent variable, SWAP-CON and SAMP-SIZE as within main factors. The analysis was repeated for three different number of nodes (20, 30, 50). Acronym DOF is for degrees of freedom. The symbol (*) indicates significant effect of the factor ($p<0.01$).

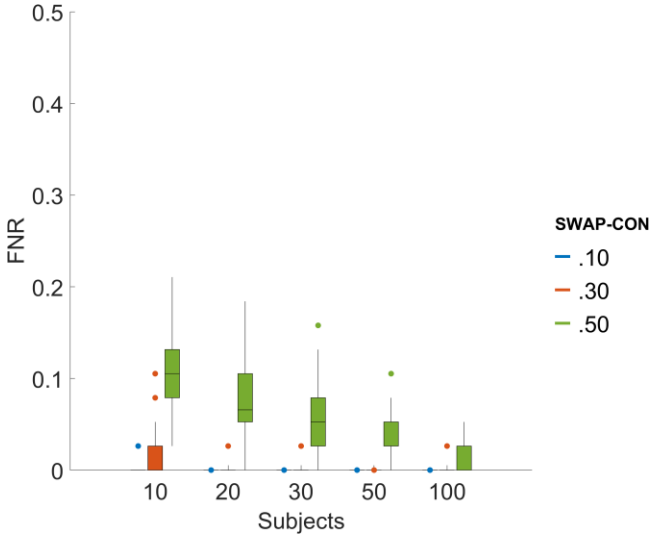

Fig.2. Boxplot diagrams reporting FNR distributions obtained applying PARAFAC algorithm on synthetic data generated using five different levels of SAMP-SIZE (along x-axis) and different levels of SWAP-CON (different colors of the bars). Results refer to synthetic datasets of dimension equal to 20 nodes.

Diagrams allow to appreciate that FNR values decrease in response to an increase in SAMP-SIZE or a decrease in SWAP-CON, as confirmed by Tukey's post-hoc test. Similar considerations were found for all NODES levels ($K = 30, 50$).

C. Performances of PARAFAC algorithm on synthetic data - AUC

Table III reported results of the 2-way repeated measures ANOVA on AUC values for different numbers of nodes. Either single or combined factors have a significant effect on AUC distribution, as confirmed by F and p values in Table III. According to boxplot representation in Fig.3, AUC values are close to 1 (i.e. optimal classification of null and non-null connections) for $s > 20$ without regarding of SWAP-CON level.

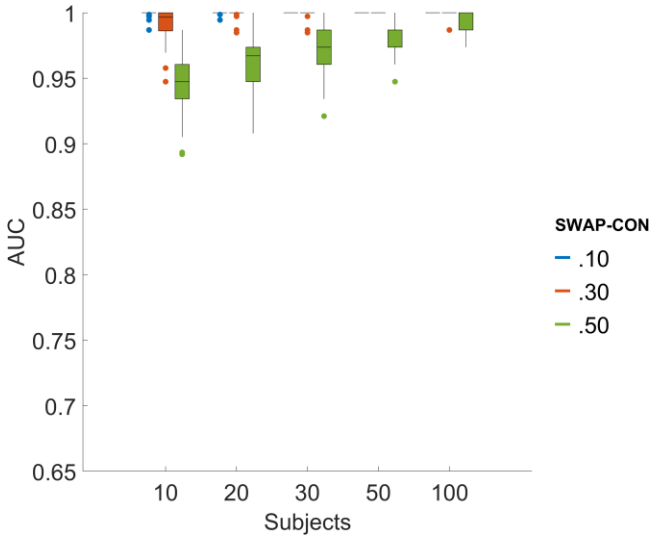

Fig.3. Boxplot diagrams reporting AUC distributions obtained applying PARAFAC algorithm on synthetic data generated using five different levels of SAMP-SIZE (along x-axis) and different levels of SWAP-CON (different colors of the bars). Results refer to synthetic datasets of dimension equal to 20 nodes.

TABLE III

Effect	DOF	F values - AUC		
		20 nodes	30 nodes	50 nodes
SWAP-CON	(2, 198)	**1160**(*)	**2428**(*)	**5053**(*)
SAMP-SIZE	(4, 396)	**137**(*)	**468**(*)	**797**(*)
SWAP-CON* SAMP-SIZE	(8, 792)	**87**(*)	**241**(*)	**466**(*)

Results of three-way repeated measures ANOVA computed considering AUC as dependent variable, SWAP-CON and SAMP-SIZE as within main factors. The analysis was repeated for three different number of nodes (20, 30, 50). Acronym DOF is for degrees of freedom. The symbol (*) indicates significant effect of the factor ($p<0.01$).

On the other hand, for $s \leq 20$ AUC values decrease when SWAP-CON level increases. As for FNR and FPR, AUC distributions confirmed that SWAP-CON and SAMP-SIZE have opposite effects on the overall result. Similar results were found for all NODES levels ($K = 30, 50$).

IV. Discussion

In this work we investigated the potentiality of a PARAFAC-based approach to extract the grand average pattern from a synthetic connectivity dataset.

As expected, noise corruption and sample size have opposite effects: low levels of noise allowed better estimation of the grand average pattern, while the opposite occurs for the sample size. Considering the noise corruption as the effect of the inter-subject variability and the number of subjects as the number of realizations of a noisy stochastic process, the research for the grand average pattern can be interpreted as the calculation of the "expected" pattern within the population. Since noise is assumed to be uncorrelated from the signal of interest (white process), under linearity assumptions the expected value for the sum between signal and noise is nothing but the summation of the expected value for the signal and the expected value for the noise. The expected value for a white noise process approaches 0 as the number of realizations of such a process approaches the infinitive, thus justifying results about the effects of sample size on the estimated common pattern.

Since we are interested in the identification of an average behavior across subjects, the best way to proceed is to set the lowest number of required rank-one tensors in order to identify the pattern in common to all the subjects included in the analysis. It has been empirically proved that when the number of required factors draw close to the rank of the original data matrix, each rank-one tensor approximates the specific pattern of each subject [2]. In the limit case for $f = rank(X) = S$, each factor (together with a residual error term) is expected to reflect the PDC pattern of each subject within the dataset, thus diverging from our purpose to look for the common mode.

V. Conclusion

In this work we investigated the potentiality of a PARAFAC-based approach for the extraction of the grand average connectivity pattern from a set of synthetic data.

Although it has been widely used for data fitting and tensor decomposition problems, our results encourage the use of PARAFAC as a useful tool for grand average estimation when dealing with group analysis. Robustness to noise as well as the proper modulation of informative content have here been proved empirically. As further analyses, we suggest to investigate the way the number of required rank-one tensors affects the grand average estimation. Moreover, an application on real EEG dataset would also be relevant to practical example of PARAFAC application in neuroscience.

***Abstract*— Cardiotocography (CTG) is the most widely used diagnostic examination to check the status of the fetus during pregnancy. The complex nature of CTG signals strongly affects the interpretation of the latter, causing a large intra and inter-observer variability in the analysis. A very challenging task in this context is the automatic identification of fetal activity and quiet periods within the tracings. The importance of distinguishing these periods resides in the fact that different neural mechanism are involved in the regulation of fetal heart, depending on quiet or activity fetal stages. This would also allow the evaluation of any differences present in diverse fetal stages between signals from healthy and pathological fetuses, increasing the diagnostic capability of CTG analysis. With the present work we address the problem of fetal state clustering in a totally unsupervised manner, resorting to the use of Hidden Markov Models. The obtained results have been brought to the attention of an experienced clinician, who expressed a 93% level of agreement between his interpretation and the fetal state clustering obtained with the model.**

***Keywords*—Hidden Markov Models, signal segmentation, activity recognition, time series clustering.**

I. Introduction

CARDIOTOCOGRAPHY (CTG) is the most widely spread diagnostic examination to ascertain the status of the fetus during pregnancy. CTG consists of simultaneously recording the fetal heartbeat signal (FHR) and the uterine contractions (TOCO), to check the proper development of the fetus during pregnancy [1]. Despite its wide diffusion, the reliability of a CTG exam still suffers of misleading interpretations, due to large intra and inter-observer variability in the analysis, generally resulting from eye inspection of the tracings by an expert Ob-Gyn specialist. This derives from the complex nature of FHR signals, which are strongly non-deterministic and non-stationary. Over the last few decades, research has focused on the development of systems capable of carrying out an automatic interpretation of CTG recordings, starting from the computation of indices related with the neural control mechanisms of fetal heart, either in time, frequency and nonlinear domains. The use of Information Technology support in the analysis of CTG recordings has the potential to stem these limitations, conferring objectivity and reproducibility to the method [2].

A very challenging task is this context is the identification of fetal states. This means being able to identify, within a FHR tracing, the time periods when the fetus is in a condition of activity and those when it is in a quiet phase. Knowledge of the current fetal stage is of fundamental clinical relevance. In fact, from the duration of the different phases, important information about the state of fetal well-being is derived.

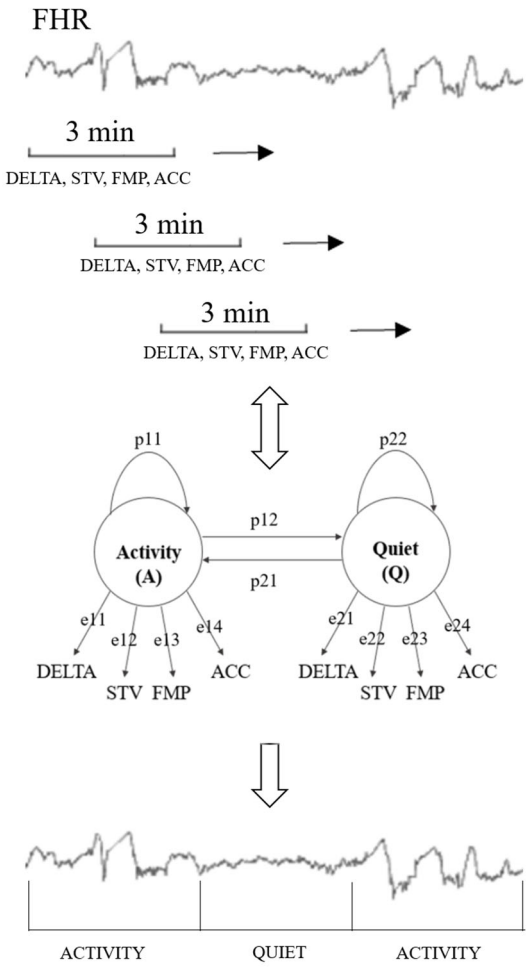

Fig.1*:* Scheme of the proposed fetal state detection method. A set of features is computed on windows of 3 minutes sliding on the FHR signal. The latter is seen as the set of emissions of a HMM consisting of two possible states, i.e., Activity (A) and Quiet (B). The pij and eij represented on each arrow of the HMM respectively stand for the transition and emission probability associated to that specific branch. After the training, the HMM is able to provide an automatic clustering of the points in the FHR signal, identifying quiet and activity phases.

Indeed, it has been observed that prolonged phases of inactivity are important indicators of pathological conditions [3]. The signal trend within the different phases (especially its variability) can also allow useful information to be derived for the purpose of interpreting the tracings.

The medical literature reports 4 possible behavioral states of the fetus. The quiet state includes two distinct phases, 1F of quiet sleep and 2F of active sleep. The activity state also

includes two possible stages, the 3F of quiet wakefulness and the 4F of active wakefulness [4].

The identification of different fetal phases within CTG tracings is, to date, still left to the clinician's experience and can consequently lead to discordance in interpretations.

With the aim of pursuing the goal of automatic identification of fetal phases within the collected CTG recordings, in the present work, we present a method for the unsupervised FHR signals clustering, based on Hidden Markov Models (HMM) [5].

The choice of such an approach is motivated in part by the need to implement a fully data-driven approach and in part by the urge to adopt a method that allows for interpretable results. As a first attempt, we decide to simplify the problem by modeling the system with an HMM consisting of only two possible states, i.e., activity and quiet. The idea behind this approach is to shift a fixed length sliding window on the FHR tracing, and to extract, at each slide, a set of features describing the portion of signal contained within the window; the latter is viewed as the set of emissions of the HMM. After learning the parameters of the model, during the training phase, the latter should be able to automatically cluster each point of the FHR signal, hence being able to identify periods of fetal activity and quiet. An illustration of the procedure is shown in Fig.1.

II. Methods

A. Data description

In the present work, we used the database described in [6]. The latter contains FHR tracings sampled at a frequency of 2Hz and lasting at least 20 minutes (i.e., 2400 points). From this dataset, we selected a subgroup of n = 150 signals related to fetuses with developmental ages between 35 and 40 weeks, that were used to train our unsupervised model. Since, for different reasons, the latter are corrupted by artefacts and signal losses, a denoising pre-processing step is needed; it includes the linear interpolation of signal losses lasting less than 15 s and the removal of portions where signal is lost for a longer duration.

B. Parameters computation

According to the study design, we decided to perform the computation of a set of parameters on 3-minute moving windows, corresponding to 360 points of the FHR tracing. At each step, the window is shifted along the signal with a 5-second stride (i.e., 10 signal points), and the calculation of the set of selected features is performed onto it (Fig.1).

The parameters we decided to compute at each shift comprehend two linear features relative to the time domain, i.e., DELTA and Short-Term Variability (STV) [7]. The latter are important indicators of fetal homeostasis, and in clinical practice, abnormal values of these indices reflect acute changes in fetal condition and are associated with an increased risk of motor and neurodevelopmental delay and damage in specific areas of the brain [8].

Besides these indices of cardiac variability, perceived fetal movements (FMP) and accelerations (ACC) are considered. The FMP signal is derived at each CTG examination and is the result of the pregnant woman pressing a button at the very moment she perceives fetal movements. From a technical point of view, the FMP is a signal of the same length as the FHR trace, with values of 1 at the perceived movement points and 0 at the remaining ones. FMP, as such, may be representative of actual fetal activity but may also indicate sporadic movements that may be present even in a quiet phase or may simply be the result of a mother's misperception.

As for the accelerations, following the definition provided in [9], the latter stand for periods lasting longer than 15 seconds in which the FHR signal remains above 15 bpm as respect to the baseline (large accelerations) or between 10 and 15 bpm above baseline (small accelerations). Accelerations of the FHR are an important sign of fetal healthy (accelerations indicate the fetus is moving), but their absence in labour is not unusual [10].

For the sake of terminological clarity, we will henceforth denote by FMP the percentage of perceived fetal movements within the 3-minute window and by ACC the number of accelerations in the window.

The choice of the parameters described above integrates a group of features derived from the FHR signal itself (DELTA, STV, ACC) with a signal-independent information (FMP), allowing objective and subjective information to contribute to the process of identifying fetal states within the signals.

Parameters computation has been performed through the software MATLAB R2022b (The Math Works, Inc.).

C. HMM and their application for fetal states assessment

The intent of the present work is to demonstrate how HMMs can be used as a tool capable of enabling the identification of fetal states within a FHR signal, starting from a set of information not exclusively derived from the FHR signal itself (e.g., FMP).

Markov models are random processes in which the transition probability that determines the transition from one state of the system to another one only depends on the immediately preceding state and not on how one got to that one. In classical Markov models, the states of the system are typically observable. In HHMs, on the other hand, the states are not directly observable, but are noticeable through a set of random variables that are probabilistically related to the unobservable states [11].

An HMM is defined through:

- A set S of N possible states $\{S_1, ..., S_N\}$.
- A set A of M possible emissions $\{a_1, ..., a_M\}$.
- A $N \times N$ transition matrix called P such that $P(i, j) = pij = p(S_j|S_i)$.
- A $N \times M$ emission matrix called E such that $E(i, j) = eij = p(a_j|S_i)$.
- A $1 \times N$ vector $\pi 0$ of prior probabilities.

As a first attempt to the problem of identifying fetal states within the FHR signals, we consider a simplified case. In particular, we make the modelling assumption that the system can be described by an HMM with two possible states (N= 2), i.e., activity (A) and quiet (Q). The evolutional dynamics of this system are governed by its emission and transition probabilities, which are learnt through the training phase, as will be stated in section E.

A representation of the developed HMM is depicted in Figure 2.

The HMM was implemented in Python, version 3.7.

D. *Observation set of the HMM and their codification*

As previously anticipated, the idea behind this approach is to interpret the set of parameters extracted at each sliding of the moving window (i.e., DELTA, STV, FMP, ACC) as the set of observable random variables emitted by the actual state of the HMM. These observations are probabilistically related to the state through the emission matrix E, that is estimated during the training.

Since each of the observed variables is continuous, as a first attempt, we decide to put ourselves in a simplified situation by making a categorization of the variables. Specifically, about DELTA, STV and FMP, these are categorized in high, middle and low according to their respective 33rd and 66th percentile values. ACC, on the other hand, was categorized with respect to the presence or absence of accelerations within the 3-minute window.

In this way, a 3-minute excerpt of FHR signal is converted into a vector of 11 symbols, where the first 3 groups of 3 digits respectively indicate low, middle and high values of DELTA, STV and FMP, and the last group of 2 symbols stand for the presence or absence of accelerations. For example, assuming we consider a 3-minutes chunk of FHR signal, characterized by a high DELTA, a medium STV, a low FMP and no accelerations, this will be coded as "0 0 1 0 1 0 1 0 0 1"

The emission set A is hence composed of 11 possible emissions: A= {DELTA low, DELTA middle, DELTA high, STV low, STV middle, STV high, FMP low, FMP middle, FMP high, ACC YES, ACC NO}.

This modelling choice hence makes the matrix E of size N x M, where N=2 and M=11.

E. *HMM parameters estimation*

After defining the structure of the model and coding the 3-minutes chunks of FHR, as explained in Sections C and D we proceed to the estimation of matrices E and P.

This is achieved through the Baum-Welch algorithm. The latter is a special case of the expectation-maximization algorithm (EM) used to learn the unknown parameters of HMMs [12]. The algorithm requires to provide an initial estimate of $\pi 0$, E and P, which are then updated to the current values during the training. To avoid any kind of bias due to particular a priori modelling choices, we chose the equiprobability condition for the initialization of $\pi 0$, E and P.

The proportion of data for training and testing was respectively set to 70:30.

F. *Estimation of the most likely path of the states of the system*

Once an estimate of matrices E and P has been obtained through the Baum-Welch algorithm, the model can be exploited to make predictions. Specifically, given a particular sequence of observations, the model will use the learnt knowledge to predict the trajectory of states most likely to have given rise to the observed sequence.

This task is addressed through the Viterbi algorithm [13][14].

III. RESULTS

Table I and II respectively illustrate matrices P and E. The high values on the diagonal of P indicate the tendency of the system to remain in the actual state for a long period rather than rapidly shifting to the other one. This is consistent

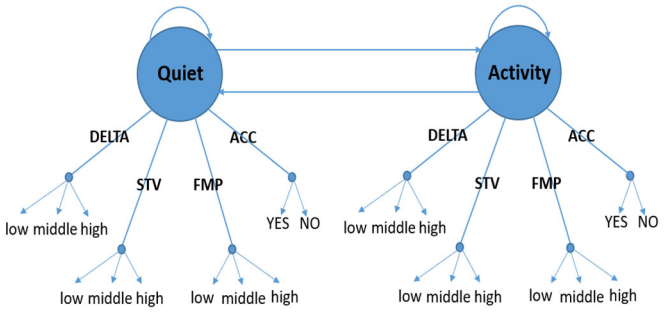

Fig.2: Scheme of the proposed HMM for the fetal state identification. The model presents two possible states, i.e., Quiet and Activity. According to its transition probabilities (P), once in a certain state, the system can continue to remain in the same state or change to the other one. The arrows branching off from the states and heading toward the bottom of the figure, on the other hand, represent the possible observable variables. These are probabilistically linked to the states its emission probabilities (E).

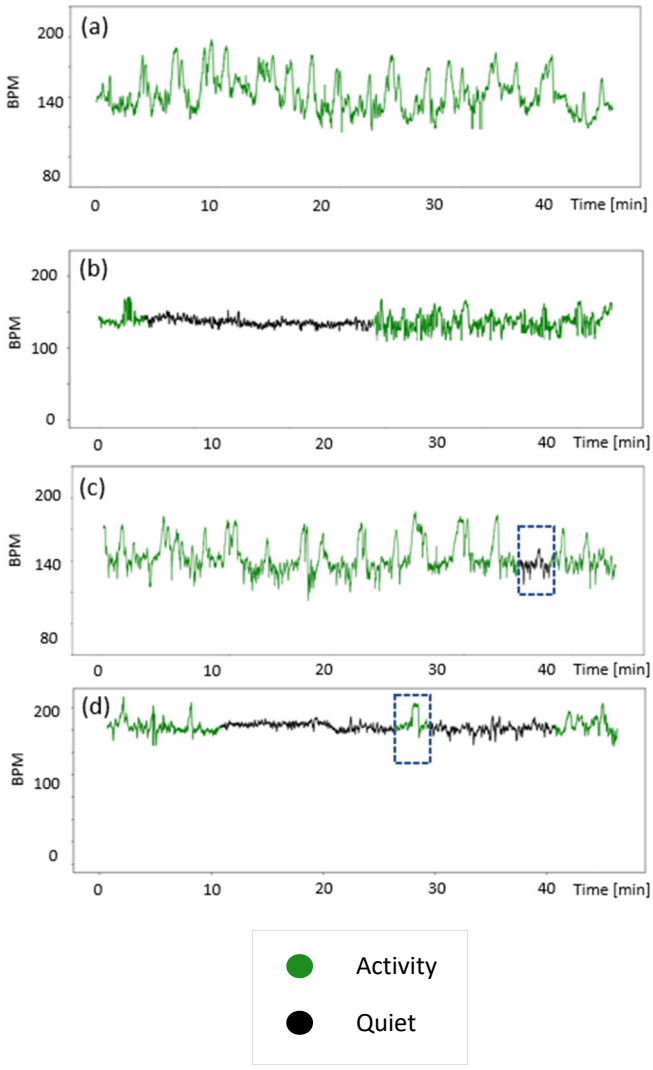

Fig.3: A set of FHR signals, together with fetal states, is shown, according to the predictions of the trained HMM. Green colour indicates the portions relating to fetal activity while black is relating to fetal quiet. The blue dashed rectangles in (c) and (d) point out that portions in which the HMM predictions are discordant with the interpretation of the clinic who analysed these signals.

with what is generally observed in clinics, since both active and quiet states are known to have a duration in the order of tens of minutes [15].

Matrix *E* shows, instead, the probability of emitting a particular variable given a certain state. By analysing *E,* we ascertain how high probabilities associated to low values of DELTA, STV and FMP are more likely to reflect a stage of fetal quiet. On the other hand, high probabilities associated to the presence of accelerations, together with high values of DELTA, STV and FMP are more probable to indicate a stage of fetal activity.

Figure 3 illustrates a set of 4 different FHR signals on which the periods related to the fetal stages predicted by the HMM were indicated. Already from an initial observation, it is evident that the portions of fetal quiet (black) exhibit lower variability and a lower tendency to accelerate, compared with the activity phases (green).

To validate the predictions provided by the model, we enlisted the help of an experienced clinician. He proceeded to analyse and annotate quiet and activity stages on a set of 10 FHR tracings provided to him from the database we have used. Comparatively, analysing the model's predictions with the clinician's annotations, we observe a 93% degree of agreement.

Discordant portions refer to short duration stretches, predicted as belonging to a certain state, that intersperse long portions of signal classified as belonging to the opposite state (see the dashed blue rectangles in Figure 3 (c) and (d)).

TABLE I: TRANSITION MATRIX *P*

State	***Quiet*** *(transition probabilities)*	***Activity*** *(transition probabilities)*
Quiet	**0.995**	0.005
Activity	0.005	**0.995**

TABLE II: EMISSION MATRIX *E*

Emission	***Quiet*** *(emission probabilities)*	***Activity*** *(emission probabilities)*
DELTA low	**0.136**	0.011
DELTA middle	**0.113**	0.018
DELTA high	0	**0.220**
STV low	**0.250**	0.027
STV middle	0	**0.106**
STV high	0	**0.116**
FMP low	**0.246**	0
FMP middle	0.003	0.009
FMP high	0	**0.24**
ACC YES	0.155	**0.238**
ACC NO	0.092	0.011

IV. CONCLUSIONS AND FUTURE DEVELOPMENTS

In this work we present a method for the unsupervised signals clustering, based on Hidden Markov Models (HMM), with the challenging aim of identifying fetal behavioral stages within FHR signals.

The obtained results seem to suggest that the developed model can identify fetal states of quiet and activity with a certain degree of reliability. In fact, the predictions of the model have shown a degree of agreement of 93% with the interpretations of an expert clinician.

The analysis of discordances could suggest an intrinsic limitation of HMM, i.e., the lack of memory. However, since fetal stages are known to have a duration of the order of the ten of minutes, the introduction of a threshold on the minimum acceptable duration of a fetal phase might be sufficient to curb the limitation.

Further developments for the current work include the introduction of new possible states in the HMM and the testing of the effects of a new set of observations, including parameters grasping different aspects of the FHR signals, not only related to time domain.

V. ACKNOWLEDGEMENTS

The authors are grateful to Dr. S. Tagliaferri, Dept. of Obstetrical– Gynaecological and Urological Science and Reproductive Medicine, Federico II University, Naples, Italy, for his help in inspecting and identifying fetal states in the FHR traces provided to him.

***Abstract*—The conditions of subjective cognitive decline (SCD) and mild cognitive impairment (MCI) are two ordered stages in cognitive decline. The transition between the SCD stage and MCI is a phenomenon that largely depends on the individual's neurological characteristics. Monitoring these characteristics through non-invasive and portable methods such as electroencephalography (EEG) allows for extracting information that can be associated with the patient's clinical condition. Here, we investigated the differences between SCD and MCI in the P300 event-related potential obtained during a visual attention task. By looking central EEG channels (FC1, FCz, FC2, C1, Cz, C2), we compared the signals along the interval 300 [ms] - 500 [ms] between the two conditions, further stratifying for the task performance. We found that the P300 amplitude was larger in patient with a better performance, and that this effect was significantly more pronounced in MCI subjects. These results suggest that P300 during a simple task can be a useful neural marker to discriminate between the two conditions. In future longitudinal studies, this marker could support identify risk or protection profiles for conversion in the SCD and MCI continuum.**

***Keywords*—P300, EEG, Subjective Cognitive Decline (SCD), Mild Cognitive Impairment (MCI)**

I. Introduction

Cognitive decline is a physiological condition due to senescence. In some cases, however, this condition can become disabling for the everyday life of those affected. There is a range of cognitive decline that progresses through subjective and objective stages [1]. Subjective Cognitive Decline (SCD) is a self-reported change in memory, reasoning, and problem solving, but is not yet classified as pathological by neuropsychological tests. Mild Cognitive Impairment (MCI) is when neuropsychological tests reveal objective cognitive symptoms. SCD patient are considered a risk condition for more severe forms of cognitive decline, such as MCI and Alzheimer's disease.

A low-cost and portable methodology for studying the condition of a person's cognitive decline is the electroencephalogram (EEG). Numerous studies have focused on identifying markers that determine electrophysiological alterations in relation to the gradient of cognitive symptoms [2]. Recordings of the EEG trace in conjunction with the performance of a cognitive task are particularly suitable for this purpose. One possible marker that has been found in correspondence with altered cognitive status is the P300 potential. This voltage potential can be recorded by EEG electrodes in concomitance with decision-making during the performance of a task. The dynamics observed in the literature of this potential recognised a modulation of the P300 in relation to the quality of the decision-making process.

In this study, based on PREVIEW clinical protocol [3], we investigated the role of P300 as a neural electrophysiological correlate in patients with SCD and MCI, during a visual-attention task. The observation included the stratification of patients based on their different behavioural performances and computing a quantitative characterization of the dynamics of that event-related potential biomarker.

II. Methods

A. Patients and experimental task

The patients recruited in this study are 126, divided in 85 SCD (mean age 67.02, std 9.78) and 41 MCI (mean age 75.25, std 8.02). The cognitive task is a visual vigilance task consisting of the recognition of a target shape (triangle pointing upwards) against two confusion stimuli, i.e., 3 Choice Vigilance Test (3CVT) [4]. The patients' task performance is computed by using the F-Measure, which considers both reaction time and accuracy measures. The patients, ordered from the lowest to the highest F-Measure score, were divided into three categories sorted by low, medium, and high performance, where the cut-off between low and medium score is the 50th percentile of F-Measure, and between medium and high the 90th percentile.

B. EEG processing and statistical analysis

During the task, EEG recording was performed with a 65-channel headset (Galileo-NT system of E.B. Neuro S.p.a.) at sampling rate of 512 [KHz]. After pre-processing including band-pass filtering (1 [Hz] - 45 [Hz]) [5] , detection of noisy channels, average rereferencing and exclusion of artefactual components via ICA (Independent Component Analysis), epoching was performed for each channel, using a window of -300 to 1000ms, with onset stimulus centred on 0ms. Each trial of the experiment lasted 1000ms, with the first 200ms for stimulus presentation and the next 800ms for patients to respond. In this time window, the latent cognitive processes of decision making were studied specifically with EEG central

channels [FC1, FCz, FC2, C1, Cz, C2]. Statistical analyses were conducted to compare the EEG signals between groups by using Kruskal-Wallis H-test statistics and post-hoc and pair variables analysis were performed with Mann-Whitney U rank test, and both results were corrected using the Bonferroni technique (i.e., significative p-value if p< 7.5e-05).

C. Computation of the defined integral of voltage potential

The definite integral of EEG potential relates with the total amplitude of the P300 waveform over a specific time interval (300 [ms] - 500[ms]) and is used as a measure of the neural activity associated with performance. This integral is performed a sum of the voltage values comprised in the P300 temporal window, i.e., $\sum_{t=300\,[ms]}^{t=500\,[ms]} p_t$, where p_t is the voltage potential associated with specific time instant *t*.

III. RESULTS

A. Behavioural performances are overlapping SCD and MCI conditions

The behavioural study of the patients who performed the visual attention task showed that low, medium, and high F-Measure scores were common between the two diagnostic categories (Fig.1). Moreover, Pearson correlation between reaction time and accuracy reveals negative association for SCD (CC=-0.16, p-value=0.15) and positive association for MCI (CC=0.47, p-value=0.02). This outcome justifies the investigation into the neural mechanisms that are associated with performance.

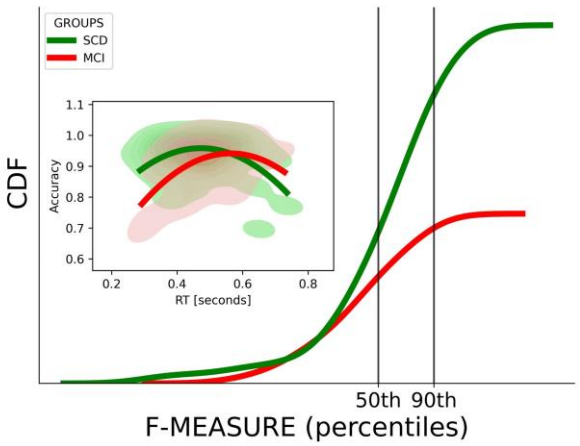

Fig. 1: Behavioural performances. Cumulative Density Function of F-Measure in SCD (in green) and MCI (in red). The 50th percentile of F-Measure defines the cut-off between low and medium performance, while the 90th percentile of F-Measure defines the cut-off between medium and high performance patients. The small scatter-density plot relates reaction time and accuracy in SCD and MCI subjects.

B. Performances are associated with specific ERP dynamic pattern shared in SCD and MCI patients

The temporal analysis of the ERP waveform, observed in central channels along the decision making process, showed that the different performance have a physiological correlate in patients (Fig2 panels A-B). In both SCD and MCI groups, the comparison of low, medium, and high performance waveforms was significant (see instant p-value above panels A-B). Post-hoc analyses, for both diagnostic categories, showed that differences were attributable to discrepancies between ERP patterns associated with low and high performance for SCD (average U statistic=9001.0, average instant p-value=0.008), and for MCI differences were related to ERP comparison between low and high performances (average U statistic=1754.0, average instant p-value=0.052) and between medium and high performances (average U statistic=964.0, average instant p-value=0.0003). Moreover, these significant differences observed when comparing the ERP waveforms with respect to performance show prolonged periods of significance (p-value blocks > 100ms). Therefore, statistical result indicates the robustness in time of the EEG dynamics associated with decision-making.

The ERP dynamics modulated with performances has changes in the prototypical P300 voltage pattern. The amplitudes of the that waveform are greater in the case of high performance, compared to medium and low performance, for both SCD and MCI conditions. The comparison between conditions also reveals that the P300 associated with high performance in MCI patients has a peak value almost double that of SCD patients (qualitative inspection in Fig2 panels A-B). This first-level observation has motivated a more rigorous treatment by extracting the integral of the P300 voltage potential defined in the 300 [ms] – 500 [ms] time interval, for both the neurological conditions and across performances.

C. The definite integral over the P300 temporal window depends on both condition and performance.

Measuring the integral of the voltage defined in the 300 [ms]-500 [ms] interval shows a positive Pearson correlation with the F-Measure in SCD (CC=0.38, p-value=0.0006) and MCI (CC=0.38, p-value=0.021)). This trend indicates a positive monotonic relationship between the amplitude of the P300 waveform and the level of performance shared between the conditions. The integral along the P300 returns a higher value as the F-Measure varies in MCI compared to SCD patients (Fig. 2 panel C).

An analysis of the integral values along the P300 was also conducted among the three performance categories (Fig. 2 panel C). The comparison between SCD patients revealed significant differences between the low and high performance categories (U statistic=173.0, p-value=0.01), while the comparison between MCI patients showed significant differences between low and medium performance categories (U statistic=17.0, p-value=0.015), as well as between the medium and high performance categories (U statistic=109.0, p-value=0.025). The comparison between the two patient groups also showed that the P300 integral levels in low performance SCD were significantly different from the values in high performance MCI (U statistic=20.0, p-value=0.0009), as were the differences between medium performance SCD and high performance MCI (U statistic=48.0, p-value=0.02).

A summary of the results can be seen in Table 1, which shows the association between diagnostic and performance category, in relation to age and measure of the voltage integral along the P300 time window. The patients who had the lowest behavioural scores during the 3CVT task were the oldest for each diagnostic category, while the patients who had the highest scores were the youngest, respect to their diagnostic category.

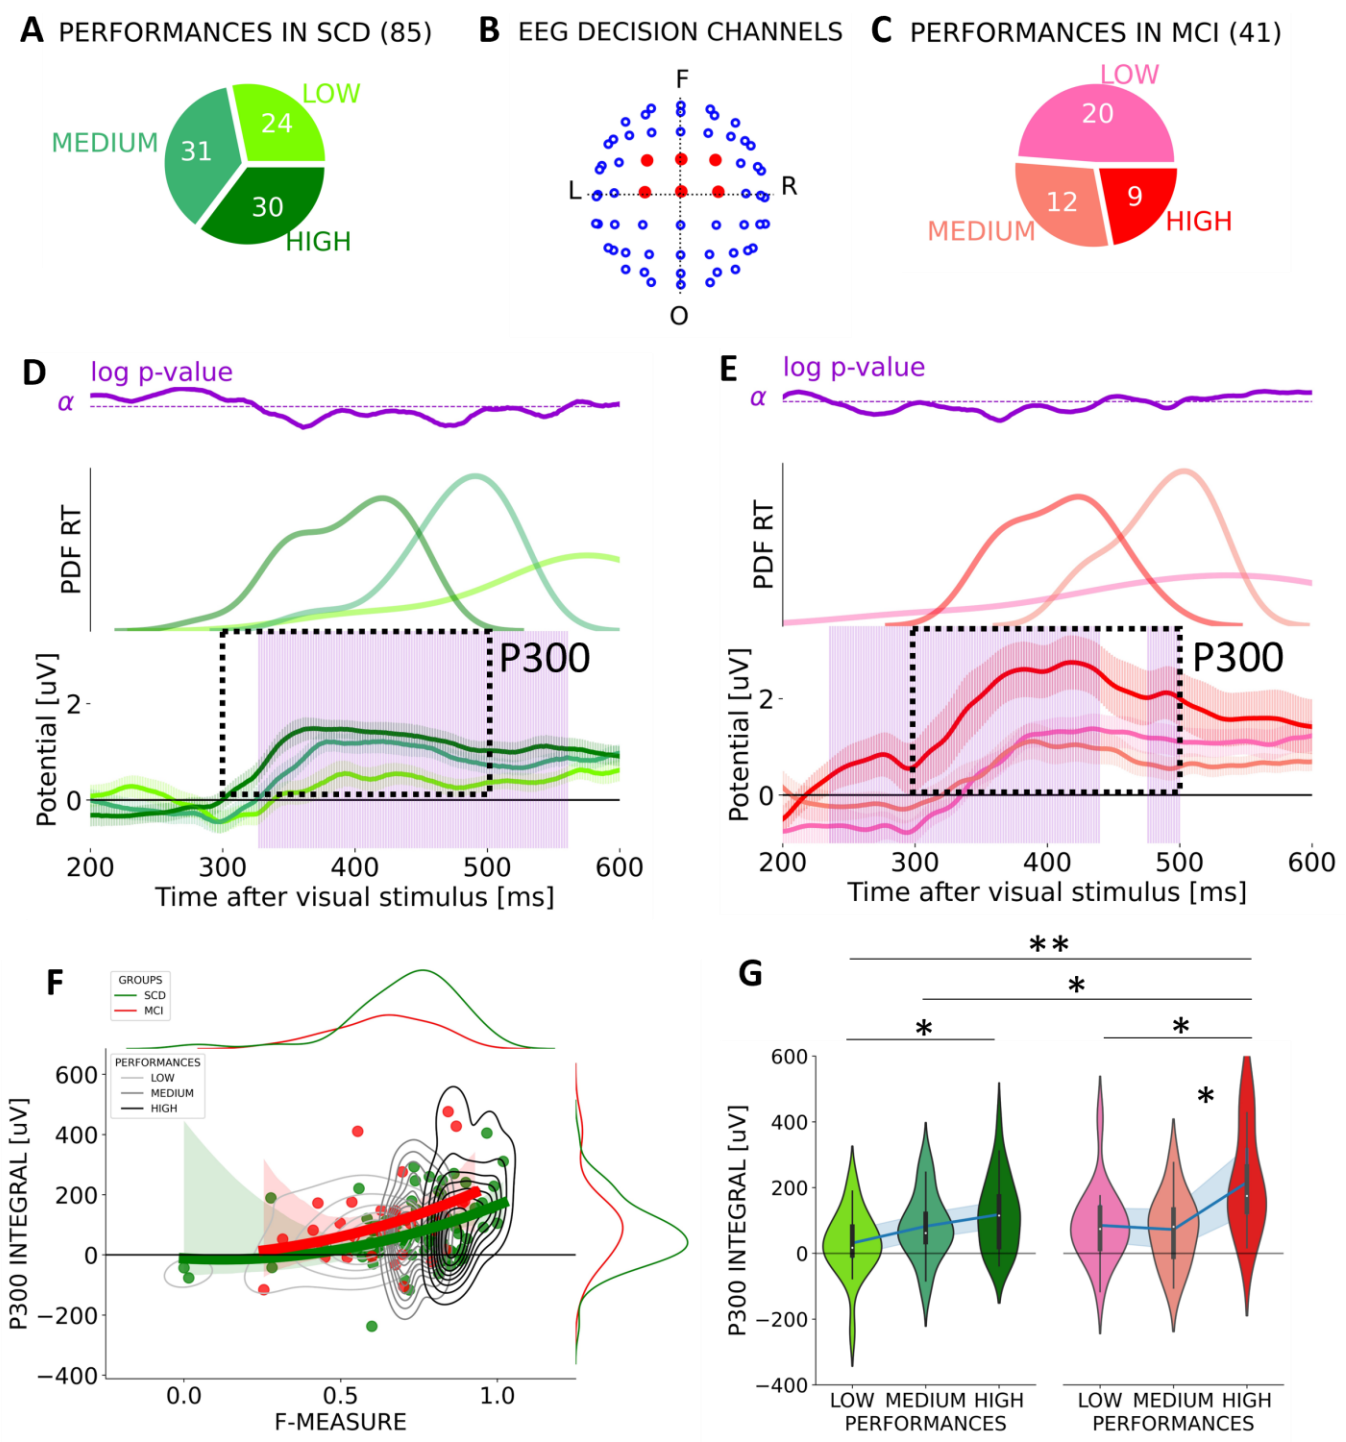

Fig 2. P300 dynamics are being investigated on EEG central channels in patients with SCD and MCI. Panel A and C are pie charts representing the number of total SCD and MCI patients and their performances, respectively, each associated with a specific colour. Panels A and C also serve as legends for all subsequent panels. Panel B indicates the EEG channels selected for the investigation of the decisional correlate, which are (FC1, FCz, FC2, C1, Cz, C2). Panel D represents the P300 dynamics in SCD patients in relation to their performances. At the bottom, the ERP correlate is displayed in the post-stimulus range. In the middle of the panel, the PSD of reaction time is presented as a function of performance. At the top, in purple, the instantaneous p-value logarithm calculated using the Kruskal-Wallis H-test, applied to the three performance categories. The term alpha indicates the Bonferroni threshold at which the p-value is significant ($p<7.5e-05$). The purple bands in the P300 graph indicate the portions of the signal for which the p-value is significant. Panel E is like Panel D but relates to MCI patients. Panel F indicates the integral of the P300 potential within the temporal range of 300 [ms] - 600 [ms] as a function of the F-Measure, with the PSDs of the dependent and independent variables at the margins. Panel G shows violin plots that identify differences in SCD and MCI conditions, stratified by performances (* if p-value < 0.05, ** if p-value < 0.01).

Diagnosis/Performance	*Age*	*P300 integral [μV]*
SCD/LOW (24#)	**71 (std 7)**	**35.52 (std 6.93)**
SCD/MEDIUM (31#)	69 (std 9)	89.10 (std 96.31)
SCD/HIGH (30#)	61 (std 9)	120.64 (std 108.62)
MCI/LOW (20#)	**79 (std 5)**	**82.15 (std 125.91)**
MCI/MEDIUM (12#)	72 (std 8)	73.94 (std 97.89)
MCI/HIGH (9#)	67 (std 8)	196.15 (std 149.28)

TABLE I: PATIENTS' NUMERICAL PROFILING

Comparing the high performance subjects with respect to the integral along the P300 potential, it can be observed that MCI patients more than double the value of SCD patients (82.15 versus 196.15), and the same applies to the values of the P300 integral with respect to low performance (35.52 versus 82.15).

IV. DISCUSSION

EEG signals of SCD and MCI patients were compared during a visual attention task. The analysis of task-related event potentials revealed specific correlates for subject performance, specifically, a modulated dynamics of P300, a marker of decision-making quality, was observed.

The voltage integral in the P300 temporal window was higher for patients with better performance and lower for those with worse performance in both SCD and MCI groups. The quantitative profiling with integral measure showed a positive correlation with performance, however, with higher values in MCI than in SCD. Conditions of high performance, as shown by a higher P300 amplitude, may indicate a level of protection from the progression of pathological conditions such as SCD to MCI. By opposition, patient with lower P300 amplitude may be at a higher risk of progression. The hypothesis of P300 dynamics as an evaluation of conversion risk is coherent with studies associating, in people affected with different stages of cognitive decline, the efficiency of P300 with high cognitive reserve[6], [7], that is a capacity of brain resilience governed by phenomena of neural plasticity [8]. By the way, this hypothesis needs more experimental support through the longitudinal observation of the same patients.

The dimensionality reduction of the ERP signal to a single value can be useful for training machine learning algorithms for the identification of risk (or protection) configurations for the onset of severe cognitive symptoms. Other studies have used measures such as negative and positive peaks [9], [10], but they lose the temporal information related to the duration of the potential of interest. Instead, the defined integral measure allows to identify in one measure both the information related to the potential (of maximum or minimum peak) and its dynamics, that is its time evolution in a defined observation window.

Potential limitations of this study include: i) the absence of control and Alzheimer's Disease (AD) subjects, which represent the low and high boundaries, respectively, along the dementia continuum for SCD and MCI conditions; ii) the use of CSF+/- biomarkers, which may have helped in discriminating actual neural degeneration in patients; iii) the lack of a machine learning decoder to validate the P300 integral as a classification feature for pathologies and performance.

***Abstract*—Adolescent idiopathic scoliosis (AIS) is the most common form of scoliosis, i.e., a three-dimensional morphological spinal deformity. So far, abnormalities in electroencephalography (EEG) power spectral density during simple motor tasks have been measured in the literature. This preliminary work investigates if nonlinear analysis is as sensitive as EEG signal spectral power changes. For such aim, we exploited a database obtained from 12 adolescent girls with AIS (8 with right main curve and 4 with left main curve) and 14 age-matched controls during a simple upright static balance task. First, we analyzed EEG data using the Higuchi's Fractal Dimension (HFD) as measure of signal irregularity. Second, we fit a linear model to HFD values using as predictors the values of theta and alpha rhythms. HFD revealed a statistically increase in EEG irregularity/complexity in adolescent girls with AIS compared to controls in line with an increase in the theta power in the central regions of the brain and a decrease of alpha power in the parietal regions of the brain. These results suggest a higher information processing load due to increased postural demands caused by the scoliosis.**

***Keywords*—Electroencephalography, Higuchi fractal dimension, nonlinear analysis, spine**

I. INTRODUCTION

Adolescent Idiopathic Scoliosis (AIS) is a three-dimensional morphological spinal deformity, characterized by the deviation of the spine in the frontal plane (> 10 Cobb degrees) and the concurrent rotation of the affected vertebral bodies [1], with a prevalence of about 1-3% in adolescents aged between 10 and 16 years with girls more severely affected. The cause and the pathophysiology of AIS is not yet completely understood, but multi-factorial hypotheses, including central nervous system abnormalities, have been proposed.

Neuroimaging studies revealed: asymmetries in brainstem corticospinal bundles [2], volumetric differences in brain regions functionally related to motor control and coordination [3], abnormal patterns in the motor network during movement execution [4]. Electroencephalography (EEG) studies reported paroxysmal activity at rest [5] i.e., bilaterally synchronous activity spread over large areas of both hemispheres. An increase of the amplitude of the peak in alpha rhythm was found at central, frontal, parietal and occipital brain regions suggesting the need for increased cortical processing to maintain balance control in normal upright standing in adolescents with AIS compared to healthy controls [6]. The increase in theta frequency power and the suppression of alpha, beta and gamma powers were also observed when proprioception was altered [7]. Results from our previous study revealed a significant increase of theta activity over central regions and a lateralized alpha activity over sensorimotor regions during four different standing positions [8].

Up to now, EEG modifications in AIS have been studied with linear analysis methods, such as spectral analysis or EEG topography. Spectral analysis reduced the EEG power spectral quantification to specific frequency range of interest to establish a priori. Nonlinear methods can increase the robustness of results obtained by linear analysis. Nonlinear analysis does not require a priori conditions as restricted as linear analysis ones. For instance, spectral analysis reduces the EEG power spectral quantification to a specific frequency range of interest to establish a priori and relies on the stationary properties of the input signal. Electrical potentials recorded at the scalp level are the coalescence of overlapping brain cell action potentials in time and space. EEG can exhibit complex behavior with nonlinear dynamic properties. Thus, nonlinear methods, such as Higuchi's measure of Fractal Dimension (FD) [9], may complement the description of cerebral electrical activity. Other indices, such as sample entropy (SampEn), empirical permutation entropy and empirical conditional entropy, can be used to detect signal complexity. The best results, obtained by training and testing a neural network on EEG data in a previous study [10], were however obtained by FD indices. Moreover, FD indices, besides having no need for storage memory, are classified as linear time algorithms (i.e., they have a time complex O(N)), whereas multi-scale entropy methods (e.g., SampEn) are classified as quadratic time algorithms (i.e., they have a complex $O(N^2)$) [11]. The Higuchi FD (HFD) identifies nonlinear dynamic properties of the brain based on the quantitative EEG data and provides complementary information to power spectral analysis. HFD tends to increase as the EEG signal irregularity/complexity increases [10], [12].

In this work, we aim to deepen the analysis of the EEG activity during a simple standing task in adolescent girls with AIS vs controls by means of HFD and the computation of power spectra in theta and alpha bands – i.e., EEG frequency bands involved in postural stability control [13]. Characterizing abnormal EEG patterns may help in describing the complex physiopathology of AIS and in promoting new multi-domain treatment approaches to improve patients' care quality.

II. MATERIALS AND METHODS

A. Experimental protocol

Twelve adolescent girls with a confirmed diagnosis of AIS (age range 13–17 years; Cobb angle: 20°–55°; Risser sign:

0–4; no spine surgery; 8 with right (right AIS) main curve and 4 with left (left AIS) main curve) and fourteen adolescent girls without AIS (age range 11–16 years; no spinal pathology or any known neurological or musculoskeletal disorders; no clinically relevant back hump), i.e., controls (CTRL), were asked to stand upright with eyes closed and with their arms raised laterally to 90° for 1 min (Fig. 1a). EEG signals (32-channels system; BrainAmp 32MRplus, BrainProducts GmbH, Munich, Germany) were acquired during the upright static balance task using an analog anti-aliasing band pass-filter at 0.1–1000 Hz and converted from analog to digital using a sampling rate of 500 Hz. The reference was between Fz/Cz and ground anterior to Fz (Fig. 1b).

For further details on the database and the experimental protocol, we refer the reader to [8].

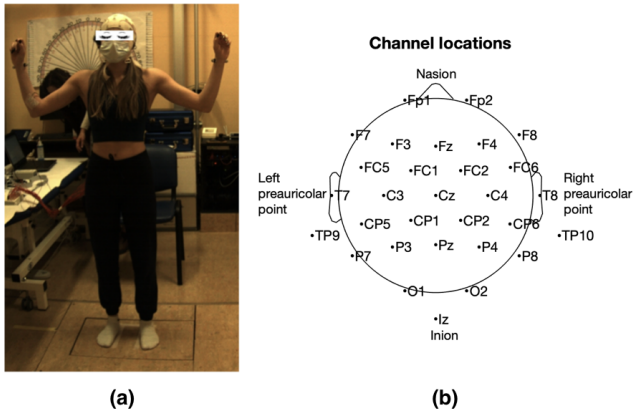

Fig. 1: **(a)** Participant standing upright with eyes closed and with arms raised laterally to 90° whilst wearing the EEG cap. **(b)** 30-channel locations according to the 10-10 system.

B. EEG data pre-processing

The data were band-pass filtered from 1 to 30 Hz considering that power spectral density shows a decrease in power with increasing frequency (1/f) and the presence of the power supply noise at 50 Hz (the optimal Chebyshev finite impulse response filters were designed using Parks–McClellan algorithm, the order was customized to minimize the error in the pass bands). Noisy channels – identified by visual inspection – were interpolated using the nearest-neighbour spline method. Cardiac activity was removed using independent component analysis (FastICA algorithm implemented in EEGLAB) based on the waveform, topography and time course of the component. Data were re-referenced to the average reference. Individual epochs containing non-stereotyped artifacts were identified by visual inspection and removed.

C. Higuchi Fractal Dimension

The FD provides a complexity index that describes how the measure of the length of a curve L(k) changes depending on the scale k used as a unit of measurement. Different approaches can be used to estimate FD [9]. The Higuchi FD standard approach calculates the FD of a time series in the time domain and is based on the log[**L**(k)] versus log(k) curve computed as follows.

(i) For each sample i of the EEG epoch **s** = **s**(1), **s**(2), …, **s**(N) of length N, the absolute differences between values s(i) and s(i-k) - i.e., the samples at distance k - are computed, considering $k = 1, \ldots, k_{max}$.

(ii) Then, each absolute difference is multiplied by a normalization coefficient that takes into account the different numbers of samples available for each value of k. The computation of this coefficient is based on the starting point m = 1, …, k and on the total number N of samples of an epoch.

(iii) $\mathbf{L}_m(k)$is computed as

$$\mathbf{L}_m(k) = \frac{1}{k} \cdot \left[\sum_{i=1}^{q} |\mathbf{s}(m + i \cdot k) - \mathbf{s}(m + (i-1) \cdot k)| \right] \cdot \frac{N-1}{q \cdot k} \tag{1}$$

where $q = int[(N-m)/k]$ and $\mathbf{L}(k)$ is computed by summing the obtained values and dividing by k:

$$\mathbf{L}(k) = \frac{1}{k} \cdot \sum_{m=1}^{k} \mathbf{L}_m(k) \tag{2}$$

(iv) From Eq. 2, the log[**L**(k)] versus log(k) curve can be derived. By definition, if $\mathbf{L}(k)$ is proportional to k^{-D} for $k = 1, 2, ..., k_{lin}$ where k_{lin} defines the upper range of the linear region of the log[**L**(k)] versus log(k) curve, then the curve is fractal with dimension D.

In this work, the linear region was defined by imposing k_{lin} equal to 5, according to [14], whilst k_{max} was set as equal to 100, $k_{max} \geq 3k_{lin}$ according to [12]. For each EEG channel, we computed the HFD of each non-overlapping 2-s EEG epoch (i.e., 1000 samples). Then, we averaged these values across epochs to obtain a single value of HFD for each EEG channel.

D. Relative power spectra

The fast Fourier transform was applied to non–overlapping epochs (Hanning-windowed to control for spectral leakage) of 2 s and then averaged across epochs. Relative power spectra (%) were calculated by dividing the power spectrum in theta band, i.e., [4.5–7.5] Hz, and alpha band, i.e., [8–12] Hz, with the total power of [1–30] Hz.

E. Multiple Linear Regression

In order to interpret and relate HFD and power spectra changes, for each group of subjects – i.e., CTRL ($N = 14$), right AIS ($N = 8$) and left AIS ($N = 4$) – a multiple linear regression model was used to predict HFD values based on the power spectral values of theta and alpha rhythms:

$$\mathbf{y} = \mathbf{X}\mathbf{a}; \tag{3}$$

where

$$\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_N \end{bmatrix}; \mathbf{X} = \begin{bmatrix} 1 & x_{1\theta} & x_{1\alpha} \\ 1 & x_{2\theta} & x_{2\alpha} \\ \vdots & \vdots & \vdots \\ 1 & x_{N\theta} & x_{N\alpha} \end{bmatrix}; \mathbf{a} = \begin{bmatrix} 0 \\ a_{theta} \\ a_{alpha} \end{bmatrix} \tag{4}$$

are, respectively, a column vector containing the HFD of the N subjects; a matrix containing the values of the power spectra in theta (second column) and alpha (third column) bands of the N subjects; a column vector containing the coefficients to be estimated using the least square estimator:

$$\hat{\mathbf{a}} = (\mathbf{X^T X})^{-1}\mathbf{X^T y} \tag{5}$$

F. Statistics

First, we compared the EEG features (i.e., theta and alpha power spectra, HFD) among the three groups through Kruskal Wallis Test. We chose a nonparametric test since: (i) the EEG features were not normally distributed in all the EEG channels, (ii) the limited number of subjects. Second, for each channel, between-group differences in each EEG feature were investigated via an unpaired two-sided Wilcoxon rank sum test ($p_{value} < 0.05$) to highlight significant statistical differences between adolescent girls with AIS and controls.

III. RESULTS

Results are reported as EEG topographies in Fig. 2, 3, 4, 5. The EEG electrodes are placed onto the head, following a geometrical array of even-spaced points. Nasion and left and right pre-auricular points are depicted as anatomical landmarks (Fig. 1b). The values to represent are plotted by coding the amplitude in several tones of color (blue and green depicts lower amplitudes, while yellow and red depicts larger amplitudes). The spatial points lying between electrodes are calculated by interpolation.

The Kruskal Wallis Test indicated that the samples did not originate from the same distribution for both HFD and theta and alpha power spectra.

A. Higuchi Fractal Dimension

HFD was statistically significantly higher ($p_{value} < 0.03$) in adolescent girls with AIS with left main curve than in controls in the left frontal, central and parietal brain areas, i.e., in F3, FZ, FC1, C3, CP1, CP2 and PZ (Fig. 2a-c, Fig. 3b). Significant differences were also found in the HFD between left AIS and right AIS: left AIS showed higher HFD in the right central-parietal brain regions, and in the frontal brain areas, i.e., in F7, FC5, FC1, F4, PZ ($p_{value} < 0.01$), F3, C3, FZ, FC2, FC6, CP1, CP2, CP6, P4, and P8 ($p_{value} < 0.03$) (Fig. 2b-c, Fig. 3c).

B. Relative power spectra

Power spectra in theta band (Fig. 2d-e-f) were statistically significantly higher in:

- C4, TP9 ($p_{value} < 0.03$) in right AIS compared to CTRL (Fig. 4a).
- C4, FC2 ($p_{value} < 0.05$) in left AIS compared to CTRL (Fig. 4b).
- FP1 ($p_{value} < 0.03$) in left AIS compared to right AIS (Fig. 4c).

Power spectra in alpha band (Fig. 2g-h-i) were statistically significantly lower in:

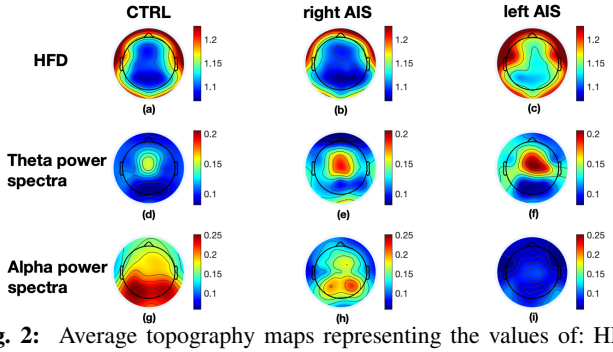

Fig. 2: Average topography maps representing the values of: HFD (first row), theta power spectra (second row) and alpha power spectra (third row) for **(a-d-g)** controls, adolescent girls with AIS with **(b-e-h)** right curve and with **(c-f-i)** left curve.

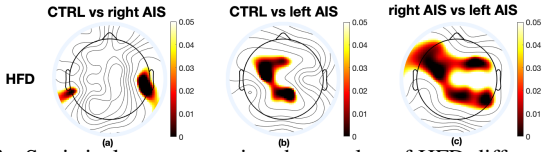

Fig. 3: Statistical maps reporting the p-value of HFD differences between: **(a)** controls vs adolescent girls with AIS with right curve; **(b)** controls vs adolescent girls with AIS with left curve; **(c)** adolescent girls with AIS with right curve vs adolescent girls with AIS with left curve.

- C3 ($p_{value} < 0.05$) in right AIS compared to CTRL (Fig. 4d).
- FZ, C3, CP5, CP6, P3 ($p_{value} < 0.02$), F3, F4, C4, P4, O1, F8, T8, P7, IZ, FC6 ($p_{value} < 0.05$) in left AIS compared to CTRL (Fig. 4e).
- P4 ($p_{value} < 0.05$) in left AIS compared to right AIS (Fig. 4f).

These results are also supported by our previous work [8].

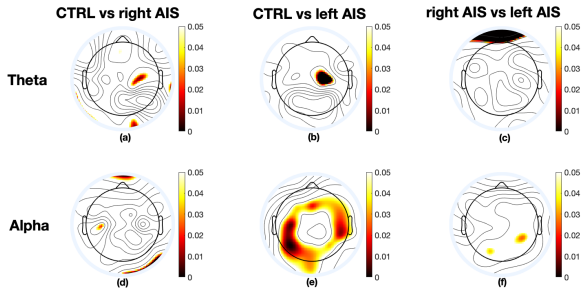

Fig. 4: Statistical maps reporting the p-value of the difference of theta (first row) and alpha (second row) power spectral between: **(a-d)** controls vs adolescent girls with AIS with right curve; **(b-e)** controls vs adolescent girls with AIS with left curve; **(c-f)** adolescent girls with AIS with right curve vs adolescent girls with AIS with left curve.

C. Multiple Linear Regression

The values of the coefficients weighting the power in theta band (i.e., a_{theta}) were distributed in a narrower range in

CTRL, i.e., [0.0469 0.0977], compared to right AIS, i.e., [0.0348 0.1163] and left AIS, i.e., [-0.0213 0.1249] (Fig. 5a-c-e).

The values of the coefficients weighting the power in alpha band (i.e., a_{alpha}) had values near to zero for CTRL and right AIS whilst had higher values in the occipital, parietal and temporal lobes in left AIS (Fig. 5f).

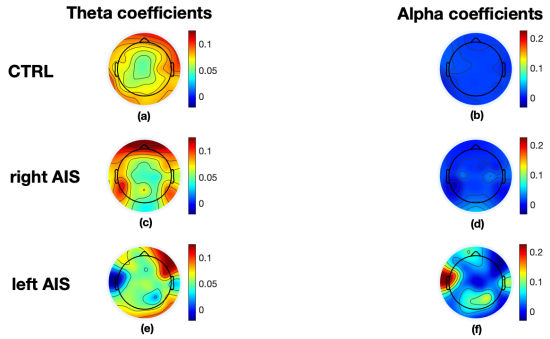

Fig. 5: Topography maps representing the coefficients of the linear regression model between the HFD values (dependent variable) and values of power in theta and alpha frequency bands (regressors) for **(a-b)** controls, adolescent girls with AIS with **(c-d)** right curve and **(e-f)** left curve. The first column reports theta coefficients and the second column alpha coefficients.

IV. DISCUSSION

Our preliminary results evidenced: (i) an increased of theta power in central clusters, (ii) a decrease of alpha power in parietal clusters parallel to (iii) an increase in Higuchi FD in girls with AIS (mainly with left curve) compared to CTRL. Interestingly, there is evidence that changes in the EEG power spectrum due to postural instability occur predominantly in the theta and alpha frequency bands [13]. In healthy adolescents, an increase in theta band power in frontal and central brain areas and a decrease in alpha power in central and parietal brain areas were evidenced with increasing balance task difficulty [13]. Similar EEG power spectral changes were found in our AIS participants compared to controls supporting the hypothesis that a simple symmetric static balance task requires an increased attentional processes and/or error monitoring as well as increased sensory information processing due to increasing postural demands in girls with AIS compared to controls.

In parallel, Higuchi FD revealed an increase in signal complexity mainly in brain regions in the brain hemisphere ipsilateral to the main curve (Fig. 3b). This suggests that girls with AIS seem to recruit the muscles contralateral to their main curve, thus activating the ipsilateral brain hemisphere, in order to maintain a symmetric static balance position.

V. CONCLUSION

In this preliminary study, Higuchi Fractal Dimension proved to be suitable to capture region-specific neural changes during static balance in girls with adolescent idiopathic scoliosis. The increase in theta rhythm in the central brain regions and the decrease of alpha rhythms in the parietal brain areas in girls with AIS compared to controls were paralleled by an increase of EEG complexity as evidenced by an increase of HFD.

Although further investigations are worth performing, adolescents with AIS show a different EEG activity compared to controls, probably related to their musculoskeletal dysfunction. Both a larger database and a longitudinal study are still needed to verify these EEG findings which may represent a valuable biomarker of scoliosis progression.

***Abstract*—The relationship between brain structural (SC) and functional (FC) connectivity changes in Alzheimer's disease (AD) is crucial for understanding the progression and impact of the disease at different stages. In this study a multivariate statistical technique called Partial Least Squares (PLS) was used to capture the variations in SC and FC between control (CN) and pathological (PAT) subjects. The focus is on the ongoing AD Neuroimaging Initiative (ADNI)-3 cohort, relying on data from diffusion (dMRI) for SC and resting-state functional magnetic resonance imaging (rs-fMRI) for FC. Once standard data preprocessing and PLS were applied, the model weights were visualized based on the functional atlas used. This visualization allowed for a clearer representation of the relationships that were identified. Statistical tests on the original SC and FC data revealed significant differences between the two populations in SC, but not in FC, demonstrating a non-clear correspondence one-to-one between them. However, the PLS model showed unique patterns of SC and FC connections that optimally covary in 13 significant components. Interestingly, anticorrelation among the top weights was found between SC and FC in several components, suggesting an opposite behaviour between these two connectivities in the same links. These findings suggest that PLS can provide a more in-depth understanding of the relationship between SC and FC in AD and highlight the importance of their coupling in determining the pathophysiological pathways of the disease.**

***Keywords*—Alzheimer's disease, resting-state functional MRI, functional connectivity, structural connectivity, PLS.**

I. Introduction

Alzheimer's Disease (AD) is the most common type of dementia characterized by a progressive neurodegeneration that affects neurological, physical and cognitive domains that eventually interfere with daily life activities. The incidence of AD appears to double every five years after the age of 65 [1], and it is estimated that the number of individuals living with AD will continue to rise, especially in non-western countries [2]. Subjects affected by AD present a degeneration of brain tissues with loss of nerve cells, formation of β-amyloid plaques, and the development of neurofibrillary tangles [3] which can be captured with imaging techniques as magnetic resonance imaging (MRI). Despite the recent technical advancements, there is currently no effective treatment or prevention for AD [4]. Therefore more in-depth studies considering the multifaceted aspects of the AD continuum are necessary to provide novel insights on the biological contributors to AD.

Understanding the relationship between functional and structural changes occurring in AD, in terms of structural and functional brain connectivity (SC/FC), is one of the hottest challenges at the state-of-the-art, and such a link is far from being straightforward even in healthy conditions [5]. While the presence of a direct connection between two nodes determines the SC strength, FC is determined by the temporal coincidence of neural activity between spatially distant regions of the brain [6]. Previous research has suggested a positive correlation between SC and FC, meaning that structural degenerations are related to functional alterations encompassing the same areas, while a few cases have demonstrated an opposite behaviour [7]. Previous studies have used different methods to relate SC and FC data, such as graph-based measures, or specific analysis on a few networks, precluding a direct generalisability of the results. Despite the heterogeneous and sometimes controversial literature findings, possibly related to the different methodologies, the sample size and the included subjects, previous studies have suggested that structural changes may precede the functional ones in AD, as structurally impaired but functionally unaffected connections have been often disclosed [8]. In this framework, important information can be derived from more comprehensive analysis based on data-driven multivariate statistical approaches, such as Partial Least Squares (PLS) and Canonical Correlation Analysis (CCA), which are able to simultaneously model multiple variables and handle possible collinearity issues [5]. The goal of this study was to exploit PLS for identifying both structural and functional patterns that highly covary with each other and investigating their relationship in the context of AD.

II. Materials and methods

A. Study cohort

Data used in this study were obtained from the Alzheimer's Disease Neuroimaging Initiative 3 (ADNI3) database (adni.loni.usc.edu). Participants were selected based

on the availability of diffusion (dMRI) and resting-state functional magnetic resonance imaging (rs-fMRI) data, leading to a cohort of 587 subjects with 288 patients across the AD continuum (PAT) and 299 healthy controls (CN).

B. Acquisition protocol and data preprocessing

Single-shell dMRI and rs-fMRI acquisitions were acquired using 3T scanners, following the protocols and parameters outlined in the ADNI-3 database. After brain extraction, dMRI data were corrected for eddy currents-induced distortion, denoised by using local principal components analysis via empirical thresholds, and non-linearly registered to the 2-mm MNI space to remove EPI deformation. Standard preprocessing was applied to rs-fMRI data, followed by nuisance regression (6 motion parameters, white matter/CSF), pass-band filtering (0.01-0.08Hz), scrubbing and non-linear spatial normalization to the 2-mm MNI space [9].

C. Structural and functional connectomes

This study used a functional atlas to derive SC/FC connectomes instead of an anatomical atlas, as usually performed in the current literature. We hypothesised that using a functional atlas can more easily establish functional relationships with anatomical counterparts and avoid subdivided functional networks for better interpretability. To this aim, the Schaefer functional atlas with 100 parcels and 7 resting-state networks (RSNs) (visual [VIS], somatomotor [SMN], dorsal attention [DAN], ventral attention [VAN], limbic [LIM], frontoparietal control [CON], and default mode network [DMN]) [10] was chosen. Concerning SC, MRtrix3 (https://www.mrtrix.org/) was employed to derive an anatomically constrained probabilistic tractography (2 million streamlines, step = 0.3 mm, maximum length = 300 mm, and backtracking) filtered with SIFT2 [11]. The individual SC was then built by counting the number of streamlines connecting all pairs of regions from the functional atlas, ignoring self-connections. Conversely, the full Pearson correlation coefficient (*r-value*) between pairs of nodes was calculated to derive FC.

D. Partial Least Squares analysis

SC and FC were related through PLS [12]. Both the independent (X) and dependent (Y) variables were matrices of dimensions M$\times$N, with M = 587 (number of subjects) and N = 4950 (number of entries of the strictly upper triangular matrix from the 100$\times$100 symmetric SC/FC matrices). The N values of X were taken from the SC matrices, while the N entries of Y were taken from the FC ones. A Z-score normalization was applied to X, Y, and the confounding variables (age and gender), followed by deconfounding via linear regression. PLS was subsequently performed choosing 55 latent components as trade-off between the performance and the computational time, using the Nonlinear Iterative Partial Least Squares (NIPALS) algorithm [13]. PLS weights of structural and functional data, reflecting feature relevance in the generation of each latent component, were hence obtained. A permutation test (1000 permutations) was used to determine the statistical significance of the model. PLS projections scores were calculated for each component and their statistical difference between PAT and CN was evaluated through a group-wise Mann Whitney non-parametric U-rank test, separately for SC and FC derived scores. The latent components were further selected based on the significance ($p < 0.05$) obtained from the statistical test.

E. Visualization approaches of results

For each component, the projection scores for SC and FC were reported as scatterplots to visualise their relationship in the latent space, and as boxplots to compare their distributions in CN and PAT. The SC and FC PLS weights for each component were summarized as symmetric "14x14 matrices". In details, for each modality, the 4950 weights were averaged according to the original organization of the connectomes and keeping separately the two hemispheres, leading to a summary weight for each of the 7 RSNs and for each between-network pair (91 inter-network combinations). The original SC and FC matrices were similarly grouped in symmetric 14x14 matrices for each subject and statistically compared between PAT and CN groups (two-sample Mann Whitney non-parametric U-rank test, $p < 0.05$ with false discovery rate multiple comparison correction). This allows to preliminary test whether significant changes are identifiable in the original matrices and to further guide the interpretation of the SC-FC component weights. The component-specific weights were also thresholded at the 85^{th} percentile to identify the connections having the highest weights, being thus the most relevant in driving the SC-FC association. These were assigned to either one of the 7 RSNs or one of the 21 inter-network combinations (considering left/right hemispheres together) and the resulting percentage was then calculated, separately for positive and negative weights. Such percentages were reported as symmetric "7x7 matrices", and the similarity across positive/negative matrices of the two modalities was quantified using a spatial correlation coefficient.

III. Results

The PLS analysis was conducted using 55 components, explaining 35% of the data variability. Among them, 13 (components 2, 6, 7, 8, 11, 13, 19, 21, 24, 32, 33, 50, and 55) had significantly different projection scores in the PAT vs CN statistical analysis for either FC or SC. The significance of our model was confirmed by a permutation test, resulting in a p-value of 0.0. We focused on the top 9 significant components, with the corresponding p-values and explained data variability reported in Table I. Component 2 explained the highest data variability, but did not show a clear separation between PAT and CN in its latent space (Fig.1a). However, significantly different projection scores for both SC and FC were depicted (Fig.1b).

The 14x14 matrices of the significant PLS components reveal a pattern of strong either correlation or anticorrelation between the FC and SC PLS weights. For instance, component 2 exhibited an anti-correlated behaviour between the two matrices, with SC having negative weights in most of intra/inter-

TABLE I: Results of the statistical tests for the top 9 significant components. The table displays the p-values for each component, with those below the significance threshold ($p < 0.05$) highlighted, and the percentage of explained data variability.

Comp	*p - SC*	*p - FC*	*%*
2	$\mathbf{4.2204 \cdot 10^{-6}}$	$\mathbf{2.4323 \cdot 10^{-5}}$	1.8755

19	**0.0452**	0.0729	0.6159
21	**0.0043**	**0.0006**	0.5836
24	0.0583	**0.0012**	0.5486

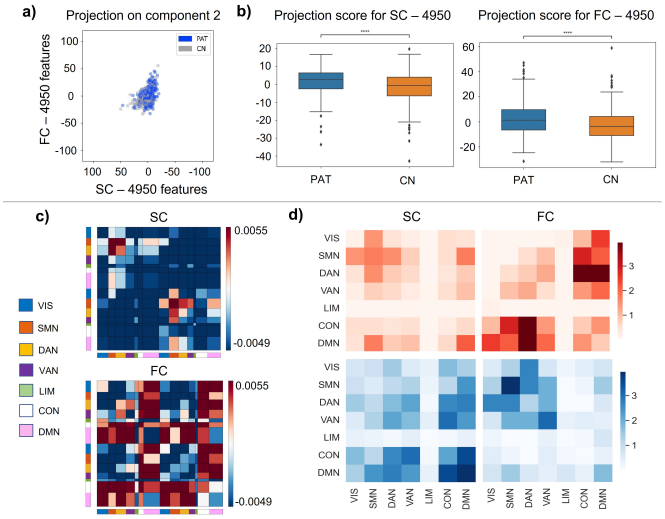

Fig. 1: Example of PLS results for component 2. **a)** Projection scores in the PLS-derived latent space, with subjects grouped as PAT (blue dots) and CN (grey dots). **b)** Boxplots representing the variability of the PAT (blue) and CN (orange) corresponding projections scores in the PLS-derived latent space for SC and FC, separately. **c)** 14×14 matrices showing the average PLS weights within/between RSNs (top: SC, bottom: FC). **d)** 7x7 matrices displaying the percentage of connections with PLS weights above the 85^{th} percentile separately for SC (left) and FC (right), further divided into positive (top) and negative (bottom) weights.

network connections while positive weights were associated with the same links in FC (Fig.1c).

When considering the most relevant weights for each component (85^{th} percentile) and the corresponding 7×7 percentage matrices, positive spatial correlations were found across the four negative/positive intermodality combinations (except for two cases), with correlation coefficients greater than 0.48 for the highest ones (Table II). Most of the components had a strong positive correlation for those matrices related to the concordant weights (i.e., positive SC [PS] - positive FC [PF] for components 6, 8, 21, and 24, or negative SC [NS] - negative FC [NF] for components 11 and 19). Interestingly, three components (2, 7 and 13) showed high spatial correlation between opposite percentage matrices, suggesting an anti-correlation between their corresponding top weights. Indeed, component 2 showed a generic covariation between PF and NS, while the highest percentages for the connections located within/between SMN and within DMN were observed for PS-NF (Fig.1d). A similar behaviour was found for component 13, in this case with a clear involvement of the within/between VIS connections for PS-NF and within DMN for PF-NS (Fig.2). Lastly, the statistical results on the original data (summarized in Fig.3) showed significant alterations between CN and PAT in both FC and SC. The differences in SC were primarily located in interhemispheric connections, whereas fewer differences were identified in FC, suggesting that there is no clear one-to-one correspondence between SC and FC.

IV. Discussion

The main focus of this study was to investigate the relationship between SC and FC in individuals affected by AD

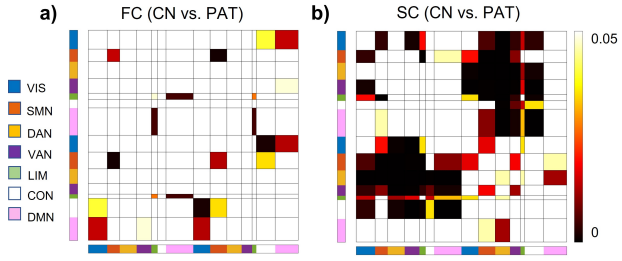

Fig. 3: Weighted matrices showing the significant differences between the CN and PAT in FC (a) and SC (b). The values shown are those that survive correction for multiple comparisons using the FDR-corrected Mann Whitney U-rank test ($q < 0.05$).

compared to controls using PLS. The results suggest that exploiting this model, though simple, can help elucidating this question. The statistical test comparing functional and structural features between CN and PAT populations shows partly divergent patterns of alteration among RSNs between the two imaging methods. On the other side, PLS analysis reveals 13 significant components that represent a unique pattern of SC and FC connections that optimally covary with each other, indicating a particular correlation or anti-correlation between the strongest weights of FC and SC. Therefore, traditional statistical analysis fails to demonstrate a clear one-to-one correspondence between network communities in FC and communities in underlying SC. In contrast, the PLS method shows what covaries between them. To the best of our knowledge, this is the first study that uses PLS to examine the coupling between SC and FC in the two populations under study, making the interpretation of the observed results challenging. Previous research in this field has mostly employed graph analysis methods to integrate information after extracting global and local network indices. Using the graph theory changes were observed in common network characteristics such as path length and global efficiency in AD [14]. Analysis of FC-SC coupling using graph theory is also a current research focus, with the DMN being a particularly important area of study. This network has been found to be highly correlated with neural activity, and changes in the DMN have been observed in both healthy aging and AD [15]. While graph network analysis has been a widely used method for investigating the two types of brain connectivity [16], PLS analysis has not been frequently used to study their coupling. A PLS model to explore the relationship between structure and function at the network level has been presented on controls by Mišić et al. [5]. They demonstrated systematic and statistically significant relationships, with a key finding being that FC patterns often diverge from SC patterns, likely due to complex network-wide interactions. Moreover, they showed that the presence of an individual structural connection can predict the magnitude of the corresponding functional connection, but the reverse is not necessarily true. However, interpreting the significance of the correlations and anti-correlations within the PLS components can be challenging as it does not directly reflect the association between values in the original domains. For example, it is difficult to interpret the relationship between the number of streamlines connecting a pair of regions and the Pearson correlation existing among them solely based on the PLS results. Despite this limitation, the PLS model remains a valuable tool for uncovering patterns in data.

In conclusion, this finding implies the potential of functional–structural network coupling as a promising biomarker for monitoring disease progression of AD.

***Abstract*—Neurostimulation is a technique that allows to study the human brain using an external signal which modifies its current activity. The stimulation is usually performed with fixed parameters, in a classical open-loop control paradigm. This strategy does not consider the current status of the brain to adaptively modify the stimulation parameters such as location, intensity and timing. In control theory, the latter strategy is called closed-loop control and it is becoming popular in neuroscience community since it allows to study the causal relationship between brain and behaviour, and it paves the way to personalize treatments in clinics. Here, we reviewed this new branch of study, by introducing control theory and presenting the neurostimulation techniques that are implementing closed-loop neuromodulation.**

***Keywords*—closed-loop control, neurostimulation, TMS, EEG.**

I. Introduction

In the last decades neuroscientists have started to inspect the brain using several techniques that allowed to study its mechanisms at different scales: spatial, temporal, and functional. A fundamental tool that has been developed to help neuroscientists is the set of neurostimulation techniques. Neurostimulation techniques are used to excite or inhibit (a set of) neurons and provoke specific patterns of neuronal activity that are supposed to elicit a proper behavioural or neurophysiological response. Characterizing how the brain reacts to stimulation is crucial, to use targeted endogenous or exogenous stimulation techniques that may help to recover or improve the brain functions and related behavioural traits.

Currently, neurostimulation techniques are mainly used with fixed parameters (i.e. they remain unchanged throughout the whole session) on the basis of the subset of brain regions and mechanisms under investigation. In control theory, this general approach is called open-loop control, since the stimulation does not depend on the previously elicited effects. On the contrary, in closed-loop control the stimulation is constantly updated based on feedback information which is dependent on the difference between the current and the expected system response. The union of closed-loop approach and neurostimulation is not a completely novel approach, since several studies have used this paradigm to automatically target stimulation in several contests and with different strategies. The ultimate goal is to build an automatic and adaptive system that allows a sort of brain control by using the signals of the brain and targeting stimulations.

Here, we will review the most used approaches to control the brain, using exogenous stimulation techniques. Our goal is to illustrate the key concepts of the brain control paradigm and explore the challenges that still need to be addressed to fully adopt these techniques which may dramatically impact clinical and therapeutic applications.

II. Control theory

A. System definition and properties

Control theory is an interdisciplinary branch of engineering and mathematics that studies how to design a set of strategies to drive a dynamical system towards a desired state, and, possibly, following an optimal trajectory [1]. In general, the equation for dynamical systems, under the assumption of time invariance and linearity (LTI), can be written as:

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t)\\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t)\end{aligned} \tag{1}$$

where $\mathbf{x}(t) \in \mathbb{R}^N$ is the internal state of the system at time t, $\mathbf{u}(t) \in \mathbb{R}^M$ represents the input signal, $\mathbf{y}(t) \in \mathbb{R}^S$ the set of measured variables and N, M and S are the dimensions of variables. In addition, $\mathbf{A} \in \mathbb{R}^{N\times N}$ represents how the different variables of the state vector are interacting and is termed as the dynamics matrix, while $\mathbf{B} \in \mathbb{R}^{N\times M}$, the control matrix, indicates the impact of input on the system. The sensor matrix $\mathbf{C} \in \mathbb{R}^{S\times N}$ and the direct term $\mathbf{D} \in \mathbb{R}^{S\times M}$ represent how much the output is influenced by the state and the input, respectively. A system is defined as controllable in N steps, if the matrix $\mathbf{W} = [\mathbf{B}, \mathbf{AB}, ..., \mathbf{A}^{N-1}\mathbf{B}]$ has rank N.

This criterion is valid only if we have a precise knowledge of the dynamics and control matrices, while in complex systems it is often difficult to estimate correctly all the entries of the matrix $\mathbf{A}$ and thus to establish whether the system is controllable or not.

Another important characteristic of a system is its observability. In other words, the ability to precisely identify the system position in the state space to correctly apply an input and bring it to the desired state. For a LTI system, we can state that the system is observable if and only if the dual system composed by $(\mathbf{A}^T, \mathbf{C}^T, \mathbf{B}^T)$, in place of $(\mathbf{A}, \mathbf{B}, \mathbf{C})$, is controllable, where T indicates the transpose of the matrix. Using this property, the observability criterion state that the system is observable if and only if the rank of the matrix $\mathbf{O} = [\mathbf{C}, \mathbf{CA}, ..., \mathbf{CA}^{N-1}]^T$ is equal to N.

In many applications, such as brain control, the system is not fully observable, but we can have access to a few state

variables that are sufficient to infer the state of the system. The brain, albeit it is a nonlinear system, at certain scales [2], can be viewed as a LTI system. System observability is then necessary to identify the model and the parameters of the system. The characterization of the system model is crucial in control theory and is defined as *system identification* [3]. The goal of system identification is to characterize the mathematical formulation of the dynamical system of interest, given the output of the system. The system models are often defined using a gray-scale naming, for example when the physical equations of the system are perfectly known we have a *white-box* model, while with a *black-box* model, we have no information about the equations of the system.

B. Control strategies

In *open-loop* control, the controller sends a stimulus to a system, which modifies its state or trajectory, but no feedback signal is provided back and because of this, the control stimulus should be designed in advance. In *closed-loop*, the controller stimulates the system and tries to adjust the stimulation to reach a final state based on the error between the desired and the current output and optionally by minimizing the costs (e.g., energy, time). The simplest form of closed-loop control is the (scalar) *on-off* control, which is formulated as:

$$u(t) = \begin{cases} u_{max}, & if \;\; e(t) > 0 \\ u_{min}, & if \;\; e(t) \leq 0 \end{cases} \tag{2}$$

The term $e(t)$ indicates the error between the current and the expected state, while u_{min} and u_{max} are arbitrary parameters of the controller. The *proportional-integral-derivative* (PID) controller is an improvement of the on-off controller, in which the input $u(t)$ is:

$$u(t) = k_p e(t) + k_i \int_0^t e(\tau) d(\tau) + k_d \dot{e}(t) \tag{3}$$

where k_p, k_i and k_d are parameters of the controller.

These strategies are used with good performance in industrial settings and do not necessitate a model of the system, but the control process is not optimal.

Optimal control can be used only when the model is known and the state is perfectly accessible. This strategy is used to reach the target state and minimize a designed cost function, at the same time [4].

Unfortunately, in real cases, optimal control assumptions are not always met. In these cases, a relaxation of these hypotheses can be beneficial to control complex systems. Control techniques that relax these assumptions are named *suboptimal control* and *adaptive control* [5]. Suboptimal control strategies approximate the cost function with one which has less complexity or a limited horizon. In adaptive control the parameters of the controller are updated continuously as the system evolves to cope with the expected system behaviour.

Learning-based control encompasses all the strategies that leverage on statistical learning to determine the system model and the control strategy. Two approaches are mainly used: *Bayesian control* and *Reinforcement Learning*. The first is based on the use of Gaussian Processes to maximize a given cost function and learn the model under Gaussian assumptions. The latter uses a trial-and-error paradigm to learn control rules while the model is assumed to be a Markov Decision Process.

III. Brain control

In the last years, the neuroscience community increased the interest in brain control paradigm thanks to the advances in reliable stimulation techniques and readout devices, as well as in algorithms to study brain signals [6].

These advances added evidence to the fact that stimulating the human brain makes possible to bring it to some safe or expected states, and thus to be controlled [2].

The vast majority of stimulation techniques encompasses all the approaches that perturb the current state of the human brain using electrical, optical or pharmacological stimuli [7]. The perturbation is caused by an external stimulus that operates directly on the brain. These techniques can be further classified based on the stimulus type (electric, magnetic, optic or pharmacologic), the spatial scale (cells, neurons or brain areas), the temporal scale (from minutes to microseconds), or on the invasiveness of the stimulation. Among these, Deep and Transcranial Brain Stimulation play a central role in closed-loop neuromodulation.

A. System identification for brain control

System identification is crucial in brain control to correctly recognize biomarkers which should be causally related to the trait we want to modulate. In many cases, assessing the brain-behavior relationship directly and causally is difficult, since it needs an accurate understanding of all the brain mechanisms involved and proper instruments to readout the biomarker.

The use of brain decoding techniques has shown great potential to investigate brain-behaviour relationship and shed light on the fine-grained differences in brain signals that are not detected using univariate analyses [8]. Decoding techniques use supervised (or unsupervised) machine learning models to automatically select the patterns of brain activity related to an experimental manipulation. This can be used to understand how the stimulation is related to the readout signal and how the brain states can influence the stimulation response.

B. Control properties of the brain

The brain is a network of communicating neurons that are organized to be efficient functionally and energetically. In this scenario, network control can be used to study the properties of brain system Specifically, at macroscale level, the brain can be hypothesized to be a LTI system (Eq. 1) [2] and thus, we can investigate its controllability properties to then target particular brain areas that allows to optimal control it.

The pioneering work made by Gu et al. [9] found the controllability properties of the brain, by modeling it as a LTI using brain fibers to define the matrix $\mathbf{A}$. They found that, the brain is controllable from a single node, but controlling

it is difficult due to the energetic cost to bring the brain in a desired state.

The controllability profile of epileptic patients has been studied by Scheid et al. [10]. They found that the temporal profile of optimal control energy to bring the brain in a safe state was minimal at the onset of the seizure. In addition, they found specific nodes that require less energy to suppress the seizure and drive the system into a safe state.

Studying brain properties with optimal control theory has great potential, but needs further studies for the application it in real scenario, given that some limitations have been recently debated [11].

C. Brain control using Deep Brain Stimulation

Deep Brain Stimulation (DBS) is a technique that uses the implanted lead-mounted electrodes into deeper brain structures to perturb the flow of information at ionic, cellular, protein and network level [12]. The same set of electrodes is used to identify the brain state.

Ferleger et al. [13] used closed-loop DBS to reduce the tremor in patient with tremor. Here, they used a linear discriminant classifier to identify the brain state and to trigger the stimulation accordingly. The classifier was trained using the bandpower of DBS and ECoG signals and detects when the subjects are in the rest state or in the tremor state.

Similarly, Scangos et al. [14] used a penalized logistic regression algorithm with feature selection to identify major depressive disorder traits and stimulate the ventral striatum. They used, after a system identification step, the gamma band amygdala activity to target the stimulation with an *on-off* controller.

D. Brain control using Transcranial Stimulation

Non-invasive brain stimulation techniques elicit a change in the brain functions by a perturbation performed outside the skull. The two most popular techniques are the transcranial electrical (tES) and magnetic stimulation (TMS). TMS uses a magnetic field to induce an electric current in the brain tissues, while tES devices produce an electric current flowing between two electrodes that can depolarize the neurons beneath the stimulated area. Here, several techniques can be used to read out the status of the system and trigger the stimulation such as EEG, MEG and EMG.

A real-time EEG-TMS experiment by Zrenner et al. [15] found a relationship between the phase of the mu-rhythm and the amplitude of the motor evoked potential. In particular, they used the negative peak of the C3-Hjorth signal to stimulate the motor area and elicit a higher motor evoked potential amplitude and vice versa. Then an on-off controller was implemented in a closed-loop experiment to demonstrate the long-term plasticity effect of the cortico-spinal excitability.

Tervo et al. [16] carried out a EEG-TMS experiment to optimize the orientation of the TMS stimulus. They found that the difference between P20 and N40 components was influenced by the orientation. Then, they used a Bayesian controller to optimize in real-time the coil orientation and maximize the P20-N40 amplitude in a short amount of stimulations.

E. Brain models for control

Another crucial step for brain control is testing and building brain models. A fundamental tool to model and control brain signals is machine learning, specifically though deep learning and reinforcement learning approaches. These techniques can be used to test cutting-edge control techniques before applying them in-vivo given their similarity with brain functioning.

Tafazoli et al. [17] used a convolutional neural network to simulate the model of the visual cortex and properly stimulated to elicit specific patterns. They also tested this approach, in four mice, finding that the proposed algorithm correctly provoked the targeted response.

In Krylov et al. [18] an approach based on Reinforcement Learning was used to suppress the oscillatory activity of a population of oscillators coupled using the Bonhoeffer-van der Pol and the Bursting Hindmarsh-Rose models. The reward was designed separately for each model and allowed to effectively suppress the activity of these oscillators, which can be applied in DBS scenarios.

Reinforcement Learning may be fundamental for brain control but there is the need to develop and study sophisticated brain models to unveil possible problems and to effectively target personalized stimulations.

IV. Future directions and limitations

A. Open brain control

Open science principles are fundamental to implement more sophisticated control strategies and to model the functioning of the human brain.

Sharing data of experiments is fundamental to effectively map the causal relationship between the stimulation and its effects to then predict the expected stimulation responses. The community has expressed their concerns on the reproducibility crisis and the need of sharing data, but very few datasets have been released so far [19].

In parallel, open-source platforms that deliver stimuli with precise time constraints are crucial. Several open-source platforms have been developed for these purposes, with a focus on closed-loop applications and timing constraints [20]. In this scenario, sharing open-source software increases the number of software developers that maintain and test these platforms.

B. Advances in neurostimulation techniques

The development of multi-coil TMS (mTMS) [21] can be revolutionary, since, currently, the TMS has several limitation: the brain cannot be stimulated in different locations in a short amount of time and the coil is fixed manually. The mTMS overcome these issues by adjusting the currents flowing in a set of properly arranged coils, in order to stimulate electronically different areas in a short amount of time. This technique can be disruptive in the brain control field given these possibilities and to probe the brain with innovative stimulation protocols.

The development of advanced closed-loop techniques with the possibility to stimulate the brain in multiple locations may be determinant to study the brain mechanisms at different temporal and spatial scales.

C. Limitations

A proper model of the brain is necessary for designing optimal control strategies and this process varies depending on the brain process to be modeled and the neurostimulation techniques used for this purpose.

Modeling techniques should consider the different temporal and spatial scales of brain functioning, but this is a limit from a technological point of view since recording and stimulation instruments are built for specific scales and this does not help scientists to build an effective model that can be used by control systems.

V. Conclusions

We introduced the mathematical aspects and algorithms of control theory applied to brain stimulation.

Control theory has developed a set of algorithms and techniques to solve specific industrial problems, and the increasing use of neurostimulation techniques has provided a fundamental tool to investigate the human brain. The combination of control theory and neurostimulation paved the way for the automatic control of the human brain.

The brain control approaches presented here use basic, but effective, control algorithms that rely on a solid identification of stimulus-response relationship. The combination of different techniques to stimulate and read brain signals may help to investigate the brain from different perspectives and at different temporal and spatial scales. Support for studying both control algorithms and the brain can come from simulation studies and models that helped to understand crucial properties as controllability under linear approximation.

Brain control theory will bolster neuroscience research by using cutting-edge techniques to stimulate the brain and provide a reliable causal relationship between intervention and effect, but also to reduce the burden of choices made by experimenters.

***Abstract*—Walking speed in real-life conditions is typically estimated through wearable inertial sensors mounted on waist, lower limbs, or wrists. Very recently, head-mounted inertial sensors are emerging for gait assessment. The present study explores the feasibility of measuring the stride speed with a head-mounted inertial sensor in both laboratory and real-world settings. The developed algorithm exploits a Temporal Convolutional Network for the detection of the gait events and a Gaussian Process Regression for the stride speed estimation. The experimental evaluation was carried out on healthy young participants during both standardised indoor and real-world walking trials. For indoor trials, errors were smaller than previous studies (0.05 m/s). As expected, errors increased at lower speed regimes due to a reduced signals amplitude. During 2.5-hours real-world evaluation, errors were slightly larger but acceptable (0.1 m/s). Reported results are encouraging and show the feasibility of estimating gait speed with a single head-worn inertial sensor.**

***Keywords*— machine learning, gait analysis, head IMU, gaussian process regression**

I. Introduction

GAIT is the main form of locomotion for human beings, and it is strictly related to the individual's quality of life [1]. For this reason, gait-related spatio-temporal parameters have been widely explored in both healthy and pathological cohorts [2]. Walking speed is particularly relevant in the assessment of mobility and it is an indicator of one's health status [3]. In the last decades, accelerometers and gyroscopes housed within a single Inertial Measurement Unit (IMU) have emerged as the election technology for the tracking of gait in the real-world, thanks to their wearability and affordability [1]. Multiple body-worn IMUs configurations for estimating walking speed have been extensively explored in literature [4]. Although multi-sensor configurations provide more accurate results, they are less likely to gain acceptance in customer-oriented solutions, as they are less easy to use and comfortable for the subject [5]. Therefore, research groups have started to focus on single-sensor configurations [5]. The most exploited body sites for the positioning of single sensors include wrist [6], foot [7], and waist [8]. However, current IMU-based solutions typically lack in aesthetics and ease of use, resulting in low user engagement [9]. Recently, the use of head-worn devices with IMUs started to spread due to the unique characteristics of this location [10] and its potential integration in smart-glasses for daily life use [9]. Some head- worn devices with inertial sensors have already been translated into commercial solutions and validated for walking speed estimation, such as the Recon Jet [11] smart glasses. Not surprisingly, the use of head-mounted IMUs (H-IMUs), and head-worn devices in general, is expected to grow in the healthcare sector [12]. Traditionally, IMU-based walking speed estimation methods include biomechanical models of gait, direct integration methods and machine learning techniques [2]. Human gait models and direct integration methods respectively suffer from lack of customisation and drift errors [2]; moreover, walking speed is derived indirectly by estimating time and distance. Instead, machine learning allows to directly infer the stride speed through a mapping between stride-specific features and the walking speed [11]. The purpose of the present study is the estimation of the stride speed from signals recorded by a single H-IMU. Foot-to-ground initial contacts (ICs) are estimated through a Temporal Convolutional Network (TCN) and used to segment the strides. Then, time and frequency-domain features are extracted from the stride acceleration norm and fed to a GPR model that outputs the stride speed. The models are trained using data recorded in indoor standardised conditions and tested on data not used for training recorded in both standardised and real-world conditions.

II. Materials and methods

A. Experimental setup

Each subject was equipped with the INertial module with DIstance sensors and Pressure insoles (INDIP) system [14] with the configuration shown in Fig. 1. For the purpose of this study, it included an H-IMU positioned on the left side of the head, in addition to the standard INDIP setup used as wearable reference system (three IMUs on right foot, left foot and lower back, two pressure insoles and two distance sensors). Each INDIP IMU contains a 3-D gyroscope (±2000 dps), a 3-D accelerometer (±16 g) and a 3-D magnetometer (±50 G, not used in this study).

B. Experimental protocol

The experimental protocol included: i) a standardised indoor session comprising two motor tasks (12m-straight walk and double-ring walk, Fig. 2), each performed at different speeds (slow, comfortable, and fast) and repeated thrice, for a total of 12 trials; ii) a 2.5-hour unsupervised real-world acquisition in which the participants were asked to follow their daily life routine. All the INDIP sensors, sampling at 100 Hz, were synchronised before each acquisition by setting the timestamp of each unit. Data acquired during the standardised indoor session and the 2.5-hour real-world acquisitions will be referred to as the "standardised" and the "real-world" datasets, respectively.

C. Participants

Data were collected on fourteen young healthy adults (YHA) (6 females, age: 25 ± 3 years, height: 1.73 ± 0.08 m,

weight: 65 ± 10 kg). All participants provided written informed consent before taking part to the study. Of the 14 participants recruited, 11 participated to the standardised indoor session, while the remaining 3 performed the 2.5-hour real-world acquisition.

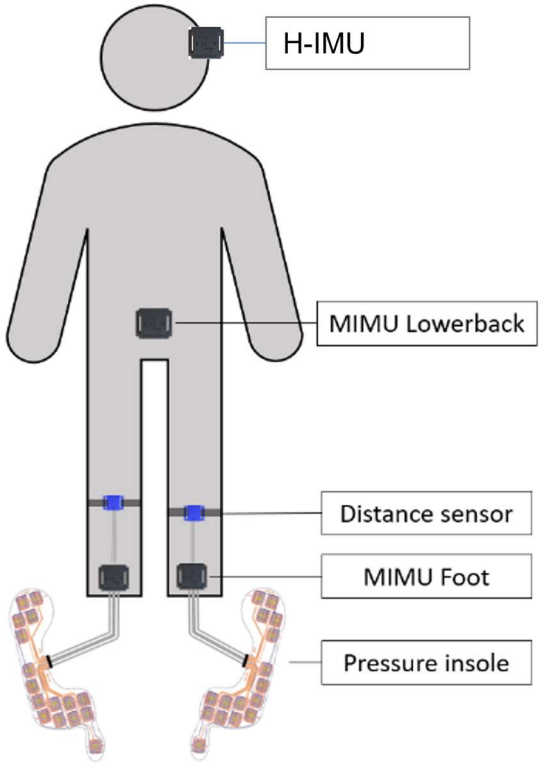

Fig. 1: The INDIP setup. IMUs and distance sensors are firmly attached to the body through Velcro bands to prevent any slippery o motion artifact.

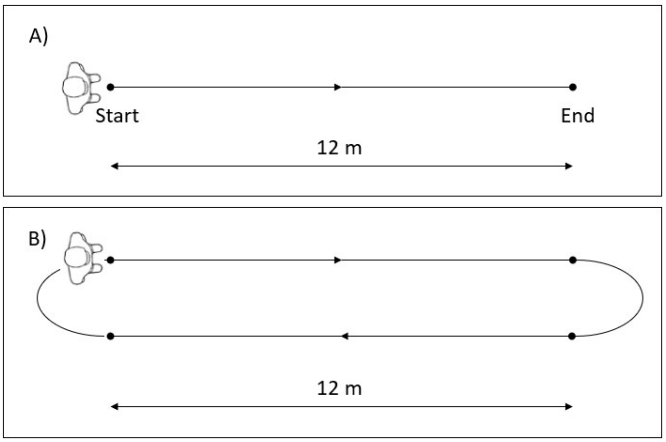

Fig. 2: Walking paths for the standardized acquisitions. A) Straight walk; B) "Double-ring" walk.

D. H-IMU algorithm

The estimation of the stride speed requires the previous segmentation of the stride. Therefore, the work was outlined as a two-tasks process:

i. Gait events detection
ii. Speed estimation

The gait events detection task was thought as a sequence classification task and was performed through a TCN [15], while the speed estimation task was organised as a regression task and was performed through a GPR model [11].

1) Pre-processing: H-IMU signals were virtually aligned to the direction of gravity, so that the x, y and z components of 3-D acceleration and angular rate were considered as parallel to the anteroposterior (AP), vertical (V) and mediolateral (ML) directions, respectively (Fig. 3).

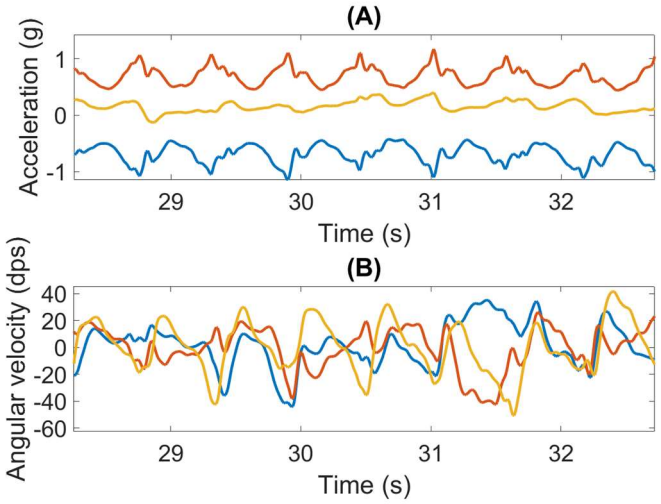

Fig. 3: A) Acceleration and B) angular velocity over four strides during a trial of standardized straight walking at comfortable speed. Acceleration is rotated with respect to gravity. Red: V component; Yellow: ML component; Blue: AP component.

2) *Gait events detection*: Norms of 3-D acceleration and angular rate were computed (Eq. 1).

$$a_n = \sqrt{{a_v}^2 + {a_{ml}}^2 + {a_{ap}}^2} \quad \omega_n = \sqrt{{\omega_v}^2 + {\omega_{ml}}^2 + {\omega_{ap}}^2} \qquad (1)$$

The six acceleration and angular rate components plus their norms were smoothed with a 5-points moving average filter and passed as predictors to a TCN. The network response was a binary signal of 0s and 1s with the same number of samples of the input sequence, with 0 denoting the double support phase (DS: both feet in contact with the ground, ~ 60% of the gait cycle) and 1 denoting the single support phase (SS: only right or left foot in contact with the ground, ~ 40% of the gait cycle). Portions of non-walking signals were ignored.

3) *Stride segmentation*: The ICs were detected at the falling edges of the network binary output i.e. at the end of the SS phases. Strides were determined as the time intervals between two ICs of the same foot. Since the TCN did not make a distinction between right and left SS phases, left and right ICs were not distinguished; however, the succession was preserved by picking adjacent ICs with a step of two.

4) *Stride speed estimation*: The raw acceleration norm of the segmented stride was filtered with a 4th-order Butterworth low pass filter with cut-off frequency of 5 Hz. A set of 134 features in the time and frequency domains were derived from the filtered norm and passed - together with height and weight of the subject - as input predictors to a GPR model (Table I). The decision regarding the number and typology of the input features was performed according to previous similar studies [11].

TABLE I: FEATURES FOR STRIDE SPEED PREDICTION

Domain	*Parameter*	*Definition*
Time (6)	Median	[g]
	Mode	[g]
	Signal Magnitude Area (SMA)	$\sum_{i=1}^{N}\lvert a_i\rvert$ [g]
	Energy	$\sum_{i=1}^{N}(a_i)^2$ [g^2]
	Zero-crossing rate	-
	Mean Absolute Value (MAV)	$\frac{1}{N}\sum_{i=1}^{N}\lvert a_i\rvert$ [g]
Frequency (128)	FFT coefficients	$\left\lvert\sum_{i=1}^{N} a_i e^{\frac{2\pi i}{N}(i-1)(k-1)}\right\rvert$ [g]
Anthro (2)	Weight	[kg]
	Height	[cm]

Features used by the GPR model to predict the stride speed. *Frequency (128)*: magnitudes of the 128 coefficients of the Fast Fourier transform (FFT). *g*: norm of gravity acceleration (9.81 m/s^2); *a*: samples of the acceleration norm for the current stride; *N*: number of samples of a; *Anthro*: anthropometric.

E. Training and testing

Both the TCN and the GPR models were trained with data of the standardised dataset (11 out of 14 participants). Data from participants 1-10 (construction set) were aggregated and used to train the models, while data from participant 11 (standardised test set) were used only for testing the trained architecture at the end of training. The TCN architecture included four residual blocks, a dilation base of 2, 64 filters of size 5 and a drop-out factor of 0.005. The TCN layer was followed by a fully connected layer, a SoftMax layer and a classification layer. The TCN was trained with a hold-out cross-validation scheme. The construction set was randomly split into a training set (TRS) of 7 subjects (for network training) and a validation set (VS) of 3 subjects (to evaluate the network performance and prevent overfitting) for five times. The network was trained for each of the five TRS-VS combinations for 60 epochs with the ADAM learning rule. Eventually, the network with the best performance overall was selected. At training stage, a label "0" was associated to samples in the DS phase, while a label "1" was associated to samples in the SS phase. To determine the beginning and the end of the DS and SS phases at training stage, gait events estimated by the INDIP reference system were exploited. The performance of the best TCN was evaluated on data of subjects not used for training, *i.e.* participant 11 of the standardised dataset and on the real-world dataset (3 out of 14 participants). The GPR model was trained according to a 5-fold cross-validation scheme on the construction set. At training stage, the GPR model was fed with 136 stride-derived features (predictors) and the reference value of the stride speed (target response) estimated by the INDIP system. At training stage, subjects' anthropometric features were used as constant predictors for their respective strides. An exponential kernel was selected for the GPR model basing on previous studies [11]. Performance of the best GPR model was evaluated on the standardised test set and on the real-world dataset.

F. Data analysis

Stride speed values predicted by the H-IMU algorithm were compared to the ones estimated by the INDIP reference system, that leverages validated algorithms [13] to predict gait parameters and events from data recorded by the pressure insoles and the IMUs (except the H-IMU). The adopted metrics for the method evaluation included mean absolute error (MAE), mean squared error (MSE), root mean squared error (RMSE), coefficient of adjusted determination (adR2) and Pearson index of correlation (ρ). Predicted and target response values were divided into three groups according to speed regime with two thresholds at 1 m/s and 1.5 m/s. Absolute percentage error was computed for each observation; then, errors out of the range [25th-percentile - 1.5 IQR; 75th-percentile + 1.5 IQR] were classified as outliers and discarded. A Shapiro-Wilk test was used to test the normality of the distribution. Then, as the distribution resulted to be non-normal, Wilcoxon ranked sum test was performed against the alternative hypothesis that the population mean of the slow-speed regime error distribution is greater than the population mean of the medium-and-fast-speed regimes error distribution. The significance level of the statistical test was set to 0.05.

III. RESULTS

Gait events, used to segment the strides, were detected by the TCN with a MAE of 0.05 ± 0.04 s on the test set and 0.02 ± 0.02 s on the training set.

Table II shows the results obtained from the comparison of the H-IMU algorithm with the reference system on the standardised dataset. Fig. 4 and 5 show the distributions of the absolute percentage errors for three speed regimes in the standardized construction set and test set, respectively. In both cases, the alternative hypothesis (Section II-F) was accepted at the specified significance level (p-value < 0.001). Table III shows the results obtained by the algorithm on the real-world dataset.

TABLE II: RESULTS ON STANDARDIZED DATASET

RW	26498	0.1 (9.2 %)	0.12	0.13	0.80	0.37

RW: Real-world dataset.

IV. DISCUSSION

As shown in Table. II, a strong correlation exists between the predicted and the actual stride speed values for the standardised walking trials (ρ = 0.97). The fact that adR^2 is significantly lower than ρ suggests that some features have small contribution to the prediction output; therefore, dimensionality reduction methods shall be employed. The TCN-GPR-based algorithm has obtained a MAE of 0.05 m/s (4.7 %) on the standardised walking trials. Previous studies based on a single H-IMU for the estimation of the stride speed [11] have obtained higher errors in standardised conditions (6.5 %). As expected, significantly greater errors (p-value < 0.001) were found at lower speed regimes (MAE = 3.3±3.0% for medium and fast speed regime, MAE = 8.0±13.0% for slow speed regimes) due to smaller signals amplitude. This also suggests that the slow speed walking patterns of the participants are remarkably different than the medium and fast walking patterns. In real-world conditions, gait features show greater variability. As a result, correlation indices decrease, as shown in Table III (ρ = 0.80). The reported error (RMSE = 0.1 m/s) was equal to the one obtained by [6] through a single wrist-IMU (RMSE = 0.1 m/s). In the present study, the impact of gait events detection errors on the estimation of the stride speed was not investigated. However, MAE values obtained by the TCN were considerably low and in line with what achieved in other studies [15].

V. CONCLUSION

In this study, feasibility of walking speed estimation based on a head-mounted IMU using a TCN-GPR-based algorithm is investigated. TCN and GPR models were trained with the data acquired from 10 young healthy adults during standardised walking trials. Performance of the model was evaluated for both standardised and real-world walking trials. Results showed that the algorithm can estimate the stride speed in standardised conditions with lower errors with respect to other IMU-based methods. Nevertheless, accuracy of the method decreases at lower speed regimes. The algorithm also showed good generalisation skill on data acquired in real-world conditions. However, training of the algorithm with data acquired in real-world settings is suggested to increase accuracy. An approach based on a single H-IMU may be successful for many applications of fitness and health monitoring; however, it also comes with some limitations, as the upper the sensor location, the harder the extraction of gait features [16]. In the future, further aspects related to the implementation of models for the estimation of the stride speed should be addressed, such as dimensionality reduction, hyperparameters tuning, dataset completeness and eventually validation on pathological patients, where a machine learning-based approach may be effective for seizing the underlying features of abnormal walking patterns.

***Abstract*— In the present study, we analysed EEG signals acquired during the execution of a visuomotor task with the right and the left hands in a group of young right-handed volunteers. The main aim was to assess differences in brain network organizations supporting movements with the dominant and non-dominant arms with respect to the resting period.**

Specifically, variations in the power content and network topology were explored in the subjective mu band with respect to a baseline condition. Our results showed that, although similar variations are observed in the power content during the movement with both hands, the motor tasks executed with the dominant hand are associated to an enhanced network reorganization with respect to the baseline condition. Conversely, the movement with the non-dominant arm was not associated to significant network reorganization. These findings are a further step towards the quantification of cortical effects related to motor training or motor rehabilitation techniques.

***Keywords*—Visuomotor task, EEG, brain, connectivity, handedness**

I. Introduction

It has been largely demonstrated in the literature that motor execution is a cognitive function that involves distributed brain areas [1]. Several studies demonstrated that, for example, besides the sensorimotor areas, also frontoparietal networks are involved in visuo-motor tasks to accomplish functions related to visual information processing and motor planning [2].

The main idea is that such a cognitive function is supported by the dynamical reorganization of brain networks consisting of the inhibition of unnecessary networks and maintenance of important ones [3], [4].These mechanisms are associated to the ability of the brain in optimizing its functioning, limiting the adopted resources. For this reason, different studies in the recent years aimed to describe these changes in distributed brain networks functioning by studying the effective and functional connectivity, mainly based on EEG and fMRI brain imaging techniques [4]. Literature evidence also showed how, the operation of brain functional networks during motor tasks could change in relation to health conditions, type of task executed and task difficulty[5], [6].

It is reasonable to speculate that even the execution of movements with the dominant and the non-dominant parts of the body could be supported by different network organization. Movement dominance consists, indeed, of the discrepancy in motor abilities performed with the two sides of the body, which depends on genetics and experience. We can reasonably hypothesize this difference in motor ability could be also accompanied to a difference in the efficiency of brain networks reorganization.

What is known from literature is that the execution of a movement with one side of the body is generally associated to a stronger activation of the contralateral sensorimotor areas. From an electrophysiological point of view, it has been shown that an event-related desynchronization (ERD) in the mu band occurs, and it is particularly enhanced in the contralateral sensorimotor cortex [7]. This reduction in power could therefore be associated to the activation and deactivation of more or less useful brain networks, respectively. Nevertheless, spectral analysis is not sufficient to describe such network reorganization and discriminate brain functional optimization processes occurring in different conditions.

Understanding the brain circuits related to such differences in motor abilities could lead to methods for the optimization of motor training and rehabilitation approaches. For example, the identification of brain functional changes induced by experience and motor training, both in healthy conditions and in neurorehabilitation frameworks could improve our knowledge in this context.

Even if some studies suggested that a different functional reorganization occurs for movements with the dominant and the non-dominant hands [8], the underlying mechanisms are still not completely understood.

In the present study, therefore, changes in brain rhythms and connectivity that occur passing from a resting condition (eyes open) to the execution of a visuo-integration motor task with the right and the left hands are explored. To the best of our knowledge, it is the first time that such a study is performed on continuous EEG data and on a comparable numerosity of the sample size.

II. Materials and methods

A. Experimental protocol and setup

EEG traces were recorded with the SD LTM 64 express recording system by Micromed (Mogliano Veneto, Italy) and sampled at 1024 Hz. Specifically, an EEG cap equipped with 61 channels placed according the international 10-20 system was, and with reference electrode placed between Pz and Cpz, was adopted.

The experimental protocol foresaw the acquisition during one minute at rest with eyes closed, one minute at rest with eyes open, two trials with the right hand and two trials with the left hand of the Nine Hole Peg Test (NHPT) [9].

For the analysis, the EEG signals acquired during the fastest execution were considered, for both the right and the left hands. Moreover, the eyes open phase was selected as baseline, given its higher similarity to the task execution.

B. Subjects

Data was acquired on a group of 44 healthy right-handed subjects (23 males, 21 females, mean age 23.3, std 2.48). All volunteers signed an informed consent, and their personal data was anonymized.
The protocol was approved by the Internal Ethical Committee of Humanitas Hospital.

C. EEG signal pre-processing

As a first step, a zero-phase pass band filter in the 1-45 Hz frequency range was applied on the raw EEG signals, and a consecutive downsampling to 256 Hz was performed.
Artefactual sources (e.g., eye blinks and muscular noise) were detected and removed by means of Independent Component Analysis (ICA).
Clean EEG signals were finally re-referenced to the common average.

D. Spectral analysis

The power variation induced by the execution of the NHPT hand with respect to the resting phase with eyes open was computed for both the dominant and non-dominant hands as follows (1):

$$P_{var} = \frac{P_{mt} - P_{rest}}{P_{rest}} \quad (1)$$

Where P_{mt} is the power content in a specific frequency band during the motor task, while P_{rest} is the power content in the same frequency band observed during the central 20 seconds of the baseline phase with eyes open.
For the present study, P_{var} was computed in the subjective mu frequency band, since this rhythm is involved in sensorimotor cortical processes.
Individual mu frequency was extracted starting from the EEG traces acquired during the baseline with eyes open on C3 and C4 electrodes, which are placed on the motor cortex. Specifically, the central mu frequency (muC) was identified as the mean between the two frequency values at which a peak in the power spectrum of C3 and C4 occurred in the frequency range 7-13 Hz. Afterwards, the individual mu (iMu) band was identified as the frequency range (muC-1Hz - muC+1Hz).

E. Connectivity analysis

Pairwise effective connectivity (EC) was studied by means of the Phase Slope Index (PSI) [10]. This index was chosen for its straightforward interpretability and for its robustness against volume conduction.

Specifically, the PSI is derived from the imaginary part I(·) of the complex coherence between two EEG channels i and j (C_{ij}) in a specific frequency band F according to equation (2).

$$\tilde{\psi}_{ij} = I(\sum_{f \in F} C_{ij}^{*}(f) C_{ij}(f + \delta f)) \quad (2)$$

C_{ij} was computed on non-overlapping windows of 1 second, resulting in a frequency resolution δf of 1 Hz.
As a result, an antisymmetric PSI matrix is extracted. If the directionality of information goes from rows to columns (i.e., from i to j) the PSI will be positive, while it will assume negative values otherwise.
The connectivity analysis was focused iMu frequency band.

F. Graph analysis

Graph analysis was performed by treating each EEG channel as a node in the graph, and the connectivity measure as the links between the nodes. This was done after a preliminary transformation process of the obtained PSI matrices: firstly, the non-significant connections were detected by means of a surrogation test [11] and set to zero; then, negative values were removed from the significant connectivity matrix in order to ignore redundant information and, finally, a matrix binarization was performed.
The Brain Connectivity toolbox (BCT) was used to compute the clustering coefficient (CC), the global efficiency (GE) and the Degree (D) on the transformed connectivity matrices [12]. Where, CC is a measure of network segregation and it is computed for each node, while GE is a measure of integration of the network as a whole. D count, instead, the total number of connections for each node of the network.

G. Statistical analysis

In order to assess differences of P_{var} between the righ-hand movement and the left-hand movement conditions, a Wilcoxon signed rank test was performed for each brain area listed in TABLE I. Differences in the graph measures among the three conditions of baseline, right-hand movement and left-hand movement, a Friedman's test with post-hoc Bonferroni correction was performed for each extracted metric. Specifically, CC and D measures were averaged within the four main brain areas listed in **TABLE I**. A separate test was performed for each area.
Concerning GE, a single statistical Friedman test was performed, since it provides a unique measure for the whole network.
Differences are considered statistically significant if associated to $p<0.05$.

TABLE I: BRAIN REGIONS OF INTEREST AND THE ASSOCIATED EEG CHANNELS

Brain area	*Electrodes*
Frontal	Fp1, Fp2, Fpz, AF7, AF3, AFz, AF4, AF8, F7, F5, F3, F1, Fz, F2, F4, F6, F8
Central	FC3, FC1, FCz, FC2, FC4, C5, C3, C1, Cz, C2, C4, C6, CP3, CP1, CPz, CP4, CP6
Parietal	P5, P3, P1, Pz, P2, P4, P6, PO7, PO8
Occipital	POz, O1, Oz, O2

III. RESULTS AND DISCUSSION

A. Spectral analysis

Fig. 1 shows the median topographical maps of P_{var} in the iMu band, both for the right and left-hand movements. As we expected, a power reduction, particularly enhanced on central areas, occurs for both conditions. Indeed, the execution of motor tasks triggers an event related desynchronization (i.e., a power reduction) in the mu band on cortical areas associated to the sensorimotor cortex [13]. The presence of both an ipsilateral and contralateral power reduction is justified by the length of the motor task.
Indeed, volunteers required on average about 20 seconds to execute the NHPT, therefore both the early desynchronization

of the contralateral cortex and the delayed desynchronization of the ipsilateral one were detected [13]. The Wilcoxon signed rank test revealed that no significant differences occur in iMu desynchronization between the movement executed with the dominant and the non-dominant hand, whatever the brain region considered. Given the simplicity of the motor task executed, a similar desynchronization in both conditions could be expected. Such a result suggests that spectral analysis could be not sufficient to discriminate possible differences in network functioning for the movement with the dominant and non-dominant hand.

B. Graph analysis

Results of the statistical analysis are reported in TABLE II. As can be observed in Fig. 2, a significantly lower GE was measured in the iMu during the right-hand movement with respect to both the baseline phase and the left-hand movement. Statistical analysis also revealed that the CC was always significantly lower during the dominant hand movement with respect to the resting condition in all brain areas, but in the occipital one. The left-hand movement, instead, differed significantly from the baseline condition only in the frontal and occipital area (Fig. 3).

D always showed a significant decrease with respect to the baseline condition during the right-hand movement. Interestingly, in the central area, associated to the motor cortex, a significant difference is also detected between the right and the left-hand movement Fig. 4.

Since the mu rhythm is associated to an idling state of the brain, it is reasonable to speculate that a motor task, beside a reduction of its power contribution, could also elicit a reduction in the number of connections (i.e., lower D), in the brain organization in functional subnetworks (i.e., lower CC) and in the ability to connect remote brain areas (i.e., lower GE). The significant decrease of CC and D observed in the frontal region during the left-hand movement could be associated to a comparable involvement of the attentional brain area during both the movement with the dominant and the non-dominant arm. Moreover, occipital CC decreases significantly only during the left-hand task: this result could be explained with a higher need to process visual input information to accomplish a motor task with the less able part of the body. These results could suggest that, in healthy conditions, a different strategy of brain networks reorganization in the iMu band is adopted for the dominant hand and non-dominant hand movement execution. Specifically, we can hypothesize that the movement of the left-hand is accompanied with a stronger involvement of the attentive and visual areas, in order to compensate a less pronounced activation of central and parietal regions, generally associated to the sensorimotor and motor planning brain areas.

IV. Conclusion

The present work had the purpose of evaluating if some differences in the brain mechanisms supporting motor tasks executed with the dominant and non-dominant hands exist in healthy conditions.

Spectral analysis showed that, during the NHPT, comparable event related desynchronizations are observed in the subjective mu band for the two conditions. This result suggests that power analysis of EEG signals is not sufficient to highlight differences in brain mechanisms associated to arm dominance, especially considering healthy volunteers and a simple motor task, such as the NHPT.

Connectivity and graph analysis, instead, revealed that dominant and non-dominant motor tasks are associated to different network reorganization processes in the iMu band. Specifically, despite the left-hand movement shows similar connectivity trends, only the right-hand movement showed a significant reduction in network integration, segregation and degree with respect to the baseline condition in almost all the brain areas considered.

A possible explanation could be associated to a different strategy for the allocation of brain resources depending on task demands, consisting of the activation of important brain networks for the execution of the motor task. These first results could lead to the identification of metrics for the quantification of the effects of motor training in healthy conditions and for rehabilitative purposes.

As a future step, we foresee to extend the analysis also to other relevant EEG rhythms. Moreover, the effect of a motor training period on the brain network reorganization will be analysed for the dominant and the non-dominant hands movements in the same group of healthy volunteers.

***Abstract*—Gait analysis has been widely adopted to describe Parkinson's disease (PD) dysfunctions. Nevertheless, only few efforts were made to investigate the role of muscle activity by surface-electromyography (sEMG). The current study aims to provide a quantification of muscle recruitment during walking in people with PD through the assessment of the sEMG-based occurrence frequency (OF). To this aim, sEMG signals from Tibialis Anterior (TA), Gastrocnemius Lateralis (GL), Rectus Femoris (RF), and Biceps Femoris (BF) of 20 people with PD and 10 age-matched healthy controls (HC) were acquired during walking. sEMG signals were processed to assess muscle-activation intervals and then the associate OF, i.e., the percentage of strides of each specific muscle activation occurrence. This OF-based analysis allowed to detect in people with PD an over-recruitment of proximal-leg muscles in the first half of stance. An impairment in muscle recruitment of proximal leg in the preparation of the transition between stance and of distal leg throughout the swing phase is also observed. The current approach provides a compact and synthetic representation of muscle recruitment alteration in PD which could turn out to be particularly suitable for application in clinics and rehabilitation.**

***Keywords*—surface electromyography, continuous wavelet transform, Parkinson's disease, clinical gait analysis.**

I. Introduction

THE number of people affected by Parkinson's disease (PD) across the world is expected to reach 17 million by the year 2040 as a consequence of the changes in aging, longevity, smoking rates, and industrialization [1]. PD is a neurodegenerative disorder associated with a deficiency of both the dopaminergic neurons located in the substantia nigra of the brain and the cells located in other regions of the neural network [2] which contributes to the arousal of motor signs affecting people with PD quality of life (e.g., bradykinesia, resting tremor, rigidity, and postural instability) [3]. Clinical gait and postural analysis have been frequently adopted to quantitatively assess the motor disorders associated with this pathology [4]. Among the motor manifestations, an altered motor control has been revealed in PD individuals in comparison with healthy age-matched controls [5].

In the last decades, an extensive involvement of surface electromyography (sEMG) to investigate the locomotion strategies in PD has been exploited [6]. Some studies highlighted a lower sEMG activity in the distal muscles of people with PD when compared with healthy peers. Meanwhile a greater muscle activity was detected in correspondence of the proximal muscles during the swing phase [7]. Further studies used sEMG signals analysis to assess the mean regions of muscle activation during PD walking in time-frequency domain [8].

In addition, sEMG analysis allows to assess the occurrence frequency (OF), a parameter recently introduced to characterize the frequency of muscular recruitment during cyclic tasks [9]. This parameter has been successfully adopted to provide a novel point of view in the characterization of muscular recruitment in healthy adults [11,12] and children [13] and in the quantification of motor control alterations in neurological patients [14,15]. Preliminary attempts of computing OF in PD have been also reported [16]. However, this analysis was performed only on Tibialis Anterior and Gastrocnemius Medialis, and without validation versus control subjects. To the best of our knowledge, an OF-based characterization of PD muscle recruitment strategy is still lacking.

The present study aims to provide a quantification of muscle recruitment during walking in PD through the assessment of the sEMG-based occurrence frequency (OF). Specifically, OF is computed as a single parameter useful to monitor the occurrence of muscle recruitment of the lower-limb muscles in people with PD. To quantify the variations with respect to healthy controls in a single compact representation, ΔOF is computed as the point-by-point difference in OF values between the two populations in every percentage of gait cycle (GC). The main hypothesis of the study is that the two populations (PD vs. HC) would portray sensitive differences in their muscle ΔOF within the gait cycle with respect to the assessed muscles. For this purpose, sEMG signals of four lower-limb bilateral muscles of 20 people with PD and 10 control subjects have been analyzed and compared.

II. Material and Methods

A. Participants and signal acquisition

Twenty people with PD (age = 64.6 ± 10.5 years, height = 1.69 ± 0.17 m, mass = 78.3 ± 16.1 Kg) and 10 age and BMI matched healthy peers (HC, age = 62.3 ± 6.4 years, height = 1.69 ± 0.12 m, mass = 76.2 ± 15.7 Kg) were considered for the study after Local Ethic Committee approval (CE/PROG 61/16–19/11/2015) at Casa di Cura "Villa Margherita" (Arcugnano (VI), Italy). Participant were considered eligible for the study if the inclusion\exclusion criteria reported in [17] were respected. Data from a stereophotogrammetric system (6 cameras, 60 Hz, SMART-E, BTS Bioengineering s.r.l., Italy), two force plates (960Hz, Bertec Corporation, USA) and an 8-channels EMG system (1000 Hz, BTS Free 1000, BTS Bioengineering s.r.l., Italy) that collected the electrical activity of Rectus Femoris (RF), Biceps Femoris (BF), Gastrocnemius Lateralis (GL), Tibialis Anterior (TA) bilaterally were

acquired synchronously at the BioMovLab (Department of Information Engineering, Università degli Studi di Padova) during self-selected speed overground gait. Spherical retroreflective markers placed on the posterior calcaneus were used to identify contralateral heel strikes. Data were collected until at least three complete GC were collected bilaterally. Steps were considered valid for the processing when the right/left foot naturally landed on the force plate.

B. Signal processing

Raw sEMG signals were segmented into separated GCs: heel strike instant was considered as the first frame at which the modulus of ground reaction force detected by the force plate was greater than 5N; toe off was considered as the first frame at which the modulus of ground reaction force was less than 5N; the consequent heel strike was considered as the minimum of the vertical component of the marker trajectory placed on the ipsilateral calcaneus [18]. sEMG signals were filtered with a band-pass Butterworth filter (20-450 Hz, cut-off frequency). Muscle activation was computed by implementing the methodology based on Continuous Wavelet Transform introduced in [19].

Muscular activation was characterized at each percentage point of the GC by the occurrence frequency (OF), a recently introduced parameter [9,10] defined as

$$OF = \frac{N_{A_{GC}}}{N_{GC}} \times 100 \qquad (1)$$

where $N_{A_{GC}}$ is the number of GCs with activation and N_{GC} is the total number of GCs. Then a point-by-point difference were computed over the two population (HC or PD) for the assessed muscles, and defined as

$$\Delta OF = OF_{PD} - OF_{HC} \qquad (2)$$

where OF_{PD} is the OF presented in the specific percentage of the GC by the PD population and OF_{HC} is the OF presented in the specific percentage of the GC by the HC.

III. Results and Discussion

The present study is fulfilled analysing 109 strides for PD group and 47 strides for HC. The comparison between the different strategies of muscle recruitment identified in PD vs HC is achieved by considering the point-by-point difference in OF values between the two populations (ΔOF), computed in every percentage of gait cycle (GC%).

A. Proximal muscles

The comparative analysis of muscle recruitment in terms of ΔOF in RF muscle is depicted in the following Fig. 1. The positive values (ΔOF > 0) of green area, detected from 0% to 35% of GC, indicate a more frequent recruitment of RF muscle in PD compared to HC, in the first half of stance phase. On the contrary, negative values (ΔOF < 0) of green area are detected from 36% to the end of GC, suggesting a reduced frequency of RF muscle recruitment in people with PD compared to HC, in the second half of stance phase and all over the swing phase.

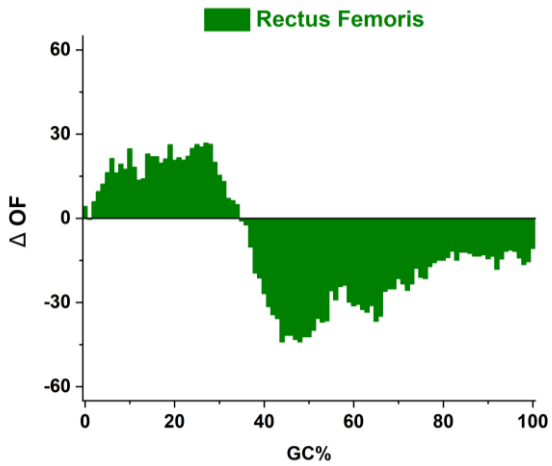

Fig. 1: Difference in occurrence frequency (ΔOF) of RF muscle recruitment during gait in PD population vs. HC population. Positive values of the green area indicate higher OF values in PD population compared to HC group. Negative values indicate lower OF values in PD population compared to HC group.

Fig. 2 shows as positive ΔOF values are detected from the beginning up to 15% of GC and from 91% to the end of GC (positive green area in Fig. 2). Otherwise, negative ΔOF values are detected in the central phases of GC, starting from 16% up to 90% of GC (negative green area in Fig. 2), except for some negligible positive values, mainly around the 80% of GC. This seems to suggest that people with PD are used to recruiting BF muscle more frequently than HC in the gait phase around the heel strike event.

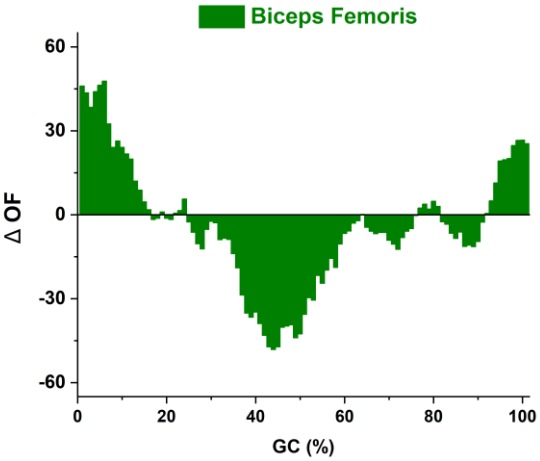

Fig. 2: Difference in occurrence frequency (ΔOF) of BF muscle recruitment detected during gait in PD population vs. Control population. Positive values of the green area indicate higher OF values in PD population compared to Control group.

Although the analysis of ΔOF for each single muscle reported in figures 1 and 2 is informative, the current study is designed to assess a further parameter useful to provide a compact description of the proximal-leg muscle recruitment in PD, i.e., the global ΔOF. This parameter represents the sum of the ΔOF computed for the RF and BF muscles. Results in function of the GC are displayed in light green in Fig. 3.

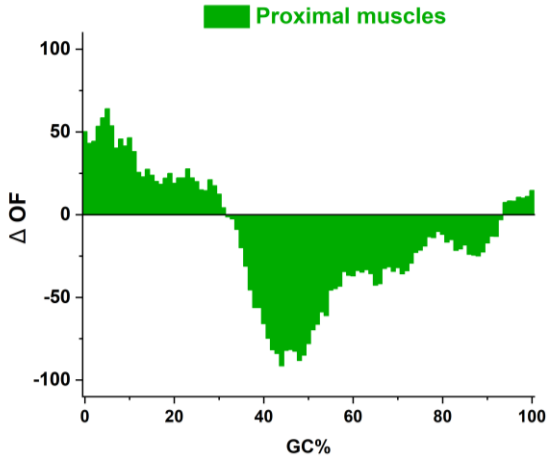

Fig. 3: Global difference in occurrence frequency (ΔOF) of proximal-leg muscle recruitment detected during gait in PD population vs. Control population. Positive values of the light green area indicate higher OF values in PD population compared to Control group.

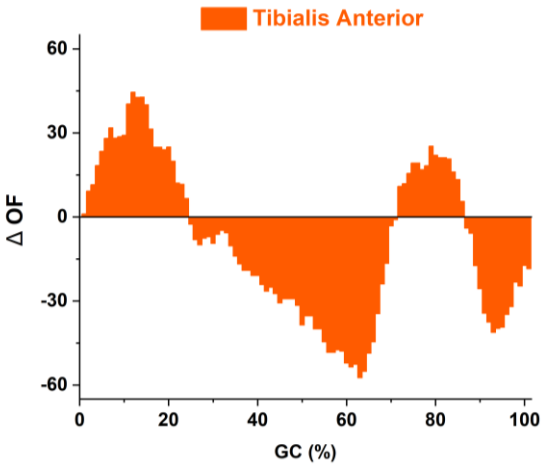

Fig. 4: Difference in occurrence frequency (ΔOF) of TA muscle recruitment detected during gait in PD population vs. Control population. Positive values of the orange area indicate higher OF values in PD population compared to Control group.

Positive values of the light green area are observed from the beginning up to 31% of GC and from 94% to the end of GC. Negative values are located in the central phases of GC, specifically from 32% to 93% of GC. Furthermore, a relevant negative peak of ΔOF is detected around the 40-60% of GC. Despite the agonist-antagonist nature of the two muscles, the concomitant evaluation of ΔOF in both proximal-leg muscles offered by Fig. 3 appears to be very appropriate to describe their recruitment in PD. Indeed, this single compact parameter allows to highlight an overall tendency of people with PD of over-recruiting the proximal-leg muscles from heel strike to loading response (≈ 0-30% of GC), compared to HC. This observation might be linked with both the loss of proprioception in the distal segments [20] and the typical camptocormic posture characterizing PD. Indeed, the bending of the trunk in a forward direction could have led towards the adoption of a hip strategy when walking [4]. Moreover, this compact representation permits also to notice as the employment of these muscles is impaired in people with PD in the preparation of the transition between stance and swing phases (≈ 40-60% of GC), which might be related with the lessen ability in shifting from double to single support [21]. The reduced range of motion on the sagittal plane of the hip joint displayed in people with PD [4] is highlighted by negative values of ΔOF in RF during the whole swing, where the muscle is not operating in its physiological range.

B. Distal muscles

The difference between PD and HC in the frequency of TA recruitment is quantified in Fig. 4 in terms of ΔOF. An alternance between two positive and two negative areas is clearly shown; specifically, a positive area from 0% to 23% of GC followed by a longer negative area from 24% to 70% of GC, covering all the stance phase. A further positive area from 71% to 85% of GC and a negative area from 86% to the end of GC cover the remaining of the swing phase. This positive-negative alternance of ΔOF impedes from identifying a clear trend in the recruitment of this muscle in people with PD.

Fig. 5 displays the trend of ΔOF between PD and HC in GL muscle. The positive area covers from 8% to 56% of GC, highlighting the adoption by people with PD of a more frequent recruitment of GL than HC during most of the stance phase. Otherwise, the negative area extends over all the swing phase up to the beginning of the following GC (from 57% of GC to the 8% of the successive GC), revealing a reduced frequency of GL muscle recruitment in people with PD compared to HC.

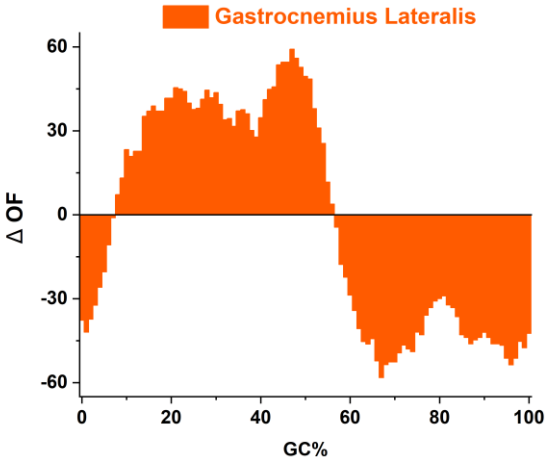

Fig. 5: Difference in occurrence frequency (ΔOF) of GL muscle recruitment detected during gait in PD population vs. Control population. Positive values of the orange area indicate higher OF values in PD population compared to Control group.

Since the approach adopting the global ΔOF turned out to be very suitable for the analysis of proximal-leg muscles, an attempt of characterizing muscle recruitment in PD by means of the same compact parameter has been made also for the distal-leg muscles (TA + GL). Results in function of the GC are displayed in Fig. 6. ΔOF assumes negative values all through the swing phase, characterized by two significant peaks around 65% and 95% of GC. Moreover, positive values of light orange area cover the most of stance from 5% up to 51% of GC. These results seem to suggest a reduced frequency

of distal-leg muscle recruitment during swing in PD people.

Compared with the promising results achieved for proximal-leg muscles, the only global ΔOF seems to be not as useful for the description of distal-leg muscle, because it tends to hide the behaviour of the single muscles highlighted by figures 4 and 5. Therefore, it has to be always interpreted together with the ΔOF analysis in the single muscle. In this case, it could really be supportive to the physiological interpretation, as for the analysis of Fig. 6 (together with figures 4 and 5) where the impaired employment during swing of distal-leg muscles detected in people with PD is mainly due to the GL muscle. This is probably associated with the altered motor control recurrent in people with PD [5]. The role of TA in this phenomenon needs to be further deepened.

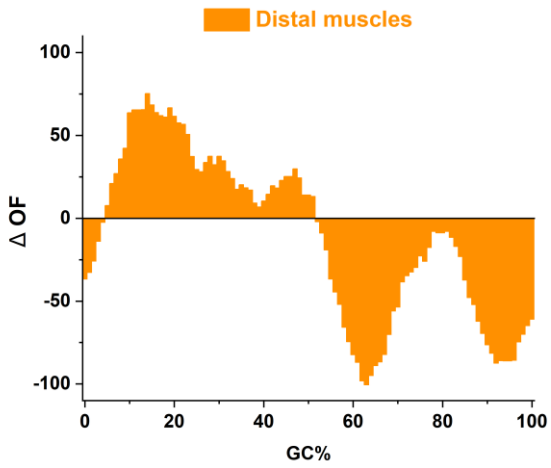

Fig. 6: Global difference in occurrence frequency (ΔOF) of distal-leg muscle recruitment detected during gait in PD population vs. Control population. Positive values of the light orange area indicate higher OF values in PD population compared to Control group.

IV. Conclusion

The main contribution of the study is to propose a novel approach for assessing the muscle-recruitment alteration in people with PD, based on the evaluation in PD of muscle occurrence frequency, OF, and its difference with a control population, ΔOF. Specifically, the point-by-point computation of ΔOF allowed to identify a PD-related tendency of over-recruiting the proximal-leg muscles in the first half of stance. ΔOF analysis highlighted also a PD-related impairment in recruiting proximal-leg muscles in the preparation of the transition between stance and of distal-leg muscles throughout the swing phase. The capability of providing a compact and synthetic representation of muscle recruitment alteration in PD makes this ΔOF-based approach particularly suitable for application in clinics and rehabilitation. Future developments will focus on comparison of present results with different classes of subjects and state of disease to further evaluate suitability and reliability of the proposed methodology.

***Abstract*—High quality dermoscopic images are a fundamental requirement for proper clinical evaluation and implementation of artificial intelligence (AI) methods. However, due to several factors that are challenging to control (e.g., the acquisition device, image compression, etc.), it is difficult to have images with a high quality standard available all the time. Therefore, a tool capable of enhancing image quality is required to make remote clinical assessment more reliable and to develop even better performing AI tools for classification and segmentation.**

In this work, we present a customized Generative Adversarial Network for super resolution that can successfully enhance the quality of dermoscopic images and double their resolution.

The enhanced images by the proposed method achieve an average PIQE (Perception based Image Quality Evaluator) score of 19.71, a 35.76% improvement over the low-resolution source images. Our method was also validated through a visual assessment performed by an AI expert and an experienced dermatologist. The enhanced images proved to be suitable for both AI applications and clinical evaluation.

***Keywords*— Dermatology, AI, Deep Networks, Generative Adversarial Networks, Skin Lesions, Image Quality, Super Resolution.**

I. Introduction

DIGITAL dermatological skin lesions are acquired through a high-resolution dermoscope under epiluminescence conditions and then digitalized. Acquisition and digitalization process is decisive to ensuring high-quality images. Image quality is an essential requirement both for clinical evaluations [1]-[4] (e.g., Teledermatology), and for the development of reliable and high-performance artificial intelligence (AI) based tools for classification and segmentation [5]-[8].

In remote dermatological services, it is essential that the images transmitted from the patient to the physician are of sufficiently high quality to make a truthful evaluation. However, image quality depends on several factors including device used by the patient, exposure conditions, and transmission protocols, some of which are difficult to control. At the same time, developing AI-based tools that can assist the dermatologist requires large amounts of high-quality data. Today several open access databases of dermoscopic images used for AI challenges contain a wide range of images from several centres, acquired and digitized with different devices and techniques. As a result, not all of them have the same quality/resolution and therefor do not meet the required quality standards.

In recent years, GANs have proven to be powerful tools that can improve image quality and resolution in healthcare and other fields [9]-[19].

In this study we successfully adapted a super-resolution GAN called RealESR-GAN [10] to enhance and double the resolution of dermoscopic images. Processed images obtained significant scores on full reference metrics and higher scores when comparing with low-resolution images.

Finally, an AI specialist (M.S.) and a dermatologist (P.S.) were involved in this study to evaluate the suitability of the images produced by our method for artificial intelligence and clinical applications, respectively.

II. Materials and methods

A. Dataset

Starting from a pool of 70000 dermoscopic images from ISIC Archive [20]-[21], we selected 18000 high-resolution images characterized by high sharpness, resolution higher than 1024x1024 and absence of invasive artifacts.

To reduce GAN overfitting and increase the heterogeneity of the dataset, a data augmentation pipeline was carried out to increase the number of training samples. This step was performed using *Albumentation library* [22]. The following transformations were applied with a 50% probability for each image: flipping, scaling, changes in contrast, brightness and gamma, grid distortion and elastic transformation. This results in 30000 high-resolution images of size 1024x1024 pixels.

The RealESR-GAN requires during training a paired dataset, consisting of high-resolution images and the corresponding low-resolution images. To obtain the low-resolution images, a two-grade degradation pipeline was implemented to simulate real-world degradations such as camera blur, sensor noise, low resolution and JPEG compression [24]. To create the synthetic low-resolution images, the high-resolution images have been sequentially subjected to:

- *Blurring*, by using a generalized Gaussian blur kernels that approximate real camera blur.
- *Noising*, adding Gaussian and Poisson noise. In particular, the Poisson one simulates the noise introduced by camera sensor.
- *Downsampling*, by using combinations of different interpolation algorithms (nearest-neighbour, bilinear, bicubic) in order to recreate a wider variety of artifacts.
- *JPEG compression*, with different compression factor.

Each step is controlled by hyper-parameters that change for each image with a given probability, so that deteriorations are always different. The entire degradation pipeline is repeated twice for each image. At the end we obtain 30000 low-resolution images of size 512x512 pixels, coupled with the corresponding high-resolution images.

Finally, about 10000 images from the starting pool that did

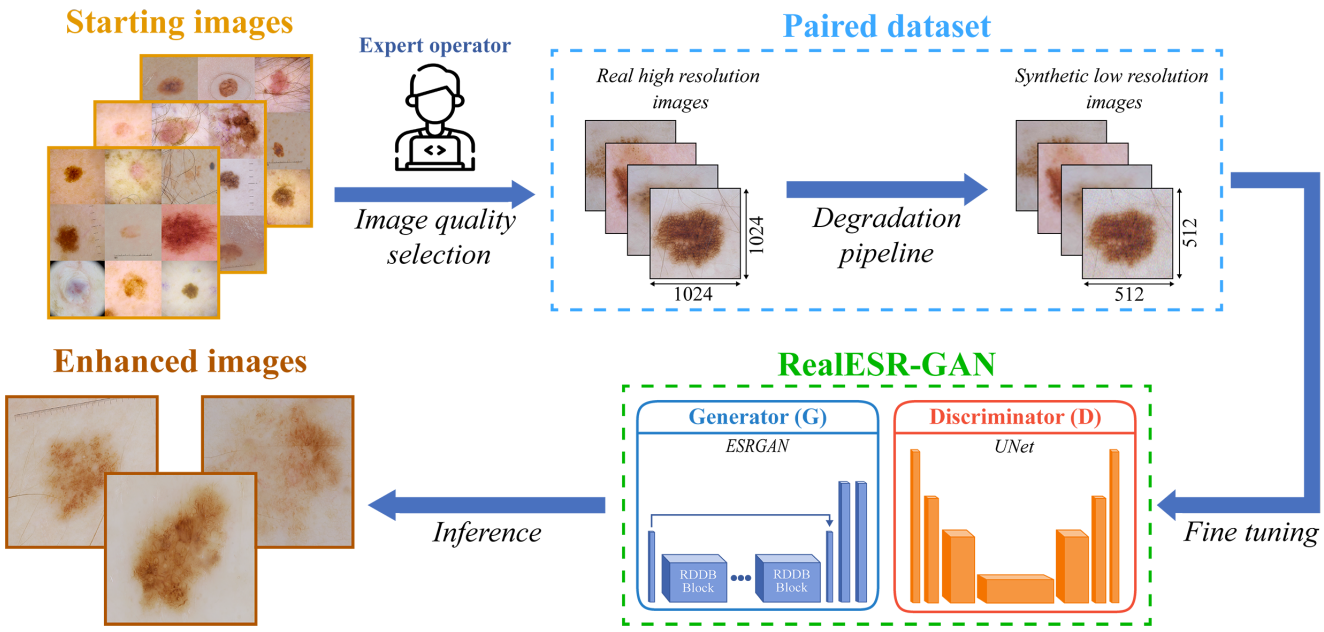

Fig. 1: Overview of the proposed pipeline.

not meet the quality requirements were used as a test set to evaluate the performance of the proposed method.

B. *Network architecture: Real-ESRGAN*

RealESR-GAN [10] is one of the most effective restoration model for real world images available today. For this reason, we chose this architecture to implement our quality enhancement task. The key features of this model are:

- A deep network generator with 23 residual-in-residual dense blocks (*RRDB*) capable of performing super resolution with a scaling factor of x2. In addition, there are no batch normalization layers, in order to reduce the generation of artifacts and increase the generalization capability of the entire network.
- A *U-Net* discriminator with skip connections and spectral normalization, able to soften oversharping artifacts introduced by GAN.
- A generator loss determined by the combination of perceptual loss, L1 loss and GAN loss, as in Eq. (1).

$$L_G = L_{percep} + \lambda L_{GAN} + \eta L_1 \qquad (1)$$

To adapt RealESR-GAN [10] to dermoscopic images, fine tuning was performed on a pre-trained model capable of super resolution with a factor of x2. The training phase was performed on a NVIDIA RTX 3090 24 GB using Pytorch framework.

Best model was chosen according to loss values. During inference, the trained model outputs an image with twice the resolution of that received as input. A complete overview of the entire pipeline (data preparation and model training) is provided in Figure 1.

C. *Evaluation metrics*

To assess the behaviour and effectiveness of the proposed method, a quantitative evaluation and a qualitative evaluate based on a visual assessment were carried out.

Performance metrics were calculated on the entire test set processed by our method. To evaluate the preservation of structural content, the following full-reference metrics were calculated between the source image and the image reconstructed by the model:

- *PSNR*, Peak Signal-to-Noise Ratio.
- *SSIM,* Structural Similarity Index Measure
- *FSIM,* Feature Similarity Index Measure.

In order to validate how well the model succeeds in enhancing image quality, the following non-reference metric was implemented:

- *PIQE*, Perception based Image Quality Evaluator, an opinion-unaware and unsupervised algorithm that provides a detailed analysis at a local level in addition to a global quality score [24]. A lower PIQE value indicates higher image quality.

All metrics are reported as mean ± standard deviation.

Qualitative visual assessment was carried out to understand how enhanced images are perceived by a human operator and to verify whether they were suitable for both AI-based methods development and clinical evaluation. For this purpose, 60 images with different quality levels (20 high-resolution images from the training set, 20 low-resolution images from the test set and 20 enhanced images generated from the test set) were submitted to an AI specialist skilled in dermatoscopic image analysis and a high experienced dermatologist.

III. Results

A. *Quantitative metrics*

Table I shows the full reference metrics calculated on the test set images processed by the proposed method. The processed images achieve an average PSNR value of 38.62 and SSIM and FSSIM values close to 1, indicating how the enhancement process preserved structures and patterns, without adding noise to the source images.

Table II shows a comparison between the original low-resolution images from the test set and the enhanced images. It is possible to see a percentage decrease in the PIQE value of 35.76%, indicating that the reconstructed images have higher quality than the originals.

TABLE I: FULL-REFERENCE METRIC

Metric	*Value*
PSNR	38.62 ± 2.27
SSIM	0.98 ± 0.01
FSSIM	0.98 ± 0.01

TABLE II: NO-REFERENCE METRIC

Metric	*Original images*	*Enhanced images*
PIQE	30.68 ± 8.02	19.71 ± 4.15

B. *Suitability assessment*

Figure 2 shows the results for the suitability assessment of images processed with our method.

Panel a. shows the scores assigned by the AI specialist. It is possible to observe that 85% of the enhanced low-resolution images are considered suitable for AI application, versus 5% for low-resolution images. The usability distribution of the enhanced images far exceeds that of low-resolution images, coming very close to that of high-resolution.

Figure 2b shows the assessment made by the expert dermatologist. Surprisingly, the enhanced images are considered more suitable for clinical evaluation than the original high-resolution images, 95% vs 45%, respectively.

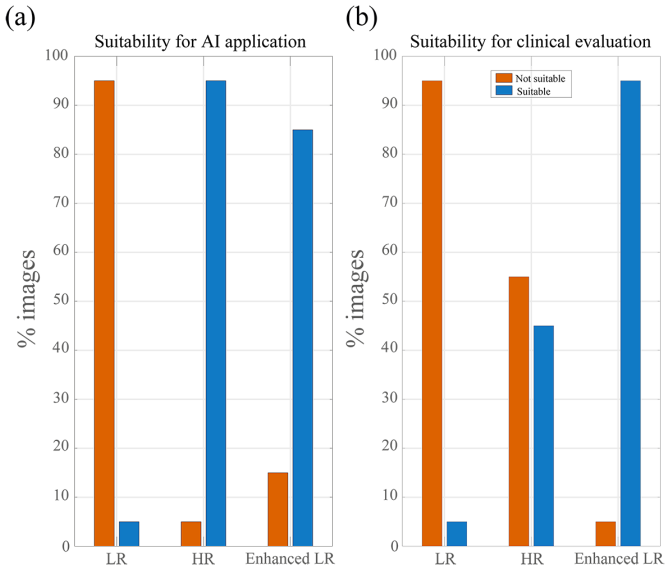

Fig. 2: Suitability assessment. Panel (a) reports the scores assigned by the AI expert, and Panel (b) those assigned by the dermatologist. LR indicates low-resolution images, HR high-resolution images, Enhanced LR the low-resolution images enhanced with our method.

IV. DISCUSSION AND CONCLUSIONS

In this paper, we propose a study on the application of one of the most powerful restoration models for quality enhancement of medical images. Specially, we implemented and customized the RealESR-GAN to increase the quality and the resolution of dermatoscopic images. The proposed strategy consists of three main steps:

- High-quality, sharped and artifact-free dermoscopic images selection from ISIC Archive [20]-[21].
- Degradation of high-resolution images to generate synthetic low-resolution versions that simulate realist artifacts, such as camera noise, blurring and JPEG compression.
- Fine tuning of RealESR-GAN [10] in order to realize a model that can double the resolution and enhance quality of input dermoscopic images.

To validate the proposed method, performance metrics were calculated on a test set of low-resolution images. It was observed that processed low-resolution images achieved an average PSNR value of 38.62, demonstrating how image reconstruction does not introduce noise to the original images. The enhancement process also preserved structures and patterns of the source images, as witnessed by SSIM and FSSIM mean values close to 1 (0.98 and 0.98, respectively). In addition, PIQE, a non-reference quality metric that mimics human visual perception [24], was calculated to quantify images quality for both low resolution and enhanced images. Reconstructed images obtained 35.76% lower PIQE mean value than the original images (19.71 vs 30.68, respectively), demonstrating how the proposed method succeeds in increasing image quality.

The behaviour of performance metrics, however, does not always reflect human perception. Sixty images of different quality and resolution were evaluated by an AI expert and an experienced dermatologist to test the suitability of enhanced images in AI and clinical evaluation.

From the perspective of the AI expert, 85% of the enhanced images would be suitable for AI application. The proposed method succeeds in increasing the number of suitable images by 80% compared to only 5% of low-resolution images. On the other hand, the experienced dermatologist perceived 95% of the enhanced images as suitable for clinical evaluation, with a 50% increase over high-resolution images and 90% over low-resolution images. This perception is probably explained by the fact that typical skin lesions patterns appear sharper and more defined, thus therefore easier to interpret. A comparison between low-resolution images and images enhanced by the proposed method is shown in Figure 3. It can be seen that out our method succeeds in greatly improving the definition of lesion textures definition and the overall sharpness of the image.

This study demonstrates how it is possible to successfully perform dermoscopic image enhancement by adapting an enhancing framework designed for non-healthcare applications. The produced images proved to be quantitatively better than the starting low-resolution images. Qualitatively, the proposed method can produce images that meet quality standard for both AI suitability and clinical assessment, with scores comparable with original high-resolution images.

Future development will focus on:

- Extension of the testing phase of the proposed method on different datasets.

- Further optimization and customization of the RealESR-GAN architecture.
- Implementation of the enhancement task through different models and architectures.
- Investigating the use of the enhancement tool as pre-processing step for classification and segmentation frameworks.

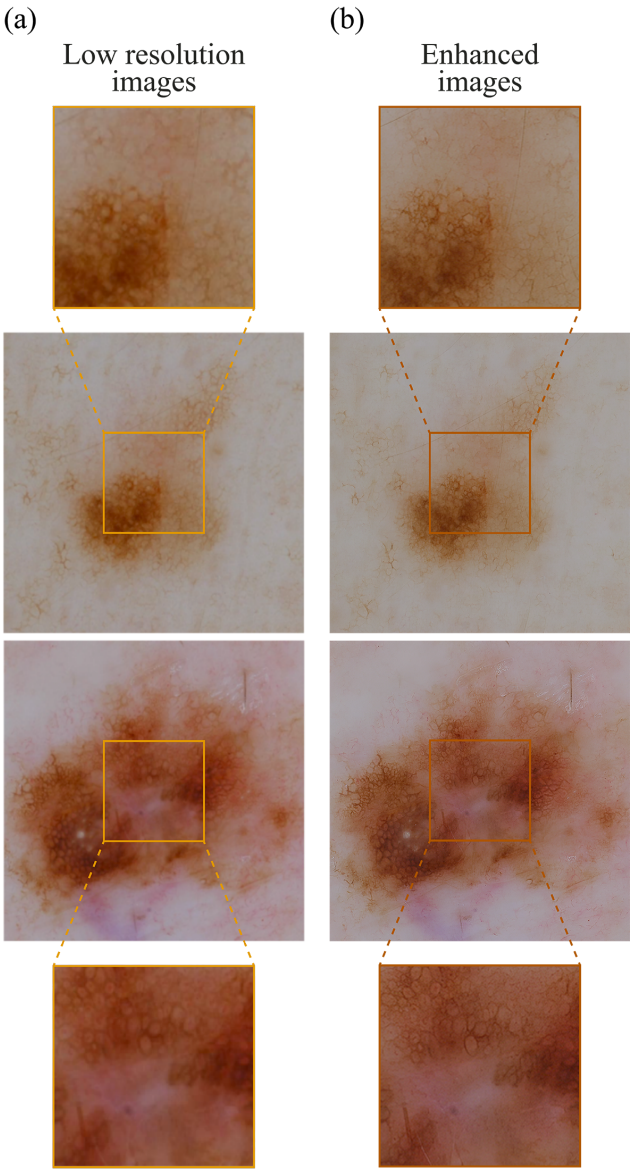

Fig. 3: Comparison between low resolution (a) and enhanced images (b). It can bee see that the proposed method succeeds in realistically enhancing low-resolution images, in detail it makes the lesion textures more sharped, preserving the macro structures.

***Abstract*— Prodromal stages of Neurodegenerative disorders represent an important phase of disease progression where novel therapeutic options might still be effective. Rapid-eye-movement sleep behaviour disorder (RBD is considered one of the principal prodromal conditions of synucleinopathies such as Parkinson's disease. In this longitudinal study, we aimed at quantifying the alterations of electroencephalographic (EEG) network-like metrics due to disease progression. Amplitude correlation and phase synchronization has been quantified using narrow-band high-density EEG recordings in 33 people with idiopathic RBD at distinct visits. We showed that phase synchrony and amplitude correlations are stronger in idiopathic RBD compared to age-matched healthy controls. A weaker amplitude correlation is linked to worst cognitive functions. Finally, our results show a significant (uncorrected) reduction of amplitude correlation but not phase synchronization over time with disease progression. Altogether these results represent additional evidence on the effects of disease progression in idiopathic RBD population.**

***Keywords*—cognitive impairment, rapid eye-movement sleep behavior disorder, large-scale network coupling.**

I. Introduction

RAPID eye-movement sleep behavior disorder (RBD) is a parasomnia associated with increased muscular tone as well as abnormal and potentially harmful movements occurring as dream enactments during REM sleep [1].
RBD can be categorized in idiopathic (iRBD) or symptomatic, that is in combination with other neurological disorders [2], and people with iRBD have a >70% chance of developing Parkinson's disease (PD), dementia with Lewy bodies (DLB), and multiple systemic atrophy [3], [4]. Clinical RBD symptoms include cognitive decline [3], impaired olfaction and color discrimination [5], abnormal metabolic network activity [6], and reduced striatal dopamine transporter (DaT) uptake [4]. Recently, numerous studies have focused on exploring the predictive value of iRBD diagnosis for α-synucleinopathies. Compared to healthy subjects, iRBD patients show a slowing of the power spectrum of the electroencephalographic (EEG) signal towards the lower frequencies [7]. However, the power spectrum is a frequency-wise measure of the amplitude distribution of individual cortical populations and lacks information about large-scale network interactions. Neurodegenerative disorders are recently considered as network pathologies, where the connectivity between different brain areas could provide a better understanding of the disorder and its progression. To investigate how RBD affects the large-scale network coupling, previous studies investigate phase synchronization, which quantifies the synchrony of the relative phase between two simultaneous signals, and amplitude correlation, which measures the correlation of the envelopes of two simultaneous oscillatory signals [8], [9]. These studies report an increment of the phase synchronization in alpha band in iRBD patients over time, and a reduction of the amplitude correlation [9]. Moreover, a weaker phase synchronization in the delta band is characteristic of iRBD compared to healthy subjects [8].
Anomalies in large-scale network coupling are reported also in a prodromal stage of Alzheimer's disease, where an increase of phase synchronization in the theta band are associated with a worsening of the cognitive functions [10]. Thus, we hypothesized that anomalies in phase synchronization and amplitude correlation could be common features in the prodromal stages of several neurodegenerative diseases. However, it remains unclear how such electrophysiological biomarkers evolve over time in prodromal synucleinopathies.
Here, we enrolled a longitudinal cohort of 33 iRBD patients to investigate disease progression-related evolution in large-scale brain network couplings through high-density electroencephalography. In addition, we correlated our findings with longitudinal clinical scores to observe whether altered large-scale network coupling are linked to a worsening of the motor and cognitive function in patients with iRBD.

II. Methods

A. Data Acquisition

A total of 33 people with iRBD (12 female; mean age 68,21 ± 7,21 years at the first clinical evaluation) were investigated at baseline and at 1st follow-up (after 17,78 ± 8,58 months), including clinical and EEG assessments. Out of these patients, a 11-subject subset also underwent a 2nd follow-up session (after 37,60 ± 11,36 months from baseline). The diagnosis of iRBD was made according to international criteria (ICSD 3) and was confirmed by overnight video-polysomnography. As a control dataset, we recruited 17 healthy people (8 female; mean age 68,48 ± 3,80 years). In accordance with the Declaration of Helsinki, all participants gave informed consent

before entering the study, which was approved by the local ethics committee.

Clinical assessment. Patients underwent general and neurological examinations to rule out other neurological and psychiatric disorders. Baseline clinical evaluations included (1) the Mini-Mental State Examination (MMSE) as a global measure of cognitive impairment; (2) the Movement Disorder Society-sponsored revision of the Unified Parkinson's Disease Rating Scale, motor section (MDS-UPDRS-III) to evaluate the presence of parkinsonian signs.

Electrophysiological signal recording. All people with iRBD underwent HD-EEG evaluation (sampling frequency = 400 Hz, electrode number = 60, cap = Grass Telefactor system, Grass Technologies, Quincy, MA) during relaxed wakefulness, late in the morning to minimize drowsiness. For each session, the acquisition protocol consisted of approximately 5 minutes of resting-state characterized by the alternance of 30 seconds with eyes-open and 30 seconds with eyes closed. Electrodes were placed according to the 10–10 International System. An EEG technician monitored the recording session to maintain a constant level of vigilance over the patient, prevent sleep and preserve a high signal quality. For each patient and for both visits, we selected the eyes closed condition for further analyses.

B. Data Preprocessing

We carried out data preprocessing and analysis in MATLAB, R2021a, using Brainstorm [11] and custom scripts. As a first step, we preprocessed the EEG data applying a zero-phase infinite impulse response notch filter (order 2) to remove the power line noise (50 Hz). Later, we excluded all channels and time windows showing artifactual activity using a combination of visual inspection and independent component analysis (ICA)-based rejection.

We thus removed an average of 0.15 ± 0.66 channels from each subject (range: minimum 0, maximum 4), and we interpolated those bad channels using spline method (kernel size: 4 cm). We used a bandpass finite impulse response filter (1–80 Hz, Kaiser window, order 1858) to suppress the low- and high-frequency artifacts.

For all cleaned datasets, we transformed the referenced EEG to scalp current densities (SCDs) [12], [13] for all clean sensors with the spline method (lambda 0.00001, order 4, degree 14).

C. Phase and amplitude correlation analyses

We computed phase synchronization and amplitude correlations across a range of frequencies for all channel pairs and for all sessions in both groups of subjects. We analyzed the broadband SCD time series by means of a time-frequency decomposition using 30 narrowband Morlet wavelets in the 2 - 70 Hz range (number of cycles = 5) [14].

To minimize the detrimental effect of volume conduction, signal mixing, and source leakage significantly on phase synchronization analyses of sensor EEG data [15], [16], we adopted the weighted phase-lag index [15] (wPLI), given its insensitivity to volume conduction and higher statistical power [15], [16] than other phase synchronization metrics. Similarly, as a volume conduction-insensitive measure, we adopted the orthogonalized Correlation Coefficient (oCC), which is defined as the Pearson correlation coefficient between two orthogonalized time series [17]. Both wPLI and oCC are limited in the [0, 1] range, where 1 represents the maximum of phase synchronization or amplitude correlation.

D. Statistical Analysis

First, we aimed to investigate whether EEG features showed significant changes between healthy controls and iRBD patients at baseline. To this end, we used the nonparametric Wilcoxon test. Later, we explored the difference in the wPLI and the oCC of subjects with iRBD to assess putative disease progression effects on large-scale brain networks. We wanted to observe whether the mean difference in the observed wPLI/oCC data was statistically significant. To assess any potential discrepancy between baseline and 1st follow-up, we resorted once again to Wilcoxon test. Conversely, we used Kruskal-Wallis as non-parametric test to inspect differences in EEG metrics between baseline, 1st, and 2nd follow-up.

As a last statistical analysis, we investigated whether there was a correlation between the altered phase synchronization and amplitude correlation with clinical data in subjects with RBD. Hence, we applied Kendall's coefficient of rank correlation tau-sub-b to these data. We FDR-adjusted all resulting p values with the Benjamini–Hochberg (BH) method.

III. Results

A. Global phase synchronization and amplitude correlation change with disease progression

We first investigated how phase synchronization and amplitude correlation changed between healthy controls and iRBD patients at baseline. We observed an increase in the strength of both populations averaged wPLI and oCC for subjects with iRBD compared to controls in theta (5-7 Hz) band (Figure 1). Nonetheless, these significant differences did not survive with BH correction ($p < 0.05$ before correction).

We then inspected how phase synchronization and amplitude correlation changed between baseline and subsequent follow-ups as for iRBD patients. In detail, we found no differences either in wPLI or in oCC between baseline and 1st follow-up (Figure 1b and 1e). Conversely, oCC in delta-theta (2-7 Hz) band exhibited a significant decrease (once again only before BH correction) over time, among recording sessions (Figure 1f). Altogether, these findings bring out the global functional modifications associated with disease progression in subjects affected by iRBD.

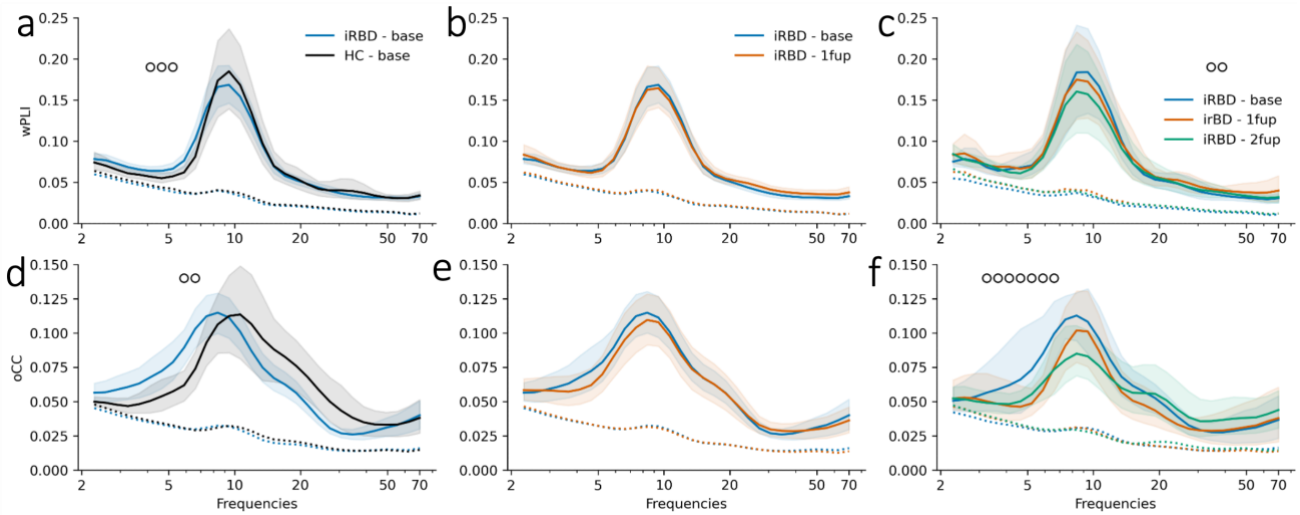

Figure 1: **Global phase synchronization and amplitude correlation change with the disease progression**. Strength of population averaged wPLI (a-c) and oCC (d-f) in iRBD patients at baseline (blue), at 1st follow-up (red), and at 2nd follow-up (red), and in HC subjects (black). Shaded areas represent confidence intervals around population mean (bootstrap, N = 1,000). Dashed lines represent surrogate averages. Empty black circles represent the significant frequency points with *(a,b,d,e)* Wilcoxon rank sums test *or (c,d) Kruskal-Wallis test*. Filled black circles represent the significant frequency points after Benjamini-Hochberg correction.

B. Amplitude correlation values correlate with clinical scores

Finally, we asked whether phase synchronization and amplitude correlation values correlate with the clinical scores. We thus computed the age-adjusted Kendall's coefficient of rank correlation tau-sub-b of clinical scores with wPLI and oCC in delta-theta, alpha-beta, and gamma bands (Figure 2), pooling subjects and visits. We observed a direct significant correlation between oCC values in alpha-beta band and MMSE score (p = .006; BH corrected).

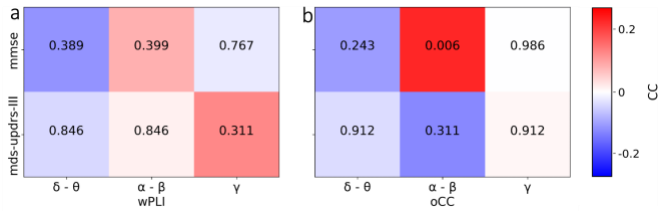

Figure 2: **Phase synchronization and amplitude correlation values correlate with clinical scores.** Age-adjusted Kendall's coefficient (CC) of rank correlation tau-sub-b with Benjamini–Hochberg correction of wPLI and oCC in delta-theta, alpha-beta, and gamma band with clinical scores. The color represents the correlation values and the number in each box represents the false discovery rate (FDR) corrected p values.

IV. Discussion

In this study, we investigated advanced electrophysiological markers in a longitudinal study of iRBD patients. They were examined at the time of iRBD diagnosis and in two following follow-ups.

Compared to other works about this topic [8], [9], the great advancement of the current study consists in increasing the number of subjects as well as of time-points under analysis, thus helping to clarify the clinical trajectories of iRBD patients with disease progression.

First, the significant increase in phase synchronization and amplitude correlation in the theta band found in iRBD patients compared to healthy subjects (Figure 1a,d) is in agreement with previous literature [9].

Moreover, we observed a significant decrease of amplitude correlation in the theta band at subsequent visits compared with the baseline (Figure 1e,f).

Conversely, the significant increase of phase synchronization in alpha band over time observed in [9] and reflecting disease progression [10], [18], [19] is not replicated here.

A potential motivation for this discrepancy may lie in the difference in (i) the kind of recording protocol, (ii) the recording duration, and (iii) the time interval of follow-ups between these two longitudinal studies.

On the other hand, significant positive correlation between oCC in the alpha-beta and MMSE score proposes that amplitude correlation is linked to cognitive function (Figure 2b). Observing that oCC decreases in the alpha band with disease progression (Figure 1e,f), we might speculate that a decrease of amplitude correlation in the alpha band reflects a worsening of the cognitive functions in iRBD patients.

V. Conclusion

In this work we inspected the modifications in phase synchronization and amplitude correlation in iRBD patients at three distinct time points using high-density EEG and correlating the data with longitudinal cognitive scores. Figuring out the coherent time-based evolution of joint clinical and EEG biomarkers in iRBD could deepen our knowledge about prodromal stages of synucleinopathy, possibly supporting in identification of those patients who are more likely candidates for neuroprotective treatment. Our results suggest that a reduction of amplitude correlation in the alpha band might reflect an electrophysiological correlation of the cognitive decline, highlighting the onset of pathological mechanisms due to the neurodegeneration.

***Abstract*—Machine learning (ML) empowered software tools play a key role in assisting and supporting physicians in clinical procedures, diagnosis and follow-up. These tools analyze data extracted by the biomedical instruments to study diseases or effects of drugs on a large population of patients enabling precision and personalized medicine. In this paper, we present the definition and the implementation of a system based on machine learning algorithms to perform semi-automatic features annotation, question answering and data enrichment. The software prototype will is currently tested in a real clinical scenario in the University Hospital.**

***Keywords*—Artificial intelligence, machine learning, features annotation, question answering.**

I. Introduction

Currently, the introduction of novel technologies for the analysis of patients is producing a large amount of data. These data are heterogeneous both in format (from images to time series) and in dimension (from few kilobytes to gigabytes). These data represents a big challenge for the machine learning domain, in order to develop efficient models of analysis for producing medical relevant knowledge.

Consequently there is the need to integrate and annotate data to create high-quality training sets for machine learning models applied in different clinical domains [1]. In bioimages or biosignals analysis, tools for annotation and semi-automatic enrichment of datasets are useful to implement a continuous cycle of metaparameters exploration, supervised by a domain expert [2], [3]. In this way, it is possible to generate large number of high-quality datasets allowing to train machine learning models to make contributions in the research. A typical application example in the bioimages is the research of areas of neighboring voxels having similar features, e.g. from a statistical point of view. Another application context concerns the biomedical signals deriving from electrophysiological tests, in which a number of derivations are generated by measuring the electrical intensity of the cardio-circulatory system [4], [5] The development of new advanced semi-automatic methods and tools for tagging and annotating features of interest in the healthcare domain has the potential to improve the effectiveness of diagnostic tools based on artificial intelligence, operating on two different aspects: (i) the quality improvement of datasets obtained by introducing an intervention by the human expert, assisted by the tools and aimed at refining the tagging of the features which can lead to an increase in the quality of the data and (ii) the semi-automatic generation of large datasets (Big Data) obtained through automatic feature extraction tools.

We present the design and the implementation of a system for semi-automatic features annotation, question answering and data enrichment. Six modules have been proposed in the system to collect and analyze clinical data from different sources. The aim is to implement dataset enrichment and refinement functions allowing the execution of expert-assisted experiments in specific case studies. This system is based on machine learning algorithms and it represents the prototype result of the VQA - Validated Question Answering project (Horizon 2020 – PON 2014-2020 FESR).The system acquires main information sources in the health domain and the extracted data are examined and used on the study and the definition of models for extracting information from data sources of health interest, supporting physician in their clinical activity and research.

II. Prototype architecture

The architecture of the proposed system is shown in Figure 1. System has three layers: Connection Layer, ML Service Layer and Domain Specific Layer.

Connection Layer includes Audit Connector and Data Importers modules, to external audit and data import from external sources, respectively.

ML Service Layer includes Active Learning (AL), Sequence Analysis, Bio-images Analysis and ad-hoc Analysis cores, to tag, annotate and extract relevant information. These cores have been designed to a specific type of information and data.

Domain Specific Layer includes vertical modules to offer services in different application domains. Currently we included following modules: (i) Dismetabolic data annotation, (ii) Bioimage Annotation, (iii) Maxillo-Facial Images Annotation, (iv) ElectroCardiograms Anomaly Detector, (v) Protein Annotation, and (vi) Active Learning.

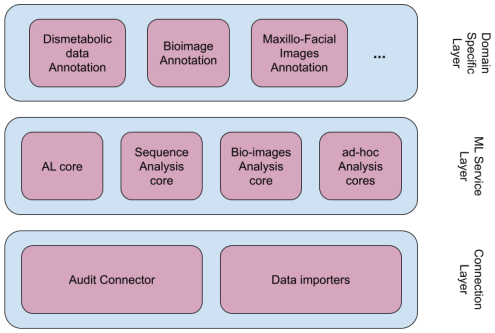

Fig. 1: Integrated system architecture for the annotation and information extraction.

Dismetabolic Data Annotation module integrates tagging techniques to extract relevant data from dismetabolic signal analysis [6] This module is useful in the evaluation of diabetes that represents one the leading cause of death with an exponential growth in recent years. In this context, the integration of heart rate data and glycemic data has been used to predict and/or follow hypo- or hyper-glycemic events.

Bioimage Annotation module performs annotations on different data sources enriching the overall information. The framework is easily usable and it offers a tool for interactive visualization, annotation and data exploration to support physicians in their daily clinical practice [7],[8].

Maxillo-Facial Images Annotation module performs graphic and textual annotations on maxillo-facial images (e.g. Magnetic Resonance or Computer Tomography Images) 2. Starting from the annotations, many tasks can be executed as meta-data extraction, image manipulation, query execution, and output visualization [9].

Electrocardiograms Anomaly Detector module uses semi-supervised learning techniques to identify points of interest within a 12-leads ECG signal synchronized with a 3-channels photoplethysmography (PPG) signal. This approach is based on the use of an Autoencoder architecture. It is used to reconstruct signal window, and to calculate its relative error due to signal reconstruction, needed to identify any possible anomaly.

Protein Annotation module allows to study and analyze protein structure by using the protein contact network (PCN) [10]. It helps to identify putative allosteric pathways and regions in protein structures. It allow the user to hypothesize the functional effect of the mutations, and (iii) recognize functional domains (communities or clusters) in proteins [11].

Active Learning module allows “learning-active-learning” algorithm execution. Initially, this technique trains a neural network with the available labeled examples. Then an initial set of samples is selected from the set of unlabeled examples using random sampling, and submitted to the clinical expert to be labeled, thus obtaining a new set of labeled examples. The neural network is trained with the labeled data, a classifier is trained using neural network gradients in order to identify the most representative examples and it is used to select the "best" examples [12].

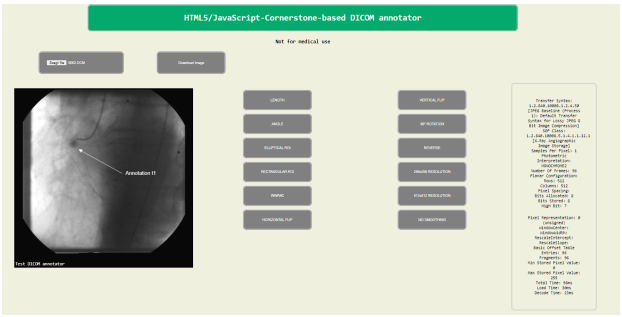

Fig. 2: Graphical user interface for Oral surgery Annotation module, with an imported DICOM image.

III. Case Studies

Experimental tests have been performed on the system to verify and validate the proposed solutions, also thank to the collaboration between biomedical and bioinformatics engineers with medical-clinical specialistis. Each module has been tested and it is currently in use at University Hospital of Catanzaro for research purposes by using anonymized data.

Dismetabolic Data Annotation module has been tested on patients with type 1 diabetes on data from a continuous blood glucose monitoring (CGM) system manufactured by DEXCOM. Results demonstrated that the module is a useful tool to identify interesting patterns from glucose daily measured values.

Testing of *Maxillo-Facial Images Annotation* module was conducted on carotid district images, for the identification of parotid tumors. The dataset consisted of a set of Magnetic Resonance images belonging to patients with neoplastic disease of the parotid gland compared with a set of control subjects. The tool allows to import and view the DICOM P10 images of interest, apply one or more annotations or transformation functions, and obtain information regarding the metadata present in the DICOM file.

All the changes made to the image can be saved in a special database to be available later. Also, the user can convert and save images in jpeg format. Furthermore, the tool allows to query datasets and this function could be very useful to the expert to study clinical cases and compare them with each other or with control subjects .

Electrocardiograms anomaly Detector have been tested by using ECG + PPG signals at 500 Hz and 15 channels (12 ECG channels and 3 PPG channels). To evaluate the module, synthetic ECG + PPG signals have been generated by the SIMARR3 arrhythmia simulator [13]. This simulator is capable of simulating normal ECG + PPG signals or containing atrial fibrillation, tachycardia and bradycardia events and at a specific sampling frequency.The results demonstrate that the autorencoder is able to perform a fairly precise identification of anomalies due to (1) atrial fibrillation events without noise,

to (2) a low-frequency noise component (breathing noise) or to (3) a component of noise deriving from muscle activity (EMG).

Protein annotation module implents Protein Contact Network Miner tool (PCN-Miner) [10], [11]. Its testing was directed towards three different case studies, relating to the study of the Spike protein of the SARS-CoV-2 virus [14], using the Protein contact network paradigm. The dataset used for test phase consists of the SARS-CoV-2 genomic sequences present in the GISAID database [16] and of the structures of main variants of the Spike protein of the virus in the RCSB Protein Data Bank [17].

Active Learning module was tested in the clinical setting on a dataset for the identification of melanoma in moles. The dataset was generated by the International Skin Imaging Collaboration (ISIC) [15] and the images come from the following sources: Hospital Clínic de Barcelona, Medical University of Vienna, Memorial Sloan Kettering Cancer Center, Melanoma Institute Australia , The University of Queensland and University of Athens Faculty of Medicine. The model obtained from training with this dataset will be able to predict a binary target for each image. In training data, 0 indicates the benign lesion and 1 indicates the malignant one.

IV. Conclusion

In this work we present a system based on machine learning algorithms aiming to perform semi-automatic features annotation, question answering and data enrichment. It consists of three layers: the Connection Layer, containing various modules dedicated to connectivity with services external to the system, the ML Service Layer, containing the basic services for labeling and extracting information based both on machine learning techniques and explicitly dedicated to a particular type of information, and the Domain Specific Layer containing, services specific to a particular application domain. Our aim is to provide a powerful tool, useful in healthcare domain for clinical decision support.

***Abstract*— Mental workload (MW) refers to the level of mental effort required to accomplish multiple concurrent tasks. Due to its correlation with the risk of traffic accidents, the assessment of MW is crucial for Advanced Driver-Assistance Systems. In this study, participants were given two cognitive tests (the Digit Span Test, DST, and the Ray Auditory Verbal Learning Test, RAVLT) while driving in a simulated environment. The tests were chosen to elicit different levels of MW from the drivers based on the task's difficulty. Electroencephalography (EEG), functional near-infrared spectroscopy (fNIRS), and heart rate variability (HRV) were used to assess features indicative of the psychophysiological states of the participants in order to feed a Support Vector Machine (SVM) classifier. Multimodal EEG + fNIRS + HRV feature-based classifiers performed better with respect to SVM fed by unimodal features (DST: 69.4% accuracy, RAVLT: 85.5% accuracy). These results showed the possibility of assessing the MW levels of drivers with high accuracy through multimodal physiological acquisitions, which could be easily implemented in ADAS applications, driving competitions, and automotive cockpit neuroergonomics.**

***Keywords*—Electroencephalography (EEG), functional near infrared spectroscopy (fNIRS), Heart Rate Variability (HRV), ADAS systems.**

I. Introduction

The underestimation of a driver's mental workload (MW) is a common cause of traffic accidents, which are a leading cause of death and injury [1]. Consequently, advanced driver assistance systems (ADAS) aim to predict excessive MW to prevent traffic accidents. According to the National Highway Traffic Safety Administration (NHTSA), the relationship between the driver's psychophysiological state and driving performance is direct. In this light, monitoring the driver's mental state is essential for enhancing road safety.

The psychophysiological state of a driver could be assessed by evaluating the driving errors made while doing the task or using questionnaires pertaining to the perception of the gravity of the task completed (e.g., NASA-TLX or the SWAT questionnaires) [2]. Moreover, the monitoring of the driver's central and autonomous neural systems, whose activity is indicative of the MW, can be performed by using neurophysiological methods during driving tasks.

Consequently, a number of machine learning (ML) and artificial intelligence (AI) frameworks have been developed to classify the psychophysiological condition of drivers based on behavioural characteristics (such as blinking frequency, percentage of eye closure, and yawning) and physiological signals (e.g., electrocardiography, ECG [3], photoplethysmography, PPG [4], electroencephalography, EEG [5], functional near infrared spectroscopy [6], infrared thermography [7,8]).

In detail, the fNIRS is a technique able to infer the functional modulations of the oxyhaemoglobin (HbO) and deoxyhaemoglobin (HbR) cortical concentrations [9]. Concerning the EEG, it is a scalp-located technique able to measure electrical brain activity. Frequency-domain approaches are often employed for EEG data analysis since the power spectral density (PSD) of different EEG frequency bands modulates according to the MW [5]. Regarding the ECG, it is possible to extract the temporal distance of successive R-peaks from the ECG signal, hence providing information about the Heart Rate Variability (HRV), which modulates secondary to the MW level [3].

Regarding MW classifications, it has been shown that multimodal approaches can enhance the performance of ML-based classifications [10]. Particularly, it has been demonstrated that combined EEG-fNIRS recordings are highly indicative of the drivers' MW [11].

To ensure driver comfort and avoid interference, contact sensors to collect physiological signals are typically avoided in common ADAS applications. However, these sensors are appropriate for racing applications, and cockpit design.

In this study, machine learning (ML) models based on multimodal measurements (EEG, fNIRS, and HRV) were developed to classify drivers' MW during the administration of two distinct cognitive tasks.

II. Material and Methods

A. Participants

Thirteen healthy adults (8 males, age range 19–42, mean 29.49, standard deviation 5.98) in possession of a valid driver's license participated in the experiment. Prior to the experimental sessions, the participants were properly instructed on the objective and procedure of the study, and they signed a Declaration of Helsinki-compliant informed consent form.

B. Experimental design

During the experimental sessions, a static driver simulator was utilized (Figure 1). The scenario was displayed on three 27-inch monitors with a total video resolution of 5760 ×1080 pixels. There was a 1.5-meter gap between the driver and the monitors. The drivers' horizontal view angle was 150 degrees.

The driving simulation software used was City Car Driving,

Home Edition, version 1.5.

Fig. 1: Driver simulator and City Car Driving, Home Edition software

The experimental protocol involved a 45-minute driving simulation in an urban setting. The experimental conditions were predetermined to ensure hazardous driving conditions and to deliver a reproducible experimental protocol to all study participants (i.e., Traffic density: 60%; Traffic behavior: Intense traffic; Pedestrian crossing the road in the wrong place: Frequently; Dangerous change of traffic: Frequently; Emergency braking of the car ahead: Frequently).

After fifteen minutes of baseline driving, two cognitive tests were administered to drivers in order to manipulate their MW relative to their baseline driving.

Specifically, the Digit Span Test (DST) is a cognitive test comprised of two distinct tasks that can evaluate short-term memory and working memory [12]. The participant was required to repeat sequences of digits presented verbally at a rate of one digit per second. The test began with a two-digit sequence, and a new set was presented each time the sequence was repeated correctly. If a participant could not recall a series, another of equal length was suggested. The test ended if the participant was unable to repeat two sequences of the same length. For the purposes of this study, the DST was administered both in the forward (repetition of digits in the same order as their presentation) and backward (repetition of digits in the reverse order of their presentation) versions.

The Rey Auditory Verbal Learning Test (RAVLT) is a cognitive task that can assess verbal learning and long-term memory [13]. It was administered by reading a list of 15 words to the participant at the rate of one word per second. At the conclusion of the reading, the participant was instructed to repeat as many words as possible, in any order. This procedure was repeated five times with the same word list, each time recording different elements. This phase of the examination is called Immediate Recall (ImmR). After a 15-minute interval during which the subject continued to drive, he/she was asked to recall as many words from the list as possible without the examiner restating the list. This second section of the RAVLT consisted of the Delayed Recall (DelR). Subsequently, the final portion of the test consisted of the Recognition (Rec) of the 15 words from the original list from a new list of 46 items. Then, the participant completed the test by driving for 10 minutes without further testing.

C. Data collection and analysis

The ADInstruments Powerlab system was used to record the ECG signals using the Standard Limb Leads configuration (i.e., electrodes placed on the right arm (RA), left arm (LA), and left leg (LL)). The ECG signals were acquired at a frequency rate of 1 kHz and band-pass filtered in the frequency band of [0.05–150] Hz. In addition, a notch filter (fnotch = 50 Hz) was used to eliminate the artifact caused by the mains power supply. Six features of HRV were computed from the ECG signal throughout the experimental phases: mean value (RRmean), Standard Deviation Normal to Normal (SDNN), root mean square of successive differences (RMSSD), mean value of the PSD evaluated in the low-frequency band (LF = [0.04–0.15] Hz), mean value of the PSD evaluated in the high-frequency band (HF = [0.15–0.4] Hz), and their ratio (LF/HF).

The ADInstruments Powerlab system was also employed to measure a 1 channel EEG, with a sample frequency of 1 kHz. Saturated or corrupted EEG data epochs were assessed by visual inspection and eliminated from the analysis. In addition, physiological artifacts were corrected using an Independent Component Analysis-based method. Data were band-pass filtered with a 2nd order, zero-lag, Butterworth digital filter (cut-off frequencies of 0.1 and 80 Hz). To estimate the MW of the drivers, the PSD of different EEG frequency bands (i.e., δ-band, 1.5-3.5 Hz, θ-band, 3.5-7.5 Hz, α-band, 7.5-12.5 Hz, β1-band, 12.5-25.2 Hz, β2-band, 25.2-35.2 Hz) were computed using Welch's method (2 s intervals, frequency resolution of 0.5 Hz). The following features were extracted from each EEG power frequency bands signal: mean value (Mean), standard deviation (SD), sample entropy (SampEn, embedded dimension=3; similarity factor:0.2*std).

The portable fNIRS Cortivision Photon cap device was used to measure the functional cortical hemodynamic (the device was provided by Cortivsion Pathfinder Program grant number CPP-2021/10/3). It is comprised of 16 LEDs emitting at 760 nm and 850 nm wavelengths and 10 detectors. The montage consisted of 34 channels that covered the frontal and prefrontal cortices, with optodes arranged according to the 10–20 system. Additionally, four short channels have been provided to reduce physiological contamination from fNIRS signals. [14]. The signals were filtered with a 2nd order, zero-lag, Butterworth digital filter (cut-off frequencies of 0.01 and 0.5 Hz) and the motion artifacts were corrected applying a Wavelet based procedure [15]. The following features were extracted from both the HbO and HbR signals and averaged across the channels: Mean, SD, and SampEn (embedded dimension=3; similarity factor:0.2*std).

In this study, a Support Vector Machines (SVM) with a radial basis function kernel was employed to classify the MW. Specifically, both unimodal (fNIRS, EEG, HRV) and multimodal (fNIRS+EEG+HRV) models were trained and tested to discriminate three MW levels for DST (i.e., baseline, forward DST, and backward DST), and four MW classes for RAVLT (baseline, immR, DelR, Rec). The input metrics were normalized (z-score) and a leave-one-subject-out cross validation was used to protect against overfitting. The feature selection was performed using F-tests, used to compare the null hypothesis that response values grouped by predictor variables are from populations with the same mean. The McNemar–Bowker was used to compare the classifiers.

III. Results

In Table 1, the features for the unimodal and multimodal frameworks are listed in the order determined by the F-tests. The first five features selected for each classifier were used for the classification.

TABLE I: Features ranking obtained through the features selection procedure

Cognitive task	*Physiological signals*	*Features selected*
DST	fNIRS	SD HbO, SD HbR, Mean HbO, SampEn HbO, SampEn HbR, Mean HbR
	EEG	Mean δ. SampEn θ, SampEn β2, Mean θ, SD δ, SD β1, SampEn δ, SampEn β1, Mean β2, Mean α, SD θ, SampEn α, SD β2, Mean β1, SD α
	HRV	LF/HF, meanRR, HF, SDNN, RMSSD, LF
	Multimodal	LF/HF, SD HbO, Mean δ, RRmean, HF, SampEn θ, SDNN, RMSSD, LF, SD HbR, SampEn β2, SampEn HbR, Mean θ, SD δ, SD β1, SampEn HbO, Mean HbR, SampEn δ, SampEn β1, Mean HbO, Mean β2, Mean α, SD θ, SampEn α, SD β2, Mean β1, SD α.
RAVLT	fNIRS	Mean HbO, Mean HbR, SampEn HbO, SD HbR, SD HbO, SampEn HbR
	EEG	SampEn θ, SD β1, Mean δ, Mean α, SampEn β1, SampEn α, SampEn δ, Mean β2, SD β2, Mean θ, Mean β1, SD δ, SD θ, SD α, SampEn β2
	HRV	LF/HF, LF, SDNN, RMSSD, MeanRR, HF
	Multimodal	LF/HF, LF, SDNN, RMSSD, RRmean, HF, SampEn θ, SD β1, Mean δ, Mean HbO, Mean HbR, Mean α, SD HbO, SampEn β1, SampEn α, SampEn δ, SD HbR, SampEn HbO, Mean β2, SD β2, SampEn HbR, Mean θ, Mean β1, SD δ, SD θ, SD α, SampEn β2

Table 2 reports the cross-validated classification performances obtained for the two cognitive tasks considered for the different physiological signals acquired.

TABLE II: Accuracies of the several models developed

Cognitive task	*Physiological signals*	*Accuracy (%)*
DST	fNIRS	66.7
	EEG	64.1
	HRV	64.1
	fNIRS+EEG+HRV	69.4
RAVLT	fNIRS	59.6
	EEG	70.8
	HRV	76.9
	fNIRS+EEG+HRV	85.4

Figure 2 shows the confusion matrix obtained for the cross-validated classification of three MW levels from DST based on the multimodal approach.

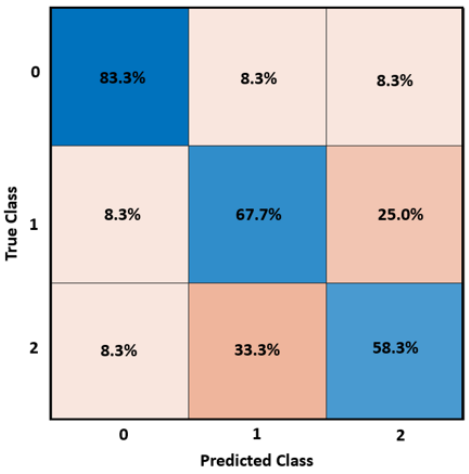

Fig. 2: Confusion matrix associated to the classification obtained to discriminate three MW levels from DST based on the multimodal approach.

Figure 3 describes the confusion matrix associated to the cross-validated classification of four MW levels from RAVLT based on the multimodal approach.

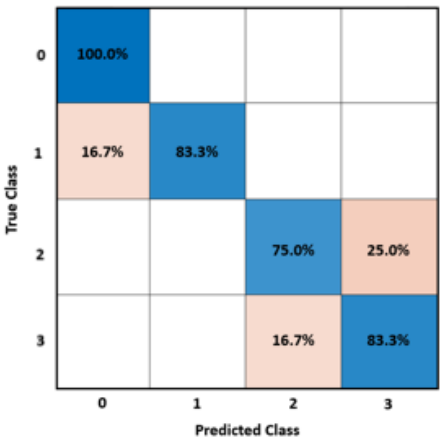

Fig. 3: Confusion matrix associated to the classification of four MW levels from RAVLT based on the multimodal approach.

The McNemar–Bowker test did not report any significant difference between the accuracies of the different models.

IV. Discussion

Monitoring the MW while driving is of the utmost importance due to its close correlation with the risk of car accidents. The primary objective of the present study was to develop models capable of classifying drivers' MW based on their psychophysiological characteristics.

DST and RAVLT were chosen to investigate different levels of MW, since it has been reported that the Backward DST and the DelR-RAVLT are more demanding with respect to forward DST and the other phases of RAVLT, respectively [16].

In the present study, the possibility of recognizing different levels of MW through non-invasive techniques and an SVM-based model was investigated. During the experimental

phases, fNIRS, EEG, and HRV characteristics were extracted.

Concerning the fNIRS signals, the feature selection analysis demonstrated that the SD and mean values of the HbO and HbR are relevant to discriminate the MW (Table I). In fact, it is known that cortical activations require increased oxygen consumption, producing functional hyperaemia, which is visible with an increase in the mean value of the HbO, a decrease in the mean value of the HbR, and an increase in the SD of the two signals [9].

Concerning the EEG, variations of the power in θ and δ bands seem to be relevant for the detection of MW (Table I). These results agree with previous findings demonstrating that increased EEG power in θ band occurred in high MW, and that increased EEG power in θ, δ and α bands characterize the transition between MW and mental fatigue [17].

Regarding the HRV, the LF/HF metric is the most crucial to estimate the MW (Table I), in line with previous findings [18].

Although an improvement in classification performance is present when comparing the multimodal approach with the different unimodal procedures (Table II), it is worth noticing that the McNemar–Bowker test did not highlight any significant difference between the accuracies of the different models. This result could be related to the poor sample numerosity. In fact, as the number of participants in the study sample has a significant impact on the supervised learning performances, further research is required to expand the sample size. In addition, the risk of overfitting may be decreased by increasing the number of participants. Notably, even if the findings are cross-validated and the generalization abilities of the model are thus examined, increasing the sample size might still lead to better classification results. In addition, because the participants' ages ranged from 19 to 42, the study only included young and middle-aged adults. Expanding the age range in future studies should be essential to creating models that are appropriate for older people as well. The MW examined in this study is primarily related to non-driving tasks rather than a complex driving condition, which is an important point to emphasize. Therefore, more research tracking the MW's variation in relation to driving-only tasks needs to be done. To broaden the model's scope of use, it is important to evaluate it in real-world driving scenarios as well, mainly focusing on contactless, lightweight and not-bulky sensors.

V. Conclusion

This study illustrated the benefits of using multimodal physiological acquisitions to measure the MW in drivers. Specifically, using an SVM classifier based on multimodal physiological features, MW was identified with an accuracy of 69.4% during the administration of the DST and 85.4% during the RAVLT. To lessen traffic accidents and enhance driver ergonomics, this technique could be successfully used in ADAS applications, racing competitions, and cockpit neuroergonomics.

Algorithm based on the "dynamic risk" concept allows ahead-of-time suggestion of corrective insulin boluses in type 1 diabetes therapies employing continuous glucose monitors

E. Pellizzari[1], F. Prendin[1], G. Cappon[1], G. Sparacino[1] and A. Facchinetti[1]
[1] *Department of Information Engineering, University of Padova, Padova, Italy.*

***Abstract*—Due to the lack of insulin secretion from the pancreas, individuals diagnosed with type 1 diabetes (T1D) must lower their blood glucose (BG) levels through exogenous insulin injection in order to avoid hyperglycemic episodes (BG $\geq$ 180 mg/dL). Unfortunately, excessive exogenous insulin dosing could lead patients to experience hypoglycemic episodes (BG $\leq$ 70 mg/dL). T1D management can be improved by utilizing continuous glucose monitoring (CGM) and decision support systems (DSSs), specific software tools that can assist patients during the daily decision-making process, recommending therapeutic actions such as carbohydrates intake and insulin injections. This study presents a novel algorithm, usable in a DSS, that utilizes physiological patient-specific information and a "dynamic risk" measure obtained from CGM to suggest the dose of anticipated corrective insulin boluses (CIBs), with the goal of reducing the duration of hyperglycemia. The approach has been retrospectively evaluated on a dataset of 30 T1D patients recorded in free-living conditions and compared with state-of-art approach. Results indicate that the proposed algorithm improves many indicators conventionally used in assessing the effectiveness of T1D therapies and the quality of glycemia, e.g., percentage of time spent in euglycemia ($+4.86\%$) and in hyperglycemia (-4.58%), hyperglycemia duration (-33.75 min) and glycemic control.**

***Keywords*—corrective insulin boluses, dynamic risk, preventive, type 1 diabetes.**

I. INTRODUCTION

Type 1 diabetes (T1D) is a chronic autoimmune disease characterized by the lack of pancreatic insulin secretion. Blood glucose (BG) levels in people affected by diabetes frequently exceed the safe range of [70 $-$ 180] mg/dL: hyperglycemia, i.e., BG $\geq$ 180 mg/dL can lead to serious long-term consequences as retinopathy and cardiovascular disease, whereas hypoglycemia, i.e., BG $\leq$ 70 mg/dL, can be dangerous in the short term since can cause coma or even death. Individuals with T1D must manage a lifelong therapy in order to maintain as much as possible the blood glucose concentration within the euglycemic range. The standard therapy for T1D includes frequent measurements of BG levels, estimation of carbohydrate intake at each meal, periodic administration of exogenous insulin to compensate for fluctuations in BG levels above the hyperglycemic threshold and rapid ingestion of carbohydrates when BG falls below the hypoglycemic threshold. These actions are commonly repeated throughout the day, leading to increased burden and negatively impacting patients' quality of life.

In recent years, the use of continuous glucose monitoring (CGM) devices has helped to ease the burden of standard therapy [1], [2]. CGM devices are minimally invasive sensors that provide BG measurement every 1-5 minutes for several days. Since their approval for nonadjunctive use [3], [4], patients can make treatment decisions based on the values provided by CGM. Additionally, CGM devices can provide patients with information on the glucose rate of change (ROC) and alarms when BG is outside safe range. Finally, use of CGM devices in combination with portable pumps for continuous subcutaneous insulin infusion (CSII), smart insulin pens, and dedicated mobile applications have stimulated the development of decision support systems (DSSs) [5]. These software tools can automatically record and analyze data from CGM sensors and CSII pumps to create personalized recommendations to improve BG control. For example, DSS can suggest the appropriate amount of prandial insulin or the ingestion of fast-acting hypotreatment to prevent/mitigate impending hypoglycemic events, and suggest corrective insulin boluses (CIBs) to reduce the duration of hyperglycemia. DSSs commonly incorporate multiple modules, such as insulin bolus calculators and BG ahead-of-time prediction algorithms capable of producing smart alarms targeting both hypoglycemia and hyperglycemia, thus providing the recommendations to the patients through a mobile interface.

In the literature, several CGM-based algorithms have already been published to improve the insulin bolus computation [6], [7], [8], [9] and suggest hypoglycemia treatments [10], [11], but a very few have coped with the possibility of exploiting CGM data to enhance the generation of CIBs [12], [13]. According to current guidelines, CIB is computed using the standard formula [14]:

$$CIB = \frac{BG - BG_T}{C_F} - IOB \tag{1}$$

where BG (mg/dL) is the actual BG value, BG_T (mg/dL) is the patient target BG value (e.g., 120 mg/dL), C_F (mg/dL/U) is the correction factor, i.e., how much 1 U of insulin lowers BG, and IOB (U) is the insulin-on-board, i.e., an estimate of the amount insulin still present in the blood from previous administrations. In Aleppo et al. [7], authors proposed a heuristic-based strategy for CIBs administration, modifying

the standard formula Eq. (1) by accounting for both current glucose level and its ROC provided by CGM devices. The approach proposed by Aleppo et al. achieved encouraging results, but it does not consider: i) the large variability among T1D individuals and ii) the risk associated to the upcoming hyperglycemia.

To fill this gap, this work proposes a CGM-based algorithm which, by exploiting physiological patient-specific information and a recently proposed risk measure, is able to trigger CIBs ahead-of-time and, hence, to reduce the duration of hyperglycemic events.

II. METHODS

A. The proposed approach for ahead-of-time CIB suggestion

A key input of the new algorithm for suggesting ahead-of-time CIBs is the dynamic risk (DR), a measure recently proposed by Guerra et al. [16] to improve, by leveraging the information made available by CGM sensors, the static risk (SR) measure previously proposed in [15]. Briefly, SR is a nonlinear transformation of BG designed to assign similar weighting to variations in both hypoglycemia and hyperglycemia, to obtain a symmetric distribution of glycemic ranges. SR quantifies the risk associated to a given BG level. Through a suitable modulation of SR based on the use of the ROC information, DR amplifies SR when BG is rapidly increasing or decreasing. In this way, DR measures how critical the actual BG level and trend can be for the patient, in terms of possible long- and short-term consequences. The fact that DR is sensitive to the trend allows its use for CIBs' preventive suggestion. Specifically, the novel algorithm, schematized in Fig. 1 and hereinafter referred as drCIB, is based on real-time calculation of DR and works as follows:

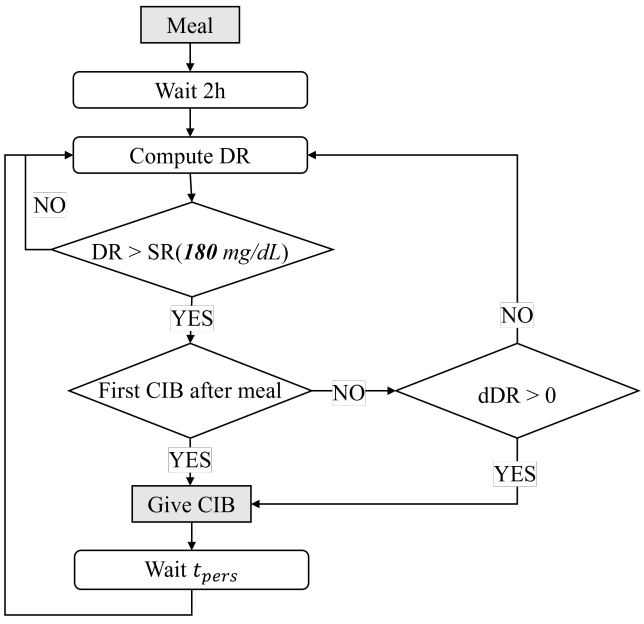

Fig. 1: drCIB flowchart. Abbreviations: dynamic risk (DR), static risk (SR), corrective insulin bolus (CIB).

1) waits two hours after meal ingestion;
2) for every new CGM sample available, computes DR;
3) if DR is greater than SR corresponding to the hyperglycemic threshold value, i.e., 180 mg/dL, and this is the first insulin bolus generated after a meal, triggers a CIB according to Eq. (1), then wait for at least a patient-specific time (t_{pers}) before delivering, if required, another CIB;
4) if DR is greater than SR corresponding to the hyperglycemic threshold value, i.e., 180 mg/dL, but a CIB has already been administered after the meal, computes the derivative of DR. If positive, triggers a CIB according to Eq. (1) and waits for at least a patient-specific time (t_{pers}) before delivering, if required, an additional CIB; otherwise, return to 2).

The patient-specific time between two insulin bolus suggestions is forced to be greater than 60 min and lower than 120 min (interquartile range [60, 91.5, 120] min) and it is retrieved from patient's personal glucose-insulin dynamics. In particular, we identified a white-box model of glucose-insulin dynamics based on the maximal physiological model of the UVa/Padova T1D Simulator [17]. Therefore, by considering the subcutaneous insulin absorption subsystem parameters, we calculated the 150% of the delay of insulin action for each patient.

B. State-of-the-art approach for CIB suggestion

As comparator, we implemented the empiric algorithm published by Aleppo et al. (AL) [7].

We precisely choose AL's approach because includes also specific post-prandial recommendation retrieved from the clinical trial REPLACE-BG [19], which fits to our purpose of managing post-prandial hyperglycemia. In particular, AL suggests to:

1) avoid correction of hyperglycemia for the first 2 hours following a meal, in order to prevent insulin stacking;
2) follow REPLACE-BG guidelines between 2 hours and 4 hours from meal, which include a CIB trigger based on BG and ROC values and the CIB entity calculated from Eq. (1);
3) follow specific guidelines for CIB correction after 4 hours from meal, which add or subtract a fixed amount of insulin to standard CIB calculated with Eq. (1) depending on ROC and patient's C_F, to be injected if BG ≥ 180 mg/dL.

C. Methodology assessment

The aforementioned methodologies were assessed through ReplayBG, an open source [18] tool that retrospectively assesses the outcome of alternative therapies on real-world T1D data. Briefly, it works in two steps: first, identifies a physiological nonlinear model of glucose-insulin dynamics from patient's data (CGM glucose, insulin, carbohydrates); second, uses the so identified model to infer the glucose concentration that would have been obtained, in the same individual and time window, by using an alternative insulin

therapy. In our case, the alternative insulin therapy is given by the delivery of CIBs suggested by the algorithms.

D. Dataset

The two approaches have been retrospectively assessed via ReplayBG on a dataset of 30 subjects acquired in free-living conditions and extracted from a larger study: the Control To Range 3 (CTR3) [20]. For each individual, CGM data, meals timing and amount, insulin boluses, basal insulin, and some personal patient information (carbohydrates-to-insulin ratio, C_F) are available. We partitioned the dataset into daily traces according to the following criteria: i) at least 3 meals per day (breakfast, lunch, and dinner) and ii) a three-hour average hyperglycemia duration. The identification procedure provided a total of 49 daily traces. For the second step (i.e., simulation phase) of ReplayBG we cleared the CIBs injected by the patient in order to test our new strategy. From now on, these data will be referred as baseline.

E. Evaluation metrics

For each individual, we computed time in range (TIR, i.e., 70<BG<180), time above range (TAR), and time below range (TBR); the number of suggested CIBs (CIB) and total daily insulin (INS) injected through them. We also calculated the number of hyperglycemic events per day (Hyper) and the duration of hyperglycemic events (HyperD). The efficacy in glycemic control is measured through the glycemia risk index (GRI) [21], which is an overall risk metric that accounts for very low-glucose and low-glucose hypoglycemia, very high-glucose and high-glucose hyperglycemia, time in range, mean glucose and coefficient of variation. The statistical significance was evaluated by using t-test when normality distribution assumption was not rejected, and through Wilcoxon signed-rank test otherwise, with a significance level of 5%. In particular, we assess both the statistical significance between drCIB and AL in comparison to the baseline and the statistical significance between the two methods.

III. RESULTS

Fig. 2 shows the simulation results of AL and drCIB algorithms via ReplayBG on a representative subject. In particular, it reports the glycemic traces obtained with no CIB (baseline, dotted line), CIBs generated with AL (green line) and CIBs generated with drCIB (red line).

As can be observed from the graphical representation, the dotted line, which serves as the baseline, displays a higher percentage of time spent above the hyperglycemic threshold (38.4%) as a result of the absence of any CIB being administered. AL algorithm generated two boluses (green dots) of 2.66 U and 2.86 U at time 10:25 and 15:55, reducing TAR to 35.0%. Similarly, drCIB algorithm administered two boluses (red dots) of 3.92 U and 3.61 U at time 8:25 and 13:55, just after the two hours waiting window (grey areas). As shown in Fig. 2, drCIB acts ahead in time with respect to AL and it lowers BG more rapidly, further reducing TAR to 22.3%, and HyperD by 31.4% when compared to AL. Notably, by considering the different risk levels, drCIB allows to avoid unnecessary CIBs, especially when glycemia is close to the normoglycemic region.

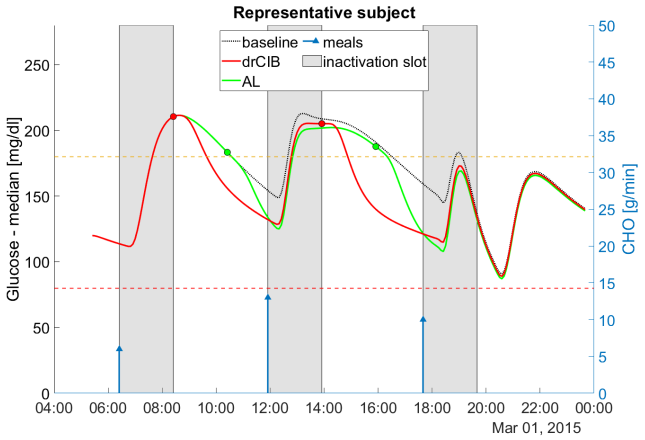

Fig. 2: Application of AL and drCIB algorithms via ReplayBG on a representative subject. The dotted line is the glycemic traces obtained with no CIBs (baseline); the green line is the glycemic trace resulting from AL guidelines and the red line is the glycemic trace resulting from drCIB algorithm. Meals are shown with the blue arrows in the bottom of the plot. The common inactivation slot after the meal of the aforementioned methodologies are highlighted.

Table I reports the main results on the 49 traces in terms of median and [25th-75th] ranges.

TABLE I: Comparison between baseline, AL and drCIB approach Metrics are reported as median [25th-75th].

Metrics	baseline	AL	drCIB
TIR (%)	52.28 [39.55, 62.61]	57.59 [47.81, 68.46]	62.45 * [49.52, 72.70]
TAR (%)	46.89 [37.39, 60.45]	39.76 [25.39, 48.15]	35.18 * [25.74, 41.53]
TBR (%)	0 [0, 0]	0 [0, 0]	0 [0, 2.63]
GRI (unit)	52.64 [35.46, 67.99]	42.14 [28.79, 62.69]	40.44 [27.87, 61.23]
Hyper (unit)	2 [1, 2]	2 [1, 2]	2 [1.75, 2]
HyperD (min)	258.75 [217.5, 325]	223.75 [180, 252.5]	190 * [141.88, 220]
CIB (unit)	-	2 [1, 2]	2 * [2, 3]
INS (U)	-	5.09 [3.15, 7.82]	6.27 * [4.76, 8.31]

* indicates a statistically significant variation of drCIB compared to AL

With respect to baseline, in which no CIBs are delivered, both AL and drCIB improve the overall glycemic control. As a matter of fact, both strategies significantly increase the time spent in the safe range reducing TAR, HyperD and GRI with statistical significance. Comparing drCIB and AL instead, drCIB significantly reduces both TAR (from 39.76% to 35.18%) and HyperD (from 223.75 min to 190 min), achieving the goal in mitigating post-prandial hyperglycemia. drCIB also significantly increases TIR (from 57.59% to 62.45%) without affecting median TBR, and reduces the overall risk index GRI (from 42.14 to 40.44), resulting in a safer approach compared

to AL. It is worth noting that the two approaches deliver a similar number of insulin boluses but the amount suggested by the drCIB is larger than the one provided by AL.

IV. DISCUSSION AND CONCLUSION

In this paper, a novel strategy for post-prandial CIB administration based on DR and a personalized time for CIB injection has been proposed. The new strategy is characterized by a trigger method based on actual DR value, which is easily computed in real-time from CGM values, and a personalized timing for CIB injection, directly estimated from easily accessible patient data e.g., during a medical examination. Preliminary results show that the use of DR to trigger CIBs suggestions proved to be effective in proactively manage hyperglycemia. Indeed, drCIB leads to an improve of TIR and TAR without affecting median TBR and increasing also patient safety in terms of GRI, compared to one of the most recent literature recommendation. For the assessment of the methodologies, data from the CTR3 closed-loop dataset have been used. Since our goal is to develop an open-loop algorithm, we replaced the time-varying basal insulin of the data with the mean across the entire data traces for each subject before the physiological model identification step via ReplayBG. This allowed us to simulate the effect of a long-acting insulin bolus in patients undergoing to multiple daily injections (MDI) therapy, typically administered in the morning. Thereby, we were able to determine the best open-loop therapy that replicates the original data and align the dataset with our aim of developing a therapy for MDI diabetic patients. We acknowledge this as limitation of the study and we will address it in future works when larger datasets, recorded in free-living conditions and in an open-loop set-ups, will be available.

In conclusion, drCIB, which is based on DR measure and a personalized time for CIB delivery, is a valuable alternative to the state-of-art heuristic based strategy for CIB suggestions. It is also suitable to be implemented in the insulin bolus calculators module of a DSS, particularly targeting CIBs.

It is worth underlying that we focused only on trigger and timing condition of CIBs while the amount is defined by Eq. (1). For this reason, future works will examine how changing the glycemic value for the threshold affects the performances, in order to optimize the risk threshold, and optimize the amount of injected insulin based on real-time DR.

***Abstract*— Spatial macroscale gradients have proved useful for understanding the relationship between specific cortical regions and function, by mapping brain connectivity matrices on a low-dimensional representational hierarchy that encodes increasingly abstract levels of cognition. While this approach is well-established with functional connectivity, it has never been applied to whole-brain effective connectivity, which accounts for the direction of propagating information. In addition, the study of EC has rarely been applied in brain pathology.**
In this work, we identified the so-called "gradients" of brain organization from effective connectivity matrices. In neuroscience "gradients of brain organization" is referring to the use of the Laplacian matrix to study spatial modularity and transitions of brain network structure. The aim was to assess the impact of glioma with respect to healthy controls on whole-brain effective connectivity gradients by accounting for the signaling directionality of the information flow. The results showed more differences between controls and tumour subjects in left-hemisphere networks, and in incoming links with respect to outgoing ones. These findings suggest that glioma has a different impact depending on the directionality of connections.

***Keywords*— resting state effective connectivity, brain gliomas, Laplacian eigenmaps, directionality**

I. Introduction

Gliomas are the most frequent malignant primary brain tumours, whose treatment requires neurosurgical resection combined with radio and/or chemotherapy[1], [2], In this view, the presurgical cognitive status has been demonstrated to be strictly linked to the patient's survival[3], [4], suggesting the importance of analyzing brain functional organization in resting-state conditions[5]–[7]. Previous studies dealing with brain connectivity in gliomas[8]–[10] have mostly focused on symmetric, undirected characterizations of the connectome. Those works have been developed through structural or functional connectivity, which respectively gives information about the anatomical and correlation links between regions, without considering any form of directionality in the information flow. On the other hand, the inference of effective connectivity (EC) allows the measure of directed interactions and, as a result, of causality between brain regions. EC has shown to be a more sensitive biomarker outperforming functional connectivity (FC) for other brain pathologies[11], motivating its study in the case of brain tumours. Moreover, previous work has shown that localized brain tumours cause widespread brain connectivity alterations[6], demonstrating that the disruption of a single region extends beyond the affected network and leads to global functional modifications of brain networks.

In this work, we employed a sparse Dynamic Causal Modelling framework[12] to infer whole-brain directional effective connectivity at rest from patients with brain gliomas. Specifically, we aimed to capture the alterations induced in EC through hierarchical processing gradients[13] (i.e. the spectral partitioning of the EC-based Laplacian matrix), which can provide a low-dimensional space to describe the brain macroscale hierarchy. Differently from other graph descriptions that usually discretize functional networks, connectivity gradients allow uncovering transitions in connectivity patterns along a continuous space[14], providing a novel framework for investigating gradual whole-brain perturbations induced by the lesion on brain functional organization[6], [9]. Given the broad need to better understand the mechanisms underlying spatiotemporal brain dynamics, this framework has been widely applied to functional and structural connectomes to both characterize brain regions in terms of the similarity between their connectivity profiles (i.e., spectral clustering[13]) and to provide a set of basis functions for the spectral decomposition of the graph signal (i.e., graph signal processing[15]).

To the best of our knowledge, this represents the first attempt at applying such a low-dimensional transformation to EC in patients with brain gliomas, while very few applications of undirected connectivity gradients to brain pathology can be found in the literature[16]. We analyzed the distribution of gradient values in each brain region and compare it with estimates extracted from a healthy cohort to assess possible alterations induced not only in areas overlapping with the lesion but also in pseudonormal nodes. We performed the analysis by discriminating between incoming and outgoing connectivity profiles to capture the different alterations induced by the pathology on the basis of the directionality of the information flow.

II. Materials and Methods

Pre-surgical data of 47 patients from 25 to 83 years old with de novo brain tumours collected at the University Hospital of Padova were enrolled for this study. All participants have regularly taken anticonvulsants for the control of epilepsy and corticosteroids. The protocol had been approved by the local Ethics Committee of the University Hospital of Padova and carried out in accordance with the 1964 Helsinki declaration and its later amendments. Informed consent was signed by all patients[6]. The cohort is composed of left- and right- tumour individuals affected by both high- and low- grade gliomas.

Data were acquired on a 3T Siemens Biograph mMR scanner equipped with a 16-channel head–neck coil. Anatomical imaging included T1-weighted (T1w) 3D magnetization-prepared rapid acquisition gradient-echo (TR = 2400 ms, TE = 3.24 ms, TI = 1000 ms, FA = 8°, FOV = 256 × 256 mm, voxel size = 1 mm × 1 mm × 1 mm) images acquired both before and after contrast agent injection, a 3D T2-weighted image (TR = 3200 ms, TE = 535 ms, FOV = 256 ×

256 mm, voxel size = 1 mm × 1 mm × 1 mm), a 3D fluid attenuation inversion recovery (TR = 5000 ms, TE = 284 ms, TI = 1800 ms, FOV = 256 × 256 mm, voxel size = 1 mm × 1 mm × 1 mm) image. In addition, functional imaging comprised rs-fMRI EPI scans (TR = 1260 ms, TE = 30 ms, FA = 68°, FOV = 204 × 204 mm, voxel size = 3 mm × 3 mm × 3 mm, volumes = 750, MBAccFactor = 2, iPAT = 0, phase encoding direction antero-posterior) and two spin echo-EPI acquisitions with reverse phase encoding (TR = 4200 ms, TE = 70 ms, FOV = 204 × 204 mm, voxel size = 3 mm × 3 mm × 3 mm, MBAccFactor = 1) for EPI distortion correction purposes[6].

Concerning the control cohort, resting-state fMRI scans (TR=1.400 ms, TE=39.4 ms, flip angle=69°, FOV=202x202 mm, voxel size=2.3x2.3x.2.3 mm, volumes=657, MBAccFactor=4) of 76 healthy subjects (age- and gender-balanced) were retrieved from the publicly available MPI-Leipzig Mind-Brain-Body dataset[17].

A. Tumour segmentation

For the MRI perspective, the regions affected by the tumour can be distinguished into four distinct subareas: the necrosis; the core of the tumour divided into the highly active region and the moderately active region, and the cerebral edema. Globally, this set of areas is called lesion areas, whereas the tumour consists in the first three subareas[6].

In order to exclude areas that are directly affected by the tumour (e.g., interested by necrosis), a lesion mask was manually delineated [6] and employed to disregard grey-matter voxels overlapping with the affected areas in the following rs-fMRI analysis.

B. Data preprocessing

Firstly, the canonical pre-processing of rs-fMRI data was performed as described in [6]. In addition, voxel-wise high pass filtering was applied, followed by the regression of spurious variance related to scanner artifacts by means of an ICA-based approach[6]. Moreover, the first 5 principal components related to cerebro-spinal fluid and white matter signal were regressed out from rs-fMRI timeseries, as well as head-motion parameters and the associated derivatives.

Then, fMRI signals were projected onto a 100-area cortical parcellation provided by Schaefer et al.[18]. Parcels were organized in 7 cortical large-scale Resting State Networks (RSNs). Volume despiking was then applied in order to reduce the contribution of large spikes signals that could deteriorate the accuracy of volume registration and performances of sparse DCM. After the despiking step, the timeseries were temporally filtered at ROI level with a band-pass Butterworth filter, keeping frequencies in the band 0.0078-0.2 Hz to retain the range of frequencies that is usually supported by the canonical HRF in the DCM framework[19], [20].

C. Definition of the atlas

Applying the sparse DCM algorithm is computationally demanding, thus the total number of nodes considered as inputs were reduced through a consensus clustering approach[21]. Of note, the clustering regarded only parcels that were functionally homogeneous (i.e. belonging to the same RSN) and spatially contiguous in order to preserve the spatial consistency of the hemodynamic properties. As a result, data were projected to a reduced space consisting of 62 cortical regions (henceforth referred as Schaefer62).

D. Sparse DCM

Sparse DCM allows estimating whole-brain effective connectivity from resting-state fMRI data through discretization of the original non-linear continuous-time model and statistical linearization of the hemodynamic response function, which generates a Gaussian prior on the HRF that can be later exploited for model inversion. This allows us to better exploit the low temporal resolution of fMRI scanners and decrease the computational burden without losing statistical performance. Moreover, following the Sparse Bayesian learning approach, this method is based on a sparsity-inducing prior formulated on the matrix describing the effective connectivity network, allowing the automatic pruning of irrelevant EC connections without requiring any post-hoc model selection[12]. Details of the inference method can be found in [12]. The application of sparse DCM yields a weighted sparse matrix of EC connections (including both positive and negative entries) and parcel-wise linear estimate of the hemodynamic response function for each subject.

E. Gradient analysis

Fig. 1 shows the workflow of the analyses. Sparse DCM has been first applied to the pre-processed rs-fMRI signal to obtain the EC matrices for each subject.

Analysis by gradients is performed to summarize the behavior of the network. Given the asymmetric nature of the EC matrix, both the effect that the link has on the node (incoming) and on the network (outgoing) were considered. Consequently, the method is applied separately in order to obtain, from the EC matrices, two separate affinity matrices A_{ij} (for incoming and outgoing) through a gaussian kernel.

The procedure of graph embedding through connectivity gradients requires as first step the computation of the graph Laplacian(1):

$$L_{ij} = k_i \delta_{ij} - A_{ij} \quad (1)$$

By summing a row of the affinity matrix A_{ij}, we obtain the degree of the corresponding node (k_{ij}) and by entering these values in a diagonal matrix it is possible to obtain the graph Laplacian.

From the L matrix, the eigenvectors (i.e., gradients) and corresponding eigenvalues can be obtained. Gradients computed separately for two or more individual datasets may not be directly comparable[14], thus Procrustes alignment was computed to improve comparability and correspondence across subjects.

More specifically, the computation of EC gradients was done using BrainSpace v0.2.1 Matlab toolbox, which implements various approaches to build macroscale gradients from neuroimaging and connectome data[14].

Specifically, two metrics were considered to evaluate the distributions of subjects in the space spanned by the first 3 gradients[22] proved to be those underlying the organization of intrinsic functional connectivity within the human cerebral cortex. The silhouette coefficient (SC) was evaluated for each 3D point (which represents respectively the first, second and third gradient) by considering each parcel across subjects as a cluster, both for controls and patients. This metric gives information about how a specific parcel is similar to the other parcels within that parcel/cluster (cohesion), compared to the parcels composing the other parcels/clusters (separation).

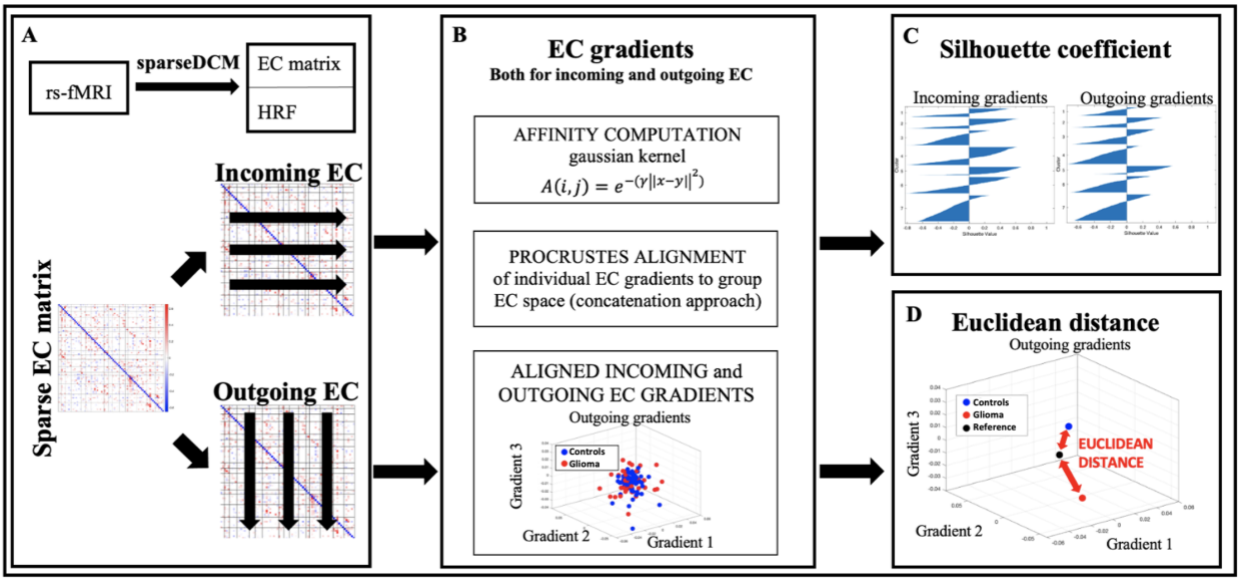

Fig. 1: Workflow of the key processing steps. Resting-state fMRI signal was provided as input to sparse DCM, which allows inferring the hemodynamic response function (HRF) and the effective connectivity (EC) matrix for each individual (panel A). By employing the Brainspace toolbox[14], Laplacian eigenmaps were inferred from each incoming/outgoing affinity matrix computed through a gaussian kernel. Procrustes alignment[14] was employed to align individual gradients to a common reference space identified by the concatenated EC gradients of the 76 healthy subjects[17]. Thus, incoming and outgoing aligned gradients are obtained for each control and glioma subject, reported in panel B for the outgoing gradients of the Vis1 parcel of the 76 controls and 47 pathological patients. Then, the silhouette coefficient was evaluated for each individual point (region in a 3D space), by considering each region across subjects as a distinct cluster (panel C). The final step regarded the computation of the Euclidean distance of each region between each subject and the corresponding reference point (panel D).

A subsequent analysis regarded the computation of the Euclidean distance for each parcel, which was carried out: 1st) by computing the pairwise distance between each individual gradient value and the reference point (i.e., the gradients of 76 controls' concatenated EC matrices); 2nd) by then comparing the distributions across control and oncological patients. For both metrics, differences between the two groups in each parcel have been assessed through t-test (significance level 5%, Holm-Bonferroni correction for multiple comparisons).

III. Results

The matrices in Fig. 2 show the percentage of directed links for control and oncological subjects for each entry. It is worth noticing that the intra-hemisphere profile of connections and inter-hemispheric diagonals are preserved, although the values for pathological subjects turn out to be scaled in terms of percentage magnitude. Therefore, the global structure of connections is preserved despite the presence of the lesion (Pearson's correlation of upper triangles: 0.928, lower triangles: 0.927), and allows the comparison of patients with healthy controls at a more specific single-parcel level.

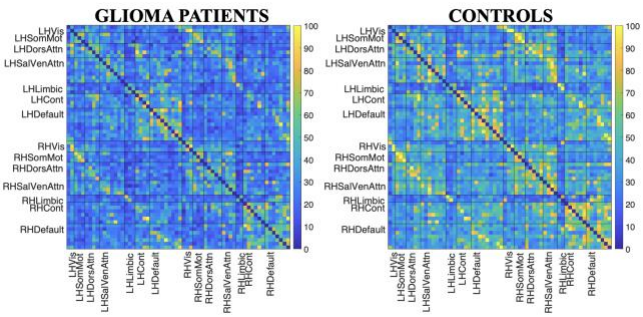

Fig. 2: Effective connectivity matrices reporting the percentage of directed links in oncological and control subjects.

The upper part of Fig. 3 shows the parcels revealing statistically significant differences in both silhouette coefficient and Euclidean distance gradients values between the two datasets.

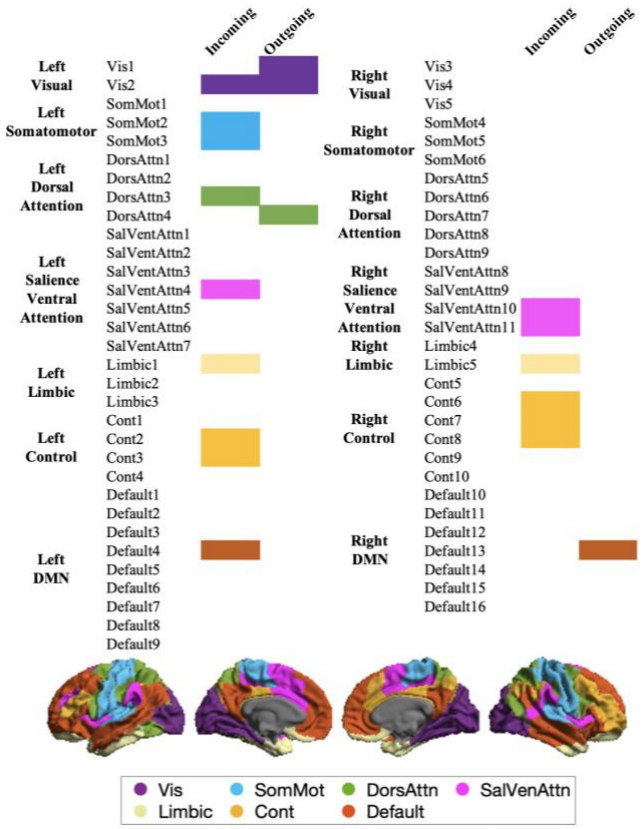

Fig. 3: Statistically significant parcels divided according to left/right network between control and oncological subjects and spatial distribution of the 7 Resting-State Networks (RSNs). Vis, visual network; SomMot, somatomotor network; DorsAttn, dorsal attention network; SalVenAttn, salience ventral attention network; Cont, control network; DMN, default mode network.

For incoming gradients, significant differences were found in parcels of all the 7 left networks, while in the right-hand side, differences are found only in the Salience Ventral Attention, Limbic and Control network.
For outgoing gradients, differences were found in all the left visual parcels, left Dorsal Attention and right DMN.
Specifically, DorsAttn3, SalVentAttn10, Cont6, Cont7 and Cont8 parcels, which result as the regions with the highest tumour overlap across subjects, revealed altered connectivity profiles only on incoming links. Nevertheless, there are also regions with a high tumour overlap that do not show any obvious alteration from such analyses, and whose role within the network needs to be further in deep investigated in future studies.

IV. Conclusions

The introduction of the notion of directionality as incoming and outgoing connections allowed us to interpret the altered nature of the communication flow associated with each RSN and region, and to unveil the altered topographic organization of large-scale brain organization in presence of brain gliomas[13]. For incoming gradients, differences between patients and controls resulted in visual, salience and control networks confirming the impact of the lesion as highlighted in [6]. Consequently, the information obtained from the incoming EC is similar to that of the FC, since the altered parcels belong to networks that appear to be impaired in both analyses.

At the parcel level we observed a hemispheric unbalance in the localization of regions that are statistically significant on the basis of the analysis computed, which may be due to the spatial heterogeneity of the tumour across subjects (24 left, 15 right and 8 bilateral lesion), and due to the fact that in healthy subjects the left hemisphere is more modular, thus presents groups of parcels with strong internal cohesion, and high separation between them[23]. This difference between the two hemispheres means that the effect of the tumour could be more evident in the left hemisphere's parcels, translating into an alteration of this cerebral organization that provides more heterogeneity between subjects (silhouette coefficient analysis), and in the distance from the reference (euclidean distance analysis).

Concerning outgoing gradients, only a few regions in visual, dorsal attention and default networks revealed statistical differences. These results also provide new insights into the key role of outgoing links in both Dorsal Attention (frequently activated in relation to other active brain networks) and Default Mode Network (DMN). Interestingly, both incoming and outgoing DMN links are compromised, which reveals a loss of connectivity investigated introducing links' directionality due to disruption of the connections, confirming the dual nature of that network[24].

In addition to regions with a non null intersection with the tumour mask that we expected to have an altered behavior due to the direct effect of the tumour, even parcels with no overlap with the lesion are altered, which can be explained by the widespread effect of the tumour even on regions that should have a potentially healthy profile.

***Abstract*— Functional hubs, defined from BOLD studies as brain regions with a large number of connections, have a crucial role in the integration and flow of information within the brain network. Furthermore, the functional configuration of hubs is correlated with individual cognitive performance and shows alterations in many neuropsychiatric disorders. However, how the spatial distribution of hubs depend on different choices in the analysis of the BOLD signal has not been extensively explored. Here we studied the influence of two major factors: the brain parcellation pattern and the spectral filtering strategy. Our findings suggest that they both affect the results. In addition, the organisation of brain network is strongly compromised when the BOLD signal does not contain the 0.01-0.05 Hz frequency range.**

***Keywords*— rsfMRI, hubs, brain parcellations, frequency bands.**

I. INTRODUCTION

Resting-state functional magnetic resonance imaging (rsfMRI) acquisitions are widely used in studies of brain functional connectivity (FC), defined as the zero-lag correlation between the BOLD (Blood Oxygenation Level Dependent) signal of spatially distant brain parcels [1]. For this purpose, volume parcellation by applying neural atlases is used [2]. Furthermore, before the FC estimation, the measured signal, BOLD signal, is filtered while generally keeping 0.01-0.1 Hz or 0.01-0.2 Hz frequency bands. This because BOLD needs to be cleaned by the contribution of the dominant noise source, and assuming that the frequency content due to the neural activity is below 0.15/0.2 Hz, while, the systemic components related to heartbeat and respiration, which represent background noise, have a frequency below 0.01 Hz [3].

In connectomics studies, the graph theory is a frequently used approach to investigate the brain network starting from FC maps, allowing functional hubs to be identified. These are regions that play crucial roles in the transmission and integration of information throughout the brain. Several studies have investigated how the spatial configuration of the hubs is linked to individual cognitive performance and that an alteration is found in many brain disorders [4].

To the best of our knowledge, little is known about the impact on hubs distribution of applying different atlases for brain parcellation [5] and filtering the temporal signal in different frequency bands [6]. Indeed, reliable network metrics are essential for inferring convincing conclusions from clinical studies and a precise identification of hubs patterns could provide rich insights into the mechanisms underlying cognition and brain disorders.

Therefore, the aim of this work is to simultaneously investigate the influence of the atlas choice and filtering of the temporal signal in different frequency bands in characterizing the spatial distribution of hubs. At the same time, an analysis of the brain networks modularity is carried out to assess which frequency bands most influence the brain organization.

II. MATERIALS AND METHODS

A. Materials

The dataset consists of 28 healthy subjects undergoing rsfMRI acquisition (Siemens 3T Biograph mMR scanner, equipped with standard head-neck coil) from two studies, *dataset A* [7] and *dataset B* [8], merged as no statistically significant difference was found [9]. During the scans, participants were instructed to remain lying down, with their eyes open and without doing any kind of activity.

Dataset A includes 11 subjects (3 F., age 52.2 ± 10.4), for each of them the rsfMRI data comprises 300 volumes acquired with gradient-echo planar imaging (GE-EPI) T2* (TR/TE=2000/30 ms and voxel-size=3x3x3.6 mm^3).

Dataset B includes 17 subjects (11 F., age 64.7 ± 7.9) with a rsfMRI data that comprises 240 GE-EPI T2* volumes (TR/TE=1920/32 ms and voxel-size=4x4x4 mm^3).

For each participant a magnetization prepared rapid acquisition gradient (MPRAGE) T1w structural image was acquired (voxel-size=1x1x1 mm^3).

B. Methods

The subjects' T1w images were bias field corrected using ANTs [10] and segmented into gray (GM) and white (WM) matter and cerebrospinal fluid (CSF) using SPM12 tool (https://www.fil.ion.ucl.ac.uk/spm/). Binarized probability maps (threshold=0.95) were linearly registered to the individual EPI space using ANTs. For each participant, the functional data were pre-processed with an FSL-based [11] in-house pipeline which included slice timing, geometric distortions, and motion corrections. In addition, further sources of noise such as white matter (WM) and cerebrospinal fluid (CSF) signals were regressed out.

To evaluate the effect of the parcellation, two atlases (3 different parcellation schemes) are tested: the AAL2 [12] and the Schaefer 7 Network at 100 and 200 parcels [13] integrated with subcortical regions from AAL2 and cerebellar functional regions from Buckner atlas [14], since the Schaefer only maps cortical area. These atlases differ in the principle used to outline their regions. In fact, the AAL2 atlas is anatomical, whereas the Schaefer and Buckner atlases are functional. The Fig. 1 shows few axial slices of the atlases used. For each parcel, the mean BOLD signal is extracted by averaging the rsfMRI data of all included voxels belonging to GM. In order

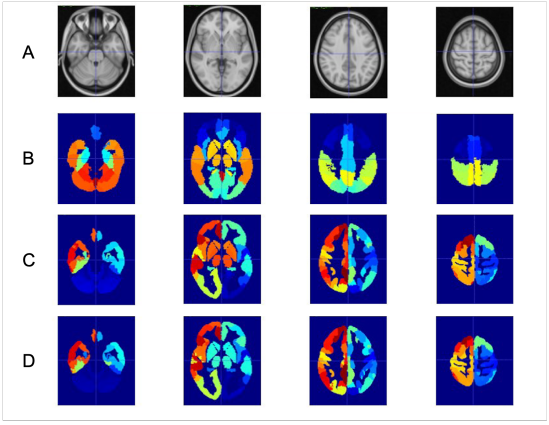

Fig. 1: (A) Structural image; (B) AAL2 atlas; (C) Schaefer 100 atlas, plus AAL2 for subcortical and Buckner for cerebellum; (D) Schaefer 200 atlas, plus AAL2 for subcortical and Buckner for cerebellum. Axial view from bottom to top.

to assess the effect on the hub regions distribution due to the frequency bands analyzed, mean BOLD signals are filtered as in [6] exploiting: 1) "canonical" bands, generally studied in literature to extract neural activity, and 2) "sub-bands" defined by dividing the entire spectrum into regular intervals of 0.05 Hz. In particular, the filter chosen is the Chebyschev type 2, with a pass-band ripple of 95%, a stop-band ripple of 5%, while transition region of 8%.

Namely, "canonical" bands are: 0.01-0.1 Hz (F1), 0.01-0.2 Hz (F2), 0.01 Hz (F3, high pass only); "sub-bands": 0.01-0.05 Hz (F4), 0.05-0.1 Hz (F5), 0.1-0.15 Hz (F6), 0.15-0.2 Hz (F7), 0.2-0.24 Hz (F8).

Next, for each subject the FC matrix is obtained by applying Pearson's correlation between the time courses of parcel pairs and z-Fischer transform. The procedure is done for each of the atlases considered and at each of the frequency bands.

In order to simplify the comparison and improve the signal-to-noise ratio, the average group matrices are calculated across subjects, therefore subsequent analyses are performed on these matrices. A binarization is applied to each matrix by defining a threshold at the 80th percentile to maintain only the most relevant interregional (positive) links in terms of functional connectivity. The node degree is calculated for each region as the total number of its connections after the application of the threshold and hubs as the 10% of nodes with the highest degree [4].

To assess the effect of the frequency, the Pearson's correlation between hub spatial distribution obtained in different bands within the same atlas is calculated. In addition, the modularity of each full FC matrix, which refers to the set of subnetworks or distinct communities that exist within the network, is investigated. Here we used the Louvain [15] implementation available in the Brain Connectivity Toolbox (http://www.brain-connectivity-toolbox.net). Finally, to evaluate the effect of parcellation, the dice coefficient between hubs spatial maps of atlas pairs within the same frequency is computed.

III. RESULTS

Fig. 2 shows the hubs distribution for each frequency band and parcellation scheme and the matrix of correlation coefficients between these distributions at different bands, within the same atlas.

The hubs pattern is similar (Fig. 2, panel A) when comparing the "canonical" bands F1 (0.01-0.1 Hz), F2 (0.01-0.2 Hz) and F3 (> 0.01 Hz, High-Pass only), but also the first "sub-band" F4 (0.01-0.05 Hz). Confirming the similarities, the correlation coefficients are significantly high (Fig. 2, panel B). Considering these bands, in AAL2 the hubs are located predominantly in the Cingulate Medial and Temporal Area,

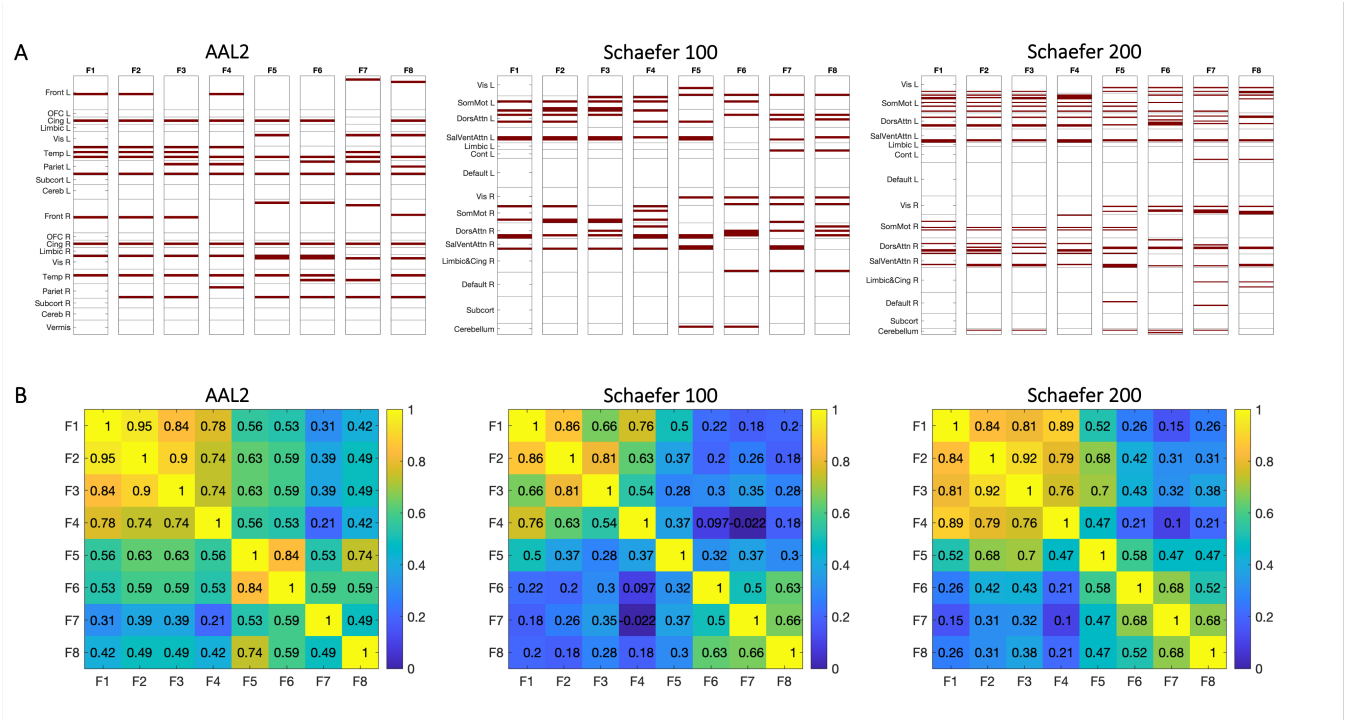

Fig. 2: (A) Distribution of hub regions in the three parcellation schemes and for each band; (B) Pearson's correlation coefficient matrices between the hubs' spatial distributions of pairs of bands. F1, F2, F3 and F4 show extremely high correlation values of hub distributions ($p < 0.05$).

whereas in both Schaefer 100 and 200 the hubs are located mainly in the in the Somato-motor Area and Dorsal Attention.

As the higher frequency bands are analyzed, the distribution of the hubs varies. F5 (0.05-0.1 Hz) and F6 (0.1-0.15 Hz), especially in AAL2 and Schaefer 200, have a similar distribution to each other, and show only partial variation in hub regions compared to the "canonical" bands and F4. The analyses of correlation coefficients confirm this finding, revealing a moderate correlation values. Then, analyzing the distribution of hub regions in the higher frequency bands F7 (0.15-0.2 Hz) and F8 (0.2-0.24 Hz), it is evident that only a few regions are preserved as hubs compared to the "canonical" bands. Pearson's coefficients confirm these results revealing the absence of correlation.

From the full FC matrices (Fig. 3 shows functional connectivity matrices only for the F1, F5 and F8 bands), the *Louvain modularity* values are derived for each parcellation pattern and frequency band (Table I).

TABLE I: LOUVAIN MODULARITY VALUES FOR EACH FC MATRIX

	F1	*F2*	*F3*	*F4*	*F5*	*F6*	*F7*	*F8*
AAL2	0.16	0.15	0.14	0.17	0.14	0.12	0.11	0.09
Sch100	0.17	0.16	0.15	0.18	0.14	0.12	0.10	0.09
Sch200	0.17	0.16	0.16	0.19	0.14	0.12	0.10	0.09

Louvain modularity of each FC matrix obtained for each parcellation and in each frequency band.

The matrix with the highest modularity is that obtained in F4, closely followed by "canonical" bands. Instead, considering higher frequency bands, from F5 the modularity progressively decreases, until it reaches its lowest value at F8. These results are consistent across the three parcellations.

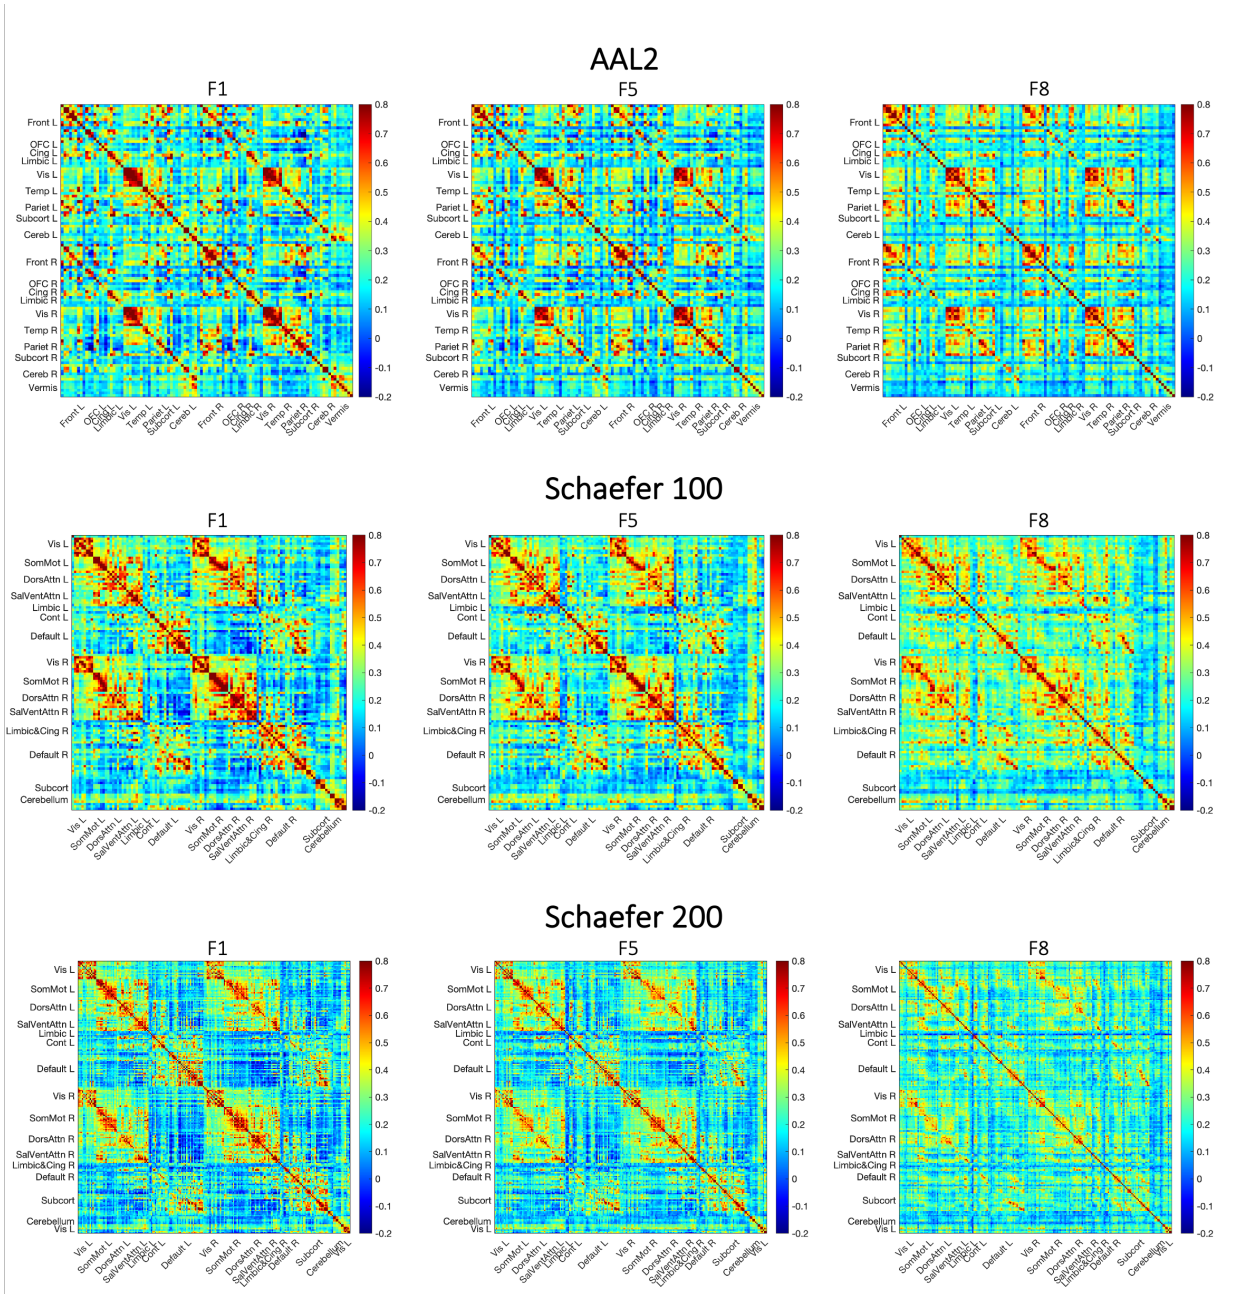

Fig. 3: FC matrices for the three parcellations schemes (AAL2, Schaefer 100 and Schaefer 200) and F1 (0.01-0.1 Hz), F5 (0.05-0.1 Hz) and F8 (0.2-0.24 Hz) bands.

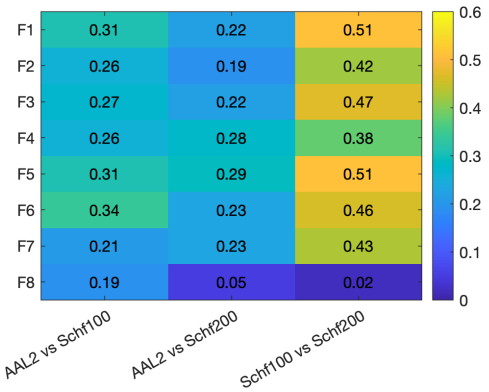

Fig.4: Values of dice coefficient between the hubs spatial maps of pairs of atlases while keeping the frequency band fixed.

To evaluate the effect of the parcellation, Fig. 4 shows the matrix of dice coefficients between the hubs' spatial maps of pairs of atlases, at a fixed frequency. Low similarities emerge, particularly when comparing AAL2 and Schaefer.

IV. DISCUSSION

Assessing the effect of the analyzed frequency bands, from the results obtained it is evident that in terms of both the spatial distribution of the hubs and the modularity, the bands containing the 0.01-0.05 Hz range (i.e., F1, F2, F3 and F4) have similar behavior. Considering the bands from F5 to F8, the spatial distribution of the hubs differs, and the modularity values progressively decrease. These discrepancies suggest that a large part of the contribution due to the description of the neuronal activity organization is already in the 0.01-0.05 Hz (i.e., in F4) and in the frequency bands containing this range.

When evaluating the effect of the parcellation scheme, the low similarity results are probably due to the different way of defining regions in the atlases: AAL2 was designed on the basis of the anatomical characteristics of each region, whereas the Schaefer atlas is functional and therefore regions were obtained by grouping voxels on the basis of appropriate functional homogeneity criteria.

V. CONCLUSION

The aim of this work is to assess whether the atlas used for the parcellation and the frequencies at which the rsfMRI signal is analyzed affect the distribution of brain regions with a central role in the brain network, i.e., functional hubs. From the results obtained, it is clear that both the parcellation using two different atlases and the extraction of the BOLD signal at different frequencies cause a variation in the functional connectivity detected and, consequently, in the spatial distribution of the hubs. In a connectivity study, therefore, the choice of atlas cannot be made exclusively based on those that are most widely used in the literature (e.g., AAL2), as this has a strong influence on the final results. In particular, due consideration must be given to the choice of an anatomical or functional atlas according to the final purpose. Concerning the effect of frequency, papers in literature that have investigated the impact of BOLD signal analysis in different frequency bands, e.g. [6], suggests that even at high frequency bands (not containing 0.01-0.05 Hz) there are significant functional hubs and network organization. However, we introduced an analysis of the modularity of brain networks to assess which frequency bands most influence brain organization. In contrast to previous findings, our results support that considering frequency bands that do not include 0.01-0.05 Hz leads to brain network disruption. Thus, the greatest contribution related to neuronal activity emerges in 0.01-0.05 Hz and in the bands containing this range (F1-F4) which reflect good spatial agreement in the pattern of hubs and similar modularity values. The disaggregation that instead emerges in the remaining bands is probably because this part of the signal starts to be strongly influenced by the presence of slow hemodynamic function information, thus driven by a purely vascular component.

ACKNOWLEDGEMENT

The authors would like to thank Dr. Valentin Riedl for making *dataset A* available.

***Abstract*— Epicardial Adipose Tissue (EAT) is a visceral fat depot whose local effects on cardiac function are incorporated into the complex pathomechanism of coronary artery disease, atrial fibrillation, and heart failure. The aim of this study is to create a radiomic signature to assess the hospitalization risk of 261 patients, from EAT cardiac magnetic resonance-based radiomics. 107 radiomic features were extracted from EAT segmented images and their robustness was assessed by means of ROI translations and intraclass correlation coefficient computation. Robust features were subjected to further selection steps comprising a statistical test and a univariate Cox regression model. Selected features were used to create the radiomic signature, testing three survival models: Cox Proportional Hazard (CPH) regression, random survival forest (RSF), and deep survival analysis (DeepSurv). Leave-one-out cross-validation was performed to build Kaplan-Meier curves and evaluate models' performances. Ten clinical variables were then added to the analysis to test that radiomic signature maintained its significative prognostic value. 56 radiomic features were identified as robust and two textural features, Gray Level Non-Uniformity Normalized and Cluster Shade, were kept to create the radiomic signature. CPH and DeepSurv significantly identified patients with a high risk of hospitalization. Fitting the CPH model with radiomic and clinical features, radiomic signature coefficients remained significant (p=0.04). In conclusion, results achieved in this study have shown that EAT-based radiomics could be a promising tool in assessing patient hospitalization risk.**

***Keywords*—Epicardial Adipose Tissue, radiomics, Survival models**

I. Introduction

Epicardial Adipose tissue (EAT) refers to the fat depot that exists between the surface of the myocardium and visceral layer of pericardium. Due to its biological activity, EAT has been suggested to have a role in the progression and development of leading causes of morbidity and mortality such as coronary artery disease (CAD), atrial fibrillation and heart failure [1]. Mancio et al. [2] provided a systematic review and meta-analysis reporting a significantly higher EAT level in subjects who experienced coronary stenosis, coronary calcification, myocardial ischemia or MACE (major adverse cardiac events. Also, EAT thickness and volume have been found to be a potential substrate for the pathogenesis of atrial fibrillation [1].

Radiomics is a rapidly developing field which allows the extraction and analysis of quantitative data from medical images. Radiomics have been widely employed in oncology, but it has gained increasing interest for the diagnosis and prognosis of cardiovascular disease.

Actually, literature reports only a few studies employing radiomic features extracted from EAT, but all of them have shown promising results in classifying and predicting atrial fibrillation [3]-[4]-[5]-[6]. In [3], a machine learning model using EAT radiomic features can distinguish patients with atrial fibrillation from those with normal sinus rhythm reaching high diagnostic performance: an AUC of 0.92 and 0.85 were achieved in the test cohorts of contrast-enhanced and non-enhanced scans, respectively. The study conducted in [4] built a radiomic model, using CT-based radiomic features extracted from EAT, whose performance achieved an area under the curve of 0.80 for discrimination between patients with post-operative atrial fibrillation and sinus rhythm. Yang et al. [5] has shown the power of left atrium EAT radiomic signature in differentiating atrial fibrillation subtype by developing a predictive model which integrates radiomic features and volume information to differentiate AF subtype. This model has provided an AUC of 0.853 in the validation cohort. In [4], textural features have been found to be a stronger predictor of lone AF recurrence compared with other established risk factors and EAT volume and attenuation.

This work aims at developing a radiomic signature to improve hospitalization risk assessment for cardiac reasons, using CMR (cardiac magnetic resonance) based radiomic features extracted from EAT.

II. Materials and methods

A. Study population

This study includes 261 consecutive patients, referred to perform clinically indicated dipyridamole stress CMR (Cardiovascular Magnetic Resonance) for suspected or known CAD between January 2011 and December 2014 at Centro Cardiologico Monzino (Milan, Italy). Clinical characteristics are shown in Table I.

B. Image acquisition

CMR has been performed with a 1.5-T unit (Discovery MR 450; GE Healthcare, Milwaukee, Wisconsin, USA). Breath-hold, steady-state free-precession cine imaging have been performed in vertical and horizontal long-axes and in short-axis orientations. A stack of short-axis slices encompassing both ventricles from base-to-apex has been used for biventricular volumes, mass, and systolic function assessment.

A contrast-enhanced breathhold segmented T1-weighted inversion- recovery gradient-echo sequence has been used for myocardial fibrosis using the late gadolinium enhancement

(LGE) imaging technique. LGE imaging has been performed 10–20 min after an intravenous bolus of 0.1 mmol/kg Gadobutrol (Gadovist; Bayer Schering Pharma AG, Berlin-Wedding, Germany). Inversion time has been individually adapted to null the signal of remote myocardium (usual range 220–30).

TABLE I: CLINICAL VARIABLES (MEAN ± STANDARD DEVIATION OR NUMBER OF PATIENTS/TOTAL NUMBER OF PATIENTS)

Features	*Hospitalized*	*Non-Hospitalized*	*Total*
Age	64.67 ± 9.63	63.08 ± 10.42	63.79 ± 10.07
Body Mass Index	25.81 ± 3.70	27.08 ± 3.54	26.49 ± 3.66
CMR Left Ventricular Ejection Fraction (%)	55.83 ± 13.11	56.45 ± 11.44	56.16 ± 12.23
Sex (F/M)	15/107	23/116	38/223
Familiar History (y/n)	30/83	30/96	60/179
Smoking (y/n)	45/68	45/81	90/149

C. Image Processing

EAT was manually segmented by expert radiologists.

Image pre-processing was performed to denoise images using a 3D Gaussian filter with a 3x3x3 voxel kernel and σ=0.5. Intensity-non uniformities were corrected using the N4ITK algorithm and intensity standardization was performed with z-score. Finally, B-spline interpolation was employed to resample the voxel size to a 2 mm isotropic resolution. MATLAB R2017a (MathWorks, Natick, MA, USA) was used to perform all the previous steps.

D. Radiomic Features Extraction

107 radiomic features were extracted from patients EAT, using Pyradiomics 3.0 [7]. Features pertain to three main classes: Shape and Size (14 Features), First Order Statistics (18 Features), and Textural features including GLCM (24 features), GLRLM (16 features), GLSZM (16 features), NGTDM (5 features) and GLDM (14 features). The full list of radiomic features is available in the Pyradiomics Python package documentation [7], [8]. A fixed-bin width histogram discretization (32 bins) was used prior to features extraction.

Since features were extracted with Pyradiomics, they were compatible with the Image Biomarker Standardization Initiative (IBSI).

E. Features Selection

A three step features selection was applied to radiomic features previously scaled with z-score normalization.

Geometrical translation method described in [9] were performed to assess features robustness. A minimal entity translation, corresponding to 0.5% of the length of the bounding box surrounding the ROI, was chosen to test features stability, while a maximal entity translation of 30% of the length of the bounding box surrounding the ROI, was considered to evaluate features discrimination capacity. Robust features were then selected by computing the Intraclass Correlation Coefficient (ICC) between the original and the translated ROI. According to the general guidelines reported in [10] two ICC threshold were set: 0.75 for ICC related to minimal entity translation (ICC_{min}) and 0.5 for ICC related to maximal entity translation (ICC_{max}). Features having an ICC_{min} higher than 0.75 and an ICC_{max} lower than 0.5 were considered robust, i.e., stable, and discriminative. Only first order statistic and textural features were subjected to robustness analysis since shape and size features of each ROI are kept constant throughout the geometrical transformations.

After this step, **Mann-Whitney U test** was applied to each feature, to identify features significantly different between the hospitalized and non-hospitalized patients.

Finally, a **univariate Cox regression model** was fitted for each of the selected feature, and p-value and Harrel's concordance index (C-index) were provided for each test. Features with coefficients not significantly different from 0 ($p>0.05$) were excluded from the analysis.

All the steps described in this paragraph were carried out using Python 3.7 [11].

F. Survival analysis models

In this work, three different survival models were tested: Cox Proportional Hazard (CPH) regression model [12], random survival forest (RSF) [13], and deep survival analysis (DeepSurv) [14].

CPH is a semi-parametric model that estimates the impact of observed variables on the risk of an event (e.g., hospitalization) occurring. The model assumes that covariate effects are additive and linear on the log risk scale: this assumption may often be an oversimplification for proper prognosis prediction.

RSF and DeepSurv models represent nonlinear alternatives to CPH.

RSF is an ensemble tree method for survival analysis which automatically assesses the complex effects and interactions among all variables.

DeepSurv is a nonlinear extension of the Cox proportional hazards model, based on a deep learning-based-survival prediction algorithm that uses a multi-layer feed-forward

network. It can model high-level interaction terms beyond the linear Cox model.

A Leave One Out Cross Validation (LOOCV) approach was used to estimate the performance of the three models. As a result, for each iteration, the test set contained only one observation, while the others were used as training.

The final feature set was used to train the three models for the risk of hospitalization. The features and regression coefficients of the optimal model were used to compute the radiomic signature, which for example for the CPH model was the linear combination of the selected features and the corresponding regression coefficients. At each LOOCV iteration the median signature in the training set was used as threshold to classify the test set subject into high and low risk groups (above and below the median, respectively). Finally, classified test set patients were gathered, and log-rank test was used to compare Kaplan-Meier curves of the two groups.

Last, ten clinical variables, reported in literature as relevant cardiovascular risk factors [15]-[16], were combined to the radiomic signature to train a CPH model. This step was performed to verify that clinical features integration did not affect the significance of radiomic signature prognostic value. Clinical variables included in the analysis are reported in Table I. Clinical data presented missing data, in a variable percentage, as shown in Table II. Missing data imputation was performed using the mode.

III. Results

A. Features selection

56 radiomic features were identified stable and discriminative after robustness analysis: 9 first-order statistic and 47 textural features. As a results, a total of 70 radiomic features, i.e., the 56 robust ones and the 14 shape-based features, were included in the further analysis.

Among the 70 selected features, four resulted statistically significant after Mann-Whitney U test: Gray Level Non-Uniformity Normalized (GLNUN), Cluster Shade, Gray Level Variance, Inverse Variance. All of them belong to the class of textual features.

Fitting the univariate Cox regression model, two of these features, Gray Level Non-Uniformity Normalized, Cluster Shade, were selected as their coefficient were significantly different from 0. P-values and C-index obtained from univariate Cox regression model are shown in Table III.

B. Survival models evaluation

The radiomic signature was obtained from the multivariate Cox model using the two features previously selected. The Kaplan-Meier curves for the final test set (obtained from LOOCV test patients merging) are shown in Fig.1. Both the Cox Proportional Hazard model and Deep Survival analysis model signature had a significant prognostic ability.

TABLE III: Univariate Cox model results

Feature	*P-value*	*C-Index*
Gray Level Non-Uniformity Normalized	0.049	0.553
Cluster Shade	0.040	0.558
Gray Level Variance	0.065	0.540
Inverse Variance	0.101	0.522

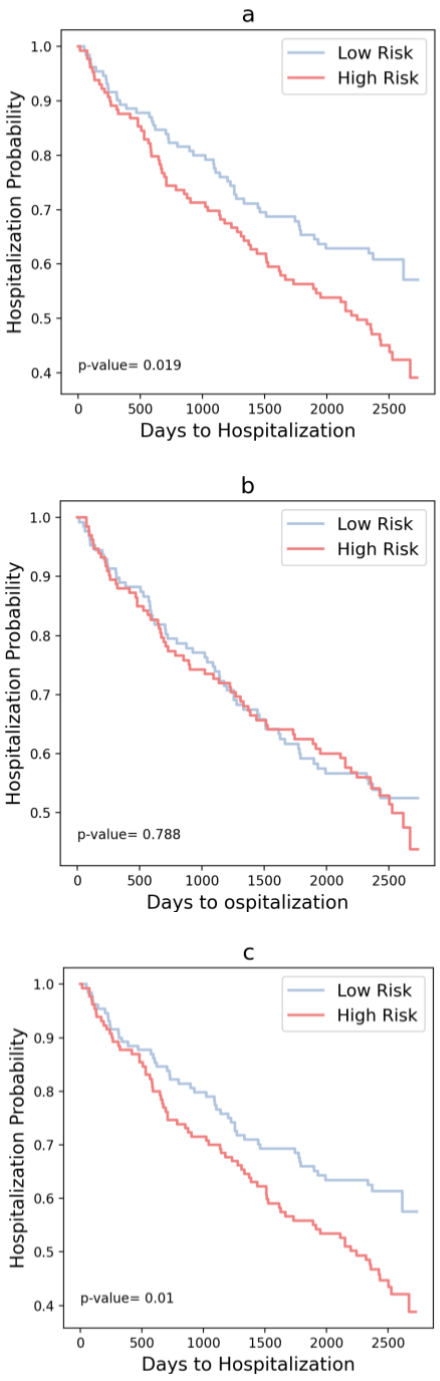

Fig. 1: Kaplan-Meier curves for the high and low risk groups obtained from (a) Cox Proportional Hazard, (b) Random Survival Forest and (c) Deep Survival analysis model signature.

Performing the log-rank test to compare the Kaplan-Meier curves obtained from CPH, RSF and DeepSurv, obtained p-values were 0.019, 0.788 and 0.01, respectively.

Finally, the results obtained fitting the CPH model with a combination of radiomic and clinical features confirmed the prognostic value of the signature (with a p-value of 0.04).

IV. Conclusion

In this work, a set of CMR based-radiomic features were extracted from EAT to investigate its association with hospitalization. The main finding of our study is that a radiomic signature can be created to divide a population into two groups according to the risk of hospitalization for cardiac reasons. Literature reports only a few studies employing CT-based radiomics features extracted from EAT [3]-[4]-[5]-[6] to investigate atrial fibrillation occurrence. To the best of our knowledge, this is the first study that developed a survival analysis model to study the relationship between EAT characteristics and hospitalization risk for cardiac reasons. Moreover, no previous studies on EAT have been performed their analysis using CMR-based radiomic features.

Also, a crucial point in the radiomic workflow is features robustness assessment as only stable and discriminative features should be used in prognostication or prediction models to improve their generalizability. Studies employing EAT radiomics models [4]-[5]-[6] have evaluated radiomic features by using repeated segmentation of the ROIs performed by multiple radiologists. Differently, in our study, features robustness has been assessed using the approach described in [9] based on ROIs geometrical translations. This method is less time-consuming than performing repeated segmentation and does not require many radiologists. In addition, small entity translations allow to evaluate features stability while large translations provide features discrimination capacity assessment.

Once identified, robust radiomic features have been selected according to their relevance with respect to the clinical question of interest. Differences in textural features, i.e., characteristics reflecting EAT graininess, uniformity, regularity, and roughness have been found to be more discriminative in dividing patients hospitalized and not hospitalized.

Thus, the radiomic signature was created for each patient testing three different survival models. DeepSurv and CPH models outperformed RSF showing a significative p-value in comparing the Kaplan Meier curves with a log-rank test. The radiomic signature remained predictive also when clinical covariates were added in the model.

The radiomic signature created in the study have included Gray Level Non-Uniformity Normalized and Cluster Shade: these texture characteristics can be signs of molecular peculiarities of adipose tissue, showing EAT dysfunction. In particular, in [6] changes of Gray Level Non-Uniformity Normalized have been suggested to be associated with morphological heterogeneity of the EAT caused by hypertrophy and hyperplasia of adipocytes, as well as by fibrotic changes.

However, one of the limits of this study is given by the lack of data on histological characteristics of EAT able to support radiomic analysis results.

Furthermore, the workflow developed in this study should be tested on different and larger dataset in order to validate the results achieved.

Despite these limitations, the results of this work were promising, indicating that the use of radiomics may be useful in investigating EAT characteristics to assess patient hospitalization risk.

***Abstract*—Augmented Reality (AR) is a technology that offers the possibility to overlap virtual objects on the real scene. In recent years, AR has been proposed and applied also in the medical field. In this study, we aimed to develop an AR application for Microsoft HoloLens 2 to be used for the evaluation of temporo-mandibular joint (TMJ) alterations in orthognathic patients. The actual procedures to diagnose TMJ alterations consist of direct palpation of the joint and/or execution of kinesiographic exam which allows to record the jaw movements. The developed AR application provides the projection of the reconstructed virtual underlying bony structures directly on the visible patient's head, thus facilitating the diagnostic evaluation of the surgeon.**

The AR application was tested on a volunteer during TMJ tasks of opening and closing of the mouth. During the tasks, video recordings were taken from the HoloLens cameras, and then they were processed by Matlab to derive the kinematic curves and values describing the jaw movements. The AR-derived TMJ trajectories were then compared with standard kinesiographic acquisitions.

The results demonstrated a good match between the AR-derived kinematics and kinesiographic curves. Future improvements are needed for the tracking modalities to allow more accurate quantification of the TMJ kinematics in the frontal view.

***Keywords*—Augmented Reality, 3D printing, image processing, orthognathic surgery, kinesiography, Microsoft HoloLens2.**

I. Introduction

Augmented Reality (AR) offers the possibility to overlap virtual contains on the real world, thus allowing the user to view hidden underlying structures and/or to have additional digital information useful for guiding a procedural task.

AR in medicine is a technology that expands on image-guided surgery, allowing intraoperative guidance and navigation. This technique integrates imaging information with the real-world surgical field to give the surgeon a sort of "x-ray vision" [1]. In recent years, AR technology has been proposed and applied in several medical fields, including neurosurgery [2,3], urology [4–7], orthopedics [8,9] and craniomaxillofacial surgery [10-15].

Several technologies have been proposed and used to perceive the augmented surgical field. Specifically, commercial optical see-through Head Mounted Displays (HMDs), such as Microsoft HoloLens (Microsoft, Redmond, WA), Google Glass (Google Inc., Mountain View, California, USA) and Magic Leap (Magic Leap, Plantation, Florida, USA) have been always more used to explore their applications in surgery.

In craniomaxillofacial surgery, the AR technology can be considered a promising tool in aiding complex surgical procedures but could represent an effective tool also for preoperative planning and diagnosis phase [16-19]. Particularly, some procedures performed routinely by surgeons to evaluate possible surgical options could be improved using the AR technology.

Temporo-mandibular joint (TMJ) articulates the mandible to the temporal bone glenoid fossa, through the mandibular condyles. TMJ is fundamental for the movements of the mandible, including chewing and speaking. The conventional diagnostic procedure for possible alterations of the TMJ kinematics involves both the clinical observation of the interincisive line during the opening and closing of the mouth and the direct palpation of the joint. However, during this clinical examination, the surgeon cannot directly see the underlying bony structures involved in the mandibular movements.

Another method to assess the TMJ kinematics is the kinesiographic exam, consisting of an electronic system designed to trace and record the mandibular movement in three dimensions [20]. Advantages over kinesiography can be provided by AR, since the surgeon has the possibility to directly see-through the anatomy of the patient, having a direct visualization of the joint superimposed on the patient's face.

The aim of this work was to develop and test an AR application for Microsoft HoloLens2 HMD, which allows the surgeon to directly see on the patient's face the digital reconstruction of the mandibular condyles and temporal bone glenoid fossa, involved in the execution of TMJ movements.

The trajectories of the mandibular movement were reconstructed from the video recordings taken with HoloLens cameras during the AR view, and then they were compared to the trajectories obtained from the kinesiographic exam.

II. Materials and Methods

In the following sections the development steps and the experimental phase are reported.

Image segmentation

Starting from the Computed Tomography (CT) scan of a volunteer, the skull, the mandible, and the head skin were segmented using D2P™ software (3D Systems Inc., Rock Hill, USA). Three-dimensional meshes were then generated from all the segmented masks and saved in Standard Tessellation Language (STL) format.

Virtual content preparation and 3D printing

The STL files were imported in Autodesk Meshmixer software (Autodesk Inc., CA, USA): the skull was cut to have only the temporal bone glenoid fossa. The developed AR application consisted of both the frontal and the lateral view of TMJ movements; for this reason, the STL file of the mandible was duplicated and cut symmetrically to have only the right branch for the lateral view. Some virtual spherical markers were added both on the mandible and the glenoid fossa, to have some landmarks in the video recordings for the further reconstruction of TMJ trajectories from AR view.

Moreover, the reconstructed mandible was used to design a patient-specific dental splint fitting the lower arch teeth of the subject. The splint was jointly connected to a QR-code, which was used for the real-time tracking of the mandible during TMJ movements (Figure 1.C).

The virtual splint was then produced with stereolitography 3D printer (Form3B, FormLabs, Somerville, MA, USA) using a biocompatible resin (Surgical guide, FormLabs, Somerville, MA, USA).

Development of the AR application

All virtual models (i.e. the glenoid fossa, the mandible, the head skin and the dental splint) were imported into Unity 3D software (Unity Technologies, San Francisco, CA, USA) extended with the Vuforia Engine Package (PTC Inc., Boston, MA, USA).

For the purposes of the study, the AR application had to recognize and track the movement of two different objects involved in the TMJ, i.e., the glenoid fossa and the mandible.

For this, two different tracking methods were implemented. For tracking the glenoid fossa, we used the "Model Target" tracking modality of Vuforia Engine, which allows a marker-less tracking of the object by recognizing its shape. In this case, the head skin model was used as Model Target for virtual-to-real scene registration of the glenoid fossa (Figure 2.A). For tracking the mandible, we chose the "Image Target" tracking modality of Vuforia Engine which is based on the recognition and tracking of a pre-defined image, in this case, the QR-code anchored to the dental splint (Figure 2.B). Working with these two tracking modalities, the movement of the mandible can be tracked continuously, and its position is displayed to the user wearing the HoloLens 2 HMD in relation to the fixed glenoid fossa (Figure 3).

Two different AR applications running on HoloLens 2 were created: one for the lateral view and one for the frontal view (Figure 3). Moreover, interactable user interface toggles (check boxes) were added to turn on/off the rendering of each virtual anatomical structure during the AR view.

Experimental Phase and processing of AR video recordings

First, the standard kinesiographic exam (Myotronics Kynesiograph K7, Harari MS, Milan, Italy) was executed on the volunteer. For the exam, the volunteer has to wear a mask, composed of sensors, which lay on the ears and nose, and a tiny magnet which is attached to the lower incisal gingiva with adhesive material (Figure 1).

Following the indications of the specialist, the volunteer performed the opening and closing jaw movements (i.e. TMJ task) five consecutive times. The mask registered in real-time the variations of the magnetic field during the movement of the magnet in the three space directions, and with these coordinates, graphic recordings of the TMJ opening/ closing paths were provided.

The AR application was then tested on the volunteer: both lateral and frontal views were tested to three-dimensionally evaluate the trajectory of the TMJ during the opening and closing of the mouth (TMJ tasks). The volunteer was asked to follow the same procedure of the kinesiographic exam, with the opening and closing of the mouth five consecutive times.

During each TMJ task, the video recordings of the AR view displayed to the user wearing the glasses were taken using the HoloLens 2 cameras. Then, the video frames were extracted and imported in Matlab App-Designer (R2019b, MathWorks, Natick, MA, USA). A Matlab script was created to recognize the mandible marker (see the pink sphere in Figure 3) in each video frame, and to plot the mandible trajectory during the TMJ tasks.

Fig. 1: Frontal view of the volunteer with the mask used during the kinesiographic exam.

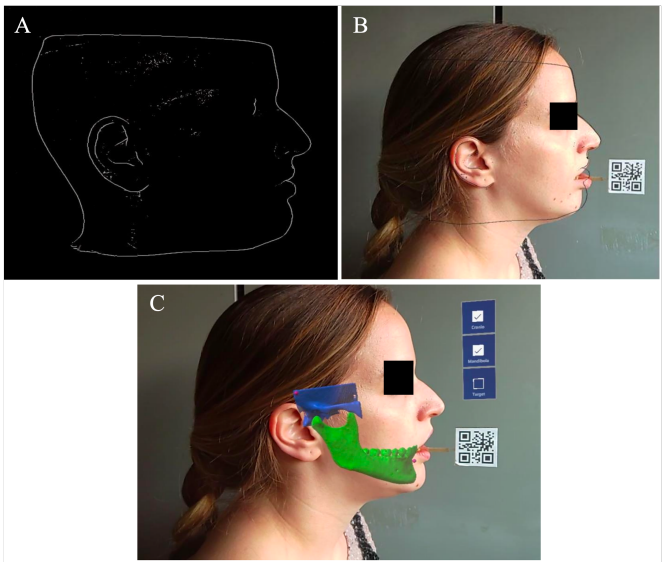

Fig. 2: A) Guide view of the Model Target tracking modality used for displaying the glenoid fossa, B) Image Target (QR-code) tracking modality used for tracking the moving mandible, C) Lateral AR view displayed from

the HoloLens 2 glasses: the fixed glenoid fossa (in blue) and the moving mandible (in green).

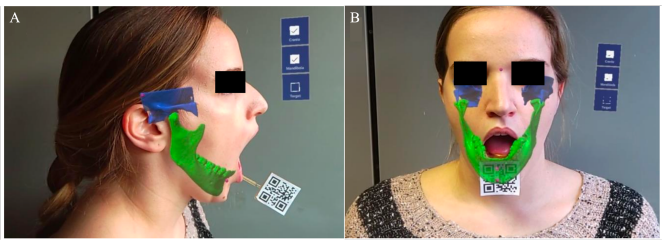

Fig. 3: Examples of AR views during the execution of TMJ tasks**:** A) Lateral view of the opening, B) Frontal view of the opening.

III. Results

The developed AR application demonstrated to work in a correct way, being able to track and display the anatomical structures of interest for evaluating the TMJ kinematics.

For the lateral view, the AR-derived trajectories of the opening and closing of the mouth showed a good match with the kinesiographic signals, both qualitatively and quantitively. Particularly considering the opening phase, we obtained a deviation of only 0.2 mm in the maximum vertical movement, and a deviation of 0.7 mm for the maximum horizontal movement, i.e. the posterior extension (Figure 4, black curve).

Regarding the frontal view, the AR application reproduced qualitatively the kinesiographic trajectory, while a considerable deviation was obtained for both the maximum vertical movement (6.5 mm) and the horizontal movement (2.1 mm), when considering the opening phase (Figure 5, black curve).

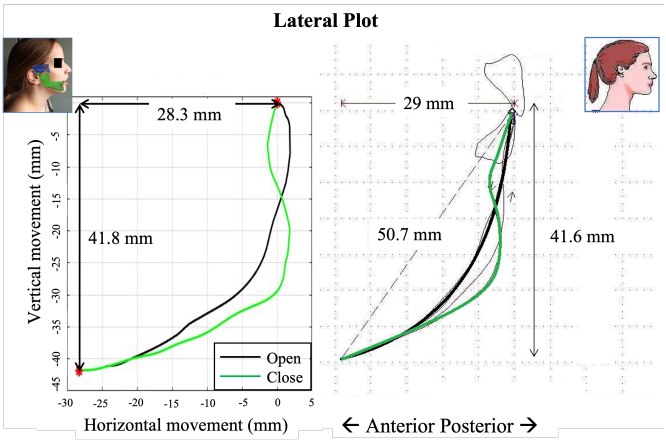

Fig. 4: Lateral plot of the opening and closing trajectories obtained from the AR video recordings (on the left) and from the kinesiographic exam (on the right).

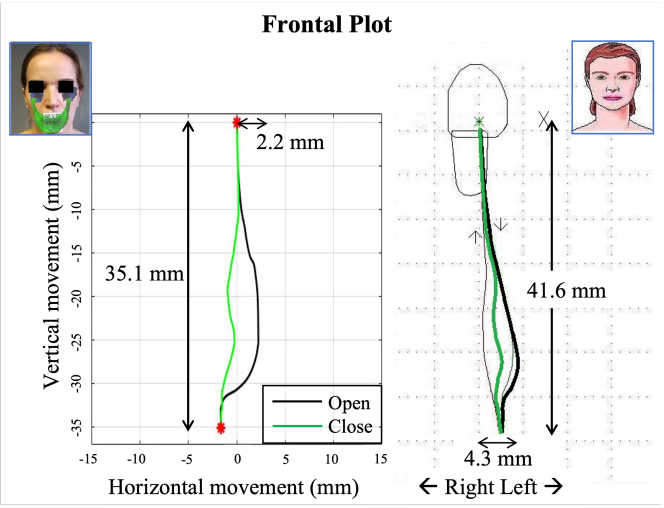

Fig. 5: Frontal plot of the opening and closing trajectories obtained from the AR video recordings (on the left) and from the kinesiographic exam (on the right).

IV. Discussion

This study aims to investigate the feasibility of an AR application for Microsoft HoloLens 2 as an additional tool to evaluate and diagnose any TMJ alterations. The developed AR application offers the advantage, over the currently used methods, to show the surgeon the underlying bony structures involved in the TMJ. Indeed, using the AR view, the surgeon may have a direct visualization of the joint superimposed on the patient's face.

Surely, as previously reported, critical points for this kind of application remain the depth perception [21] and the achievable accuracy of the virtual-to-real content registration [1, 22].

The experimental phase has shown the capability of the AR application to correctly visualize the virtual anatomical structures directly on the patient during the execution of the TMJ tasks. Particularly, the AR application was successful in tracking the moving mandible from an occlusion position to a maximum opening position and vice versa.

The trajectories obtained from the AR video recordings were qualitatively similar to the ones obtained from the kinesiographic exam. Particularly, these trajectories highlighted a non-completely symmetrical behavior between opening and closing (i.e., no overlapping of the trajectory during the opening and closing of the mouth), this suggesting a sub-optimal kinematics of the left TMJ.

Regarding the frontal view, the considerable deviation we obtained is probably due to the QR-code inclination during the mandibular movement. In fact, at the position of the maximum opening of the mouth, the QR-code no longer appears in a frontal position with respect to the observer, but is inclined; this results in a distortion of the perceived QR-code image target by the HMD cameras, which causes to lose tracking, therefore to detect a reduced vertical displacement.

Another limitation of the developed AR application regarded the speed of the performed movements: too fast opening or closing of the mouth may cause a loss of tracking, i.e., the misalignment between the virtual anatomical structures and the real scene, with consequent unreliable AR-derived

movements.
Future developments will investigate the use and accuracy of other tracking modalities that may provide more robust tracking of the moving mandible, to record the complete TMJ trajectory also in the frontal AR view. Indeed, it is extremely important to achieve the best alignment between the patient and the virtual structures, in order to avoid any effect of the rotations on the estimated kinematics.
Furthermore, it would be interesting to test the match between the AR and the reference kinematics on movements executed at different speeds. .
Finally, it could also be useful to implement a real-time quantification of the performed movement during the AR view. In this way, the surgeon could quantitatively assess in real-time the movement of interest, avoiding post-processing from videos recorded with the application.

V. Conclusion

In this study, we presented the development and preliminary testing of an AR application for Microsoft HoloLens 2, intended for the assessment of possible alterations in the TMJ. The system was tested on a volunteer during the opening and closing of the mouth: the TMJ trajectory derived from the AR application was compared to the one obtained from the kinesiographic exam. For the lateral view, the trajectories were highly comparable both qualitatively and quantitatively while for the frontal view, major deviations were found, probably due to a sub-optimal tracking modality of the moving mandible via the image target modality.
The tool seems to be promising and may represent an interesting alternative to kinesiographic exam.

***Abstract*— This study aimed at comparing the effectiveness of different Transfer Learning (TL) approaches to automatically classify intrapartum ultrasound (US) images of direct and transverse foetal occiput position.**

We prospectively evaluated women in the second stage of labour from 14 clinical centres and a total of 612 transperineal ultrasound (TPU) images of the foetal head in the sagittal plane were selected. All the images were classified as direct or transverse occiput position, by an expert gynaecologist, acting as a gold standard.

The approach of TL with ResNet-18 convolutional neural network (CNN) was used to address the scarcity of data. Cross-domain and cross-modal TL approaches were compared. To perform cross-modal TL, the ResNet-18 was pre-trained on a public large dataset of foetal ultrasound, and subsequently was re-trained on our dataset.

The cross-modal approach provided the best performances, with highest accuracy, Cohen's k and F1-score. Our approach could effectively compensate for the issue of data scarcity in medical imaging diagnostic. The developed model could be employed as medical diagnostic tool to facilitate the individuation of the foetal position and the decision-making in labour management.

***Keywords*—Deep learning, transfer learning, foetal ultrasound, medical imaging, automatic.**

I. Introduction

THE interest in employing convolutional neural network (CNN) models in the medical imaging and, in particular, in foetal ultrasound has strongly increased in the past decade.

The potentialities of Machine Learning in image classification, segmentation and identification of diseases in multiple medical field have been largely demonstrated in several biomedical applications [1]–[3]. However, the main limitation of Deep Learning (DL) application is represented by the huge amount of data required to properly train a neural network, an issue particularly relevant in medical imaging, where data availability is limited and collecting data is a long and laborious process. In this work we opted for using and comparing different approaches of Transfer Learning (TL) to overcome the lack of data. This technique consists of using a model pre-trained on a very large dataset (millions of images) to perform one task and re-training the model for the desired similar task. Depending on whether the target and source data belong or not to the same domain, TL can be performed cross-modal (es. source: medical images – target: medical images), or cross-domain (es. source: images of objects – target: medical images) [4]–[6]. Models trained on object images poorly perform on medical images, as they typically have low contrast and rich textures.

In this work, cross-domain and cross-modal TL approaches were compared to classify trans-perineal ultrasound (US) images of foetal occiput positions.

Foetal occiput position is one of the main determinants for choosing the most adequate mode of delivery, a critical issue in obstetrics, particularly important in cases of poor progression and prior to start an instrumental vaginal delivery.

This crucial parameter is traditionally assessed at digital vaginal examination (DVE). However, recent evidence showed DVE can be subjective and uncomfortable for women, and it is associate with an error rate ranging from 20% to 70% [7], [8].

Despite international guidelines [9] recommendations on the use of intrapartum US to ascertain the position of the foetal occiput, most obstetricians are not familiar with this practice.

While transabdominal (TA) ultrasound is the preferred method to determine accurately foetal occiput position during labour, the use of transperineal (TP) acquisition allows the simultaneous evaluation of foetal head station, rotation and position in a single sonographic step [10]–[12]. However, transperineal ultrasound (TPU) has the disadvantage to be technically challenging for inexperienced operators [13].

Therefore, the second aim of this research is to develop an algorithm to enable the automatic and rapid assessment of the foetal occiput position from TPU acquisitions, providing an automatic and accurate classification of direct and transverse occiput positions.

II. Methods

A. Data collection

The data collection was conducted within the framework of the 'AI Occiput' International Multicentre Clinical Study, organized by the University of Parma, in collaboration with 14 maternity hospitals worldwide. In this prospective work, a total of 612 US images were collected from women in single, full-term and uncomplicated pregnancy (> 37 gestation weeks), placing the probe transperineally in transverse orientation.

Ultrasound examinations were performed using the following settings: convex probe with 65 mm radius of curvature, field of view 60°, nominal central frequency 3MHz (band from 2 to 5 MHz), scan depth 180 mm, multi-focused image with at least 2 focuses (30-50 mm and 100-150 mm) and linear Time Gain Control. The image acquisition was accomplished as a standard B-Mode image (PNG or BITMAP format with at least 512 x 512 pixels).

All the acquisitions were performed using either a generic ultrasound machine manually set in accordance with the above-mentioned parameters or the SensUS Touch system (Amolab Srl, Lecce, Italy), a tablet-like portable ultrasound system equipped with a software module specifically dedicated to this study.

An expert gynaecologist selected only images presenting foetal occiput in transverse position and classified each image as direct or transverse occiput position. The image with the best visualization of the anatomical landmarks was selected from 100 frames acquired during each US examination.

B. Data preparation

Three different databases were created to the scope of this work:

1. The images collected for this study were pre-processed to be anonymized and labelled. Patient and acquisition data, and information about the sonographer were eliminated from each image with a binary mask. This dataset will be called "AI Occiput-database". The final database counted 612 images.
2. From the large public dataset [14], a sub-set of images was selected including images of foetal abdomen, brain, femur and thorax; images of maternal cervix and other US

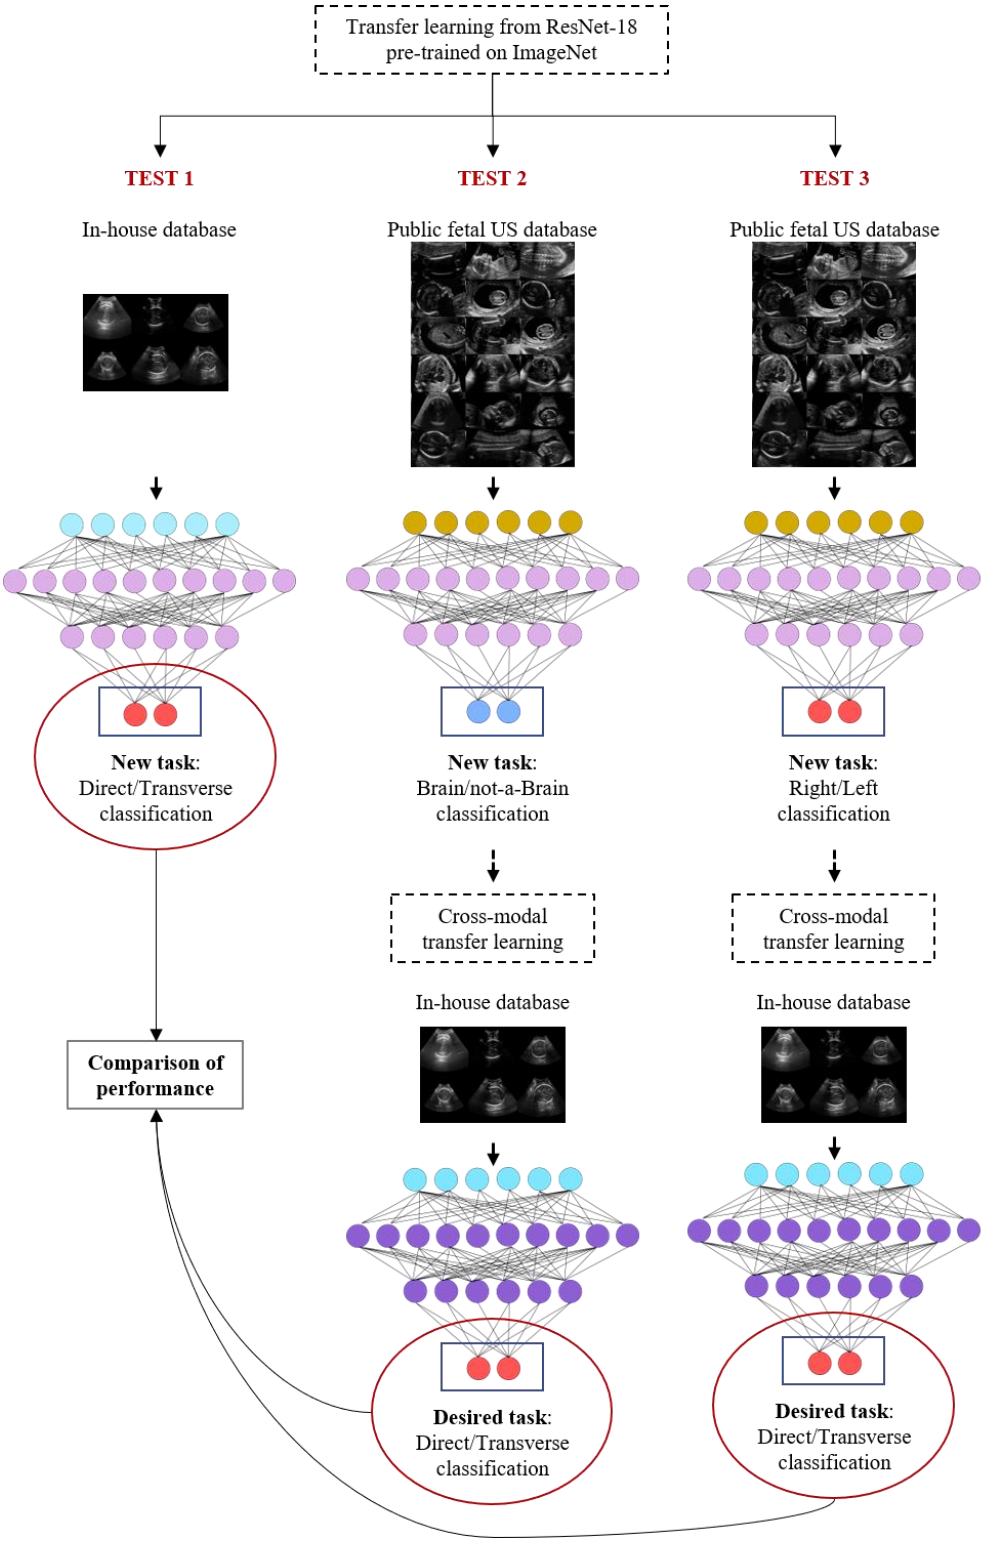

Fig. 1 – Graphical workflow of the used TL approaches.

images were excluded. Images were labelled to classify brain vs. not-a-brain task. The final database counted 8187 images. This dataset will be called "BnB-database".

3. From the large public dataset, another sub-set of images was selected, including only images of foetal brain in transversal position from TA ultrasound acquisition. Images were labelled to classify right vs. left occiput position. The final database counted 1386 images. This dataset will be called "RL-database".

Images were partitioned into train-, validation- and test-set with a ratio of 0.75/0.15/0.15 per category.

C. *Pre-training*

In this work, the approach of TL was used to address the lack of huge amount of data. We used the ResNet-18 convolutional neural network as classifier and we re-trained the network on a public large dataset of maternal-foetal screening ultrasound images [14] to perform cross-modal TL. Three different TL training processes were performed and compared (Figure 1):

1. ResNet-18 pre-trained on ImageNet [15] was re-trained on AI-Occiput database to classify direct and transverse occiput position (cross-domain transfer learning) – called Test 1;
2. ResNet-18 pre-trained on BnB-database to classify "brain, not-brain" was re-trained on AI Occiput-database to classify direct and transverse occiput position (cross-modal transfer learning) – called Test 2;
3. ResNet-18 pre-trained on RL-database to classify "right and left occiput position" was re-trained on AI Occiput-database to classify direct and transverse occiput position (cross-modal transfer learning) – called Test 3.

In summary, cross-domain TL was performed in Test 1, and two approaches of cross-modal-TL were performed in Test 2 and Test 3. The goal was to define the best TL method to train our small-sized database to classify direct and transverse occiput positions.

It is necessary to underline that the RL- and AI Occiput-database consisted of images acquired with different procedures: transabdominal and transperineal, respectively. Consequently, RL-database included higher-quality images than AI Occiput-database, since brain structures, such as choroid plexus, ventricles or cerebellum, showed low image contrast.

D. *Data augmentation*

Data augmentation was used to increase the training dataset and to enhance the model's performance. Our data augmentation strategy was based on geometric transformations (translation and shearing), noise injection (Gaussian and speckle) and contrast distortion. Each image in the original dataset thus underwent five transformations, whose parameters were chosen randomly from a continuous uniform distribution within the following intervals:

- Horizontal and vertical translation $\in [-20,20]$ $pixels$;
- Horizontal and vertical shearing $\in [-10°, 10°]$;
- Gaussian noise SD $\in [0, 1.1]$;
- Speckle noise density $\in [0.01, 0.05]$;
- Contrast distortion min $\in [0, 0.3]$, max $\in [0.7, 1]$.

E. *Statistical Analysis*

The model performances were evaluated through the confusion matrix by calculating accuracy, sensitivity, specificity and F1-score. The Cohen's kappa was also calculated to evaluate the degree of agreement between the CNN and the gold standard.

III. Results and Discussions

On the basis of sonographic findings, the AI Occiput-database images were classified as direct (n = 293) and transverse (n = 319) by the expert gynaecologist. The BnB-database included 3092 brain and 5095 not-a-brain images. Lastly, the RL-database consisted of 759 left transverse and 627 right transverse occiput position images.

The comparison of the performances resulted from the three TL approaches are shown in Figure 2.

In summary, the three classifiers tested on the in-house small database identified direct and transverse occiput position with 73.9%, 85.9% and 89.1% accuracy, respectively for Test 1, Test 2 and Test 3. The sensitivity was 71.4%, 87.0% and 92.7% and the specificity was 76.7%, 84.8% and 86.3% for Test 1, Test 2 and Test 3, respectively.

It is noticeable that between Test 1 and Test 3 there is a difference in accuracy that exceeds 15% and in sensitivity that is almost 20%. The Cohen's kappa was 0.48, 0.61 and 0.78, and the F1-score was 0.74, 0.83 and 0.88 respectively for Test 1, Test 2 and Test 3.

The results of this study indicate that our model pre-trained

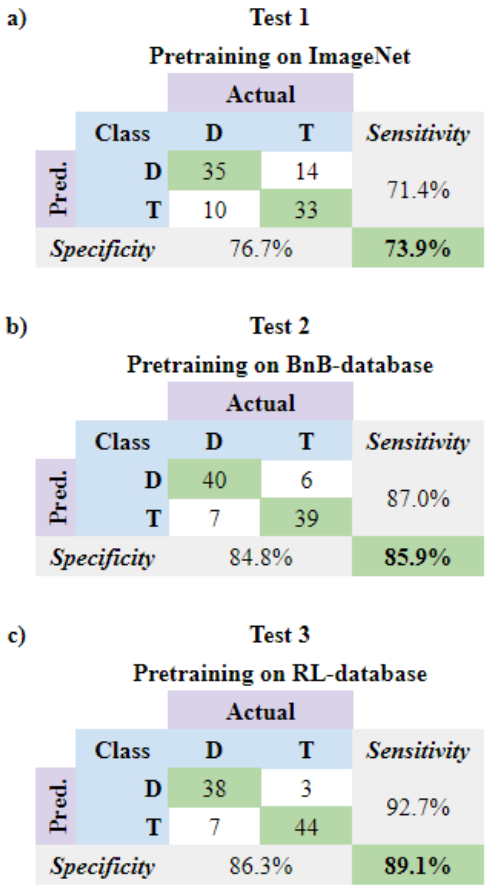

Fig. 2 - Confusion matrices of the performances resulted by: a) cross-domain TL (Test 1), b-c) cross-modal TL (Test 2 and Test 3).

on the RL-database outperformed the model pre-trained on the BnB-database in terms of accuracy (Test 3 accuracy = 89.1%; Test 2 accuracy = 85.9%). This is likely due to the similarity of the tasks and databases between Test 3 and the AI-Occiput database, which both feature foetal head with occiput in different positions. On the other hand, the BnB-database contained US images of foetal head, but also of different parts of the foetal and maternal body, making it less similar to the tested database. Therefore, the performance in Test 3 was enhanced by the representation of relevant features learned from a database more closely related to the tested database, resulting in higher accuracy and better generalizability.

The results of the cross-domain TL (Test 1), while effective, resulted in less accurate classifications of ultrasound images than the cross-modal TL (Test 2 and Test 3) tests. This is mainly due to the differences between the characteristics of ImageNet and medical images; such as contrast, shape and texture. Conversely, in cross-modal TL the weights from the pre-trained model are transferred to a model on the same domain, allowing the model to leverage the pre-trained model's general knowledge of the domain and thus recognize patterns more effectively in medical images.

Theoretically, TL could enable us to reduce the dependency on large datasets often required for automatic recognition tasks, while still providing optimal performance. While TL does require significantly fewer labelled data to be trained, the quality of the dataset remains the most important part of the re-training process. Without a well-structured and diverse dataset, the model will not be able to accurately represent the problem and generalize its solution to multiple contexts. Poor datasets will inevitably lead to poor predictions.

IV. Conclusions

In this work, three different approaches of transfer learning were compared to classify direct and transverse occiput position on TPU images.

Our research has indicated that the use of cross-modal transfer learning (TL) can result in an improved classifier performance when compared to cross-domain TL.

This study suggested that cross-modal TL could be an effective solution for medical imaging application to overcome the limitation of data scarcity and improve performance when images are affected by low contrast. Moreover, the developed model could provide a valid support to obstetricians in the delicate process of labour management, aiding the untrivial task of image interpretation, strongly dependent on the operator training experience, thus minimizing the intra-operator variability.

The future prospective of this work will be to expand the classification of additional occiput position directions and develop a model to predict the most successful delivery mode.

Acknowledgement

We would like to thank all the participants to the AI Occiput project, including midwives, obstetricians and gynaecologists, whose unceasing contribution and dedication to data collection was essential to perform this study.

***Abstract*— The cerebral cortex exhibits an intrinsic structural complexity of folding. Fractal geometry may be used to describe the structural complexity of objects (such as the cerebral cortex) that show self-similarity throughout a proper range of spatial scales. The potential value of fractal dimension, estimated from T1-weighted MRI images, has already been widely demonstrated in previous literature, but how it is related to the cyto- and myeloarchitecture of the cerebral cortex is still unknown. In this study, we computed the fractal dimension of the six cortical layers, which present various cellular compositions and distributions, developmental trajectories, connections, physiology, and functional roles. The procedure for determining fractal dimension indices was applied to segmentations obtained from the public BigBrain dataset that consists of an ultrahigh-resolution three-dimensional (3D) model of a human brain based on histologically processed post-mortem brain reconstruction. Results denote an increasing trend in fractal dimension values from the outermost (layer I) to the innermost layers (the infragranular layers V and VI) of the cortex in both hemispheres. Layers V and VI are composed of sparse, low-density pyramidal neurons and fusiform cells. Differently from the supragranular layers (i.e., layers I, II, and III), the infragranular layers are characterized by a high content of myelin belonging to the projection fibers. Consequently, the structural complexity of the cerebral cortex seems to be coupled with the projection fibers network, rather than with neuronal density, and the presence of associative and commissural fibers.**

***Keywords*—BigBrain project, cerebral cortex, cortical layers, fractal dimension, projection fibers, structural complexity.**

I. Introduction

THE human brain is a complex system. Its hierarchical organization can be studied on multiple scales, from neurons and microcircuits to macro-network. From a structural point of view, the intrinsic folding of the cerebral cortex can be described through fractal geometry. Its popular index, the fractal dimension (FD) measures the structural complexity of objects, which show, in a proper range of spatial scales, the self-similarity property (i.e., a geometrical property of objects composed of subunits and sub-subunits that resemble the whole object [1], [2]).

In recent years, fractal analysis has been successfully applied to analyze brain morphology [3]-[5]. In particular, by exploiting T1-weighted magnetic resonance imaging (MRI), the fractal properties of the cerebral cortex [6], as well as the white matter (WM) [7],[8] have been shown. Indeed, FD is considered a compact measure of the structural complexity of the brain [9]. Specifically, the FD of the cerebral cortex condenses cortical thickness, sulcal depth, and folding area into a unique numeric value [10].

Although FD is an index capable of measuring mild structural changes induced by healthy aging [11]-[17], and the onset of neurological diseases [9], [18]-[25] the link between FD and the cyto- and myeloarchitecture of the brain is still unknown. In addition, the human brain's FD is generally estimated from the cerebral cortex and WM segmentations obtained from T1-weighted MR images, which rarely have a spatial resolution of less than one millimeter.

In the present study, we performed a step toward interpreting FD in neuroimaging by directly studying the individual layers that make up the cerebral cortex, which exhibit different cellular composition and distributions, developmental trajectories, connectivity, physiology, and functional roles [26]. This processing was made possible by the BigBrain dataset, a 3D reconstruction of an individual human brain stained for cell bodies at ultra-high, nearly cellular, spatial resolution that provides considerable neuroanatomical insight into the human brain [27].

II. Materials and Methods

A. Data

In this study, we employed the BigBrain dataset created by the Forschungszentrum Jülich center in Germany and McGill University in Montréal with the supercomputer Juropa [27]. BigBrain is freely available at https://bigbrainproject.org/index.html and contains a model of the brain of a 65-year-old subject with no neurological or psychiatric diseases in the medical records at the time of death [27]. They obtained the brain model using a large-scale microtome to cut the paraffin-embedded brain coronally. Then, they acquired 7400 sections at 20-µm thickness. Histological sections were subsequently digitized, resulting in images of maximally 13,000 x 11,000 pixels. In order to generate a dataset with isotropic resolution, they scaled down all images to a resolution of 20 microns. Histological processing has inevitably introduced artifacts. Before the 3D reconstruction of the whole brain as a contiguous volume, manual and automatic repairs were performed. The repaired sections were registered to the MRI, which served as an undistorted frame of reference and further aligned section-to- section with the use of nonlinear registration [27]. The final dataset contains the 3D histological volumes at different isotropic resolutions (100,

200, 300, and 400 microns), in MNI and histological space, the 3D classified volumes, and the MR volume in the histological space. Moreover, it includes the WM-cortex interface and pial surfaces along with the cortex layers surfaces [28]. Similarly to the work of Wagstyl and colleagues [28], in the current study, we used the 3D surfaces of the cortical layers outlined on the histological sections with a spatial resolution of 400 microns.

B. *Methods*

We rasterized each 3D surface corresponding to a single cortical layer using the 3D histological volume at the resolution of 400 microns as the reference volume. Thus, we obtained twelve (six for each hemisphere) non-overlapping 3D volumes representing the cortical layers (Fig. 1). Then, we computed the FD for each layer. In particular, the fractal analysis was performed through the box-counting algorithm [29] optimized with the automatically selected fractal scaling window [13]. Briefly, the box counting algorithm consists in superimposing a grid containing 3D cubes of side s on $I(x, y, z)$ (the 3D mask of the brain portion of interest) and counting the number of not null intersections between the grid and $I(x, y, z)$. This procedure was repeated for different s values. As suggested by Goñi et al. [30], for each s value, 20 uniformly distributed random offsets were applied on the grid origin in order to reduce the bias introduced by the selection of a fixed grid origin, and all the box counts (one for each offset) were averaged to obtain a single $N(s)$ value for each s. Plotting $N(s)$ against s in a bi-logarithm plane (Fig. 2), we build a linear regression model where the absolute value of the negative slope is the FD. In the natural scale, this linear relationship in the log-log plane corresponds to a power law $N(s) = k\, s^{-FD}$, where FD is the exponent (with a negative sign), and k is the prefactor [2]. In particular, the range of spatial scales where $I(x, y, z)$ manifests its fractal properties is unknown a priori, so we used an automated selection of this spatial interval, i.e., the fractal scaling window, by maximization of the coefficient of determination (adjusted for the number of data points) R^2_{adj} of the linear regression model [13].

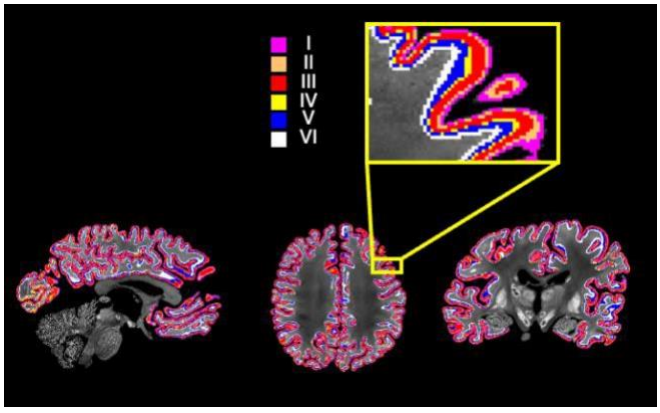

Fig. 1: 3D cortical layers. Six cortical layers segmented on the 3D volume in the three orthogonal planes, i.e., sagittal (left), axial (middle), and coronal (right). The box outlined in yellow contains an enlargement of a part of the cortex in the axial plane.

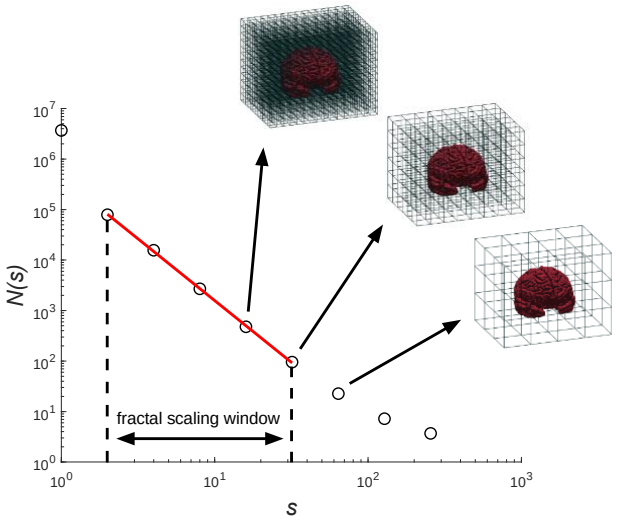

Fig. 2: 3D box-counting for computation of the FD. An example of the 3D box-counting algorithm that uses an automated selection of the fractal scaling window through the *fractalbrain* toolkit [13]. $N(s)$ is the average number of 3D cubes of side s needed to fully enclose the brain structure computed using 20 uniformly distributed random offsets to the grid origin. The regression line within the optimal fractal scaling window, whose slope (sign changed) is the FD, is depicted in red.

C. *Experimental Tests*

We performed the 3D surface voxelization using different tools. Firstly, we transformed our data into the FreeSurfer structure [31] to exploit FreeSurfer's extension for 3D Slicer (v. 5.0.3) to load, visualize, and rasterize the 3D surface meshes into 3D filled volumes with a spatial resolution of 400 microns. The final volumes of the surfaces were obtained using the mathematical manipulation tools of the FMRIB Software Library (FSL) (v. 6.0.3) [32]. Finally, for the estimation of the FD of each layer, we used the *fractalbrain* toolkit (v. 1.0) (https://github.com/chiaramarzi/fractalbrain-toolkit) [13].

III. Results and Discussion

Table I shows the FD measurements of the six layers of the cerebral cortex collected with a spatial resolution of 400 microns.

TABLE I: FD VALUES OF THE SIX LAYERS OF THE CEREBRAL CORTEX

Layer	*FD (left hemisphere)*	*FD (right hemisphere)*
I	2.2847	2.2885
II	2.3041	2.3084
III	2.3371	2.3381
IV	2.3422	2.3422
V	2.3728	2.3758
VI	2.3439	2.3466

Comparing the FD values obtained for the left and right hemispheres, a slightly higher FD is observed for the latter. This result might be explained by considering that healthy cerebral hemispheres appear perfectly symmetric only

macroscopically. A detailed examination reveals two subtle differences: 1) the right cerebral hemisphere has a larger size, and 2) it is slightly in a forward position than the left one [33]. Given the existence of a positive correlation between measures of volume and FD estimated from T_1-weighted MR images, the larger size of the right hemisphere may account for its slightly higher FD, as previously found in [15], [34], [35].

FD values tend to increase moving deeper into the cerebral cortex, highlighting that layers V and VI have higher structural complexity in both hemispheres. Given that the cerebral cortex has a cyto- and myeloarchitectonic structure that varies depending on the cortical area, each layer, with various cellular compositions and distributions, developmental trajectories, connections, physiology, and functional roles, represents a different cyto- and myeloarchitectural variety. Specifically, layers V and VI were named internal pyramidal layer and multiform layer, respectively. The internal pyramidal layer consists of large but relatively sparse pyramidal neurons, while the multiform layer has mostly fusiform cells with less dominant pyramidal cells and interneurons. Both of them are highly rich in myelin due to the high amount of projection fibers. Layer V is the source of the output of corticofugal fibers, which synapse with different subcortical motor centers. The axons of the fusiform and pyramidal cells of the VI layer, instead, distribute corticocortical commissural fibers and corticothalamic projection fibers that end in the thalamus [36]. Consequently, the structural complexity of the cerebral cortex seems to be coupled with the projection fibers network. A decrease in FD values of the cerebral cortex due to a neurological disease might therefore indicate a reorganization of the projection tracts, rather than a neuronal density decrease.

Moreover, in T1-weighted MR images, layers V and VI have an intensity similar to that of white matter. Indeed, the high presence of myelin in these cortical layers often leads to their classification as white matter [28]. Conventionally, in MRI processing, the white matter surface is placed at the maximum intensity gradient between gray and white matter, causing an outward shift in the location of the white matter surface (Fig. 3). By contrast, thanks to the high spatial resolution, the cortical layer boundaries have been manually located according to the presence of cortical neurons [28]. This has caused an inward shift in the location of the exact white matter surface.

These considerations are in line with previous literature studying structural complexity, measured by the FD, of the white matter. Notably, the FD of the white matter has generally higher FD values than the cerebral cortex [14],[20]. This could be partially explained by the fact that the most structurally complex regions of the brain are those with high intracortical connectivity, i.e., layers V and VI, which are generally included in the segmentation of white matter.

Fig. 3: Portion of the brain (in the axial plane) in which the six cortical layers and segmentation of white matter are visible. While there is no overlap between cortical layer segmentations, the white matter (green), defined by exploiting the maximum intensity gradient, partially overlaps with the VI (white) and V (blue) layers. The overlap is identified by the area where the colors combine.

III. CONCLUSION

Our findings enable a step forward in interpreting the FD as a measure of the structural complexity of the cerebral cortex. We figured out the coupling between the cyto- and myeloarchitectural composition of the cerebral cortex and its structural complexity, candidating the projection fibers network of layers V and VI as the main contributor to structural complexity of the cerebral cortex.

***Abstract*—Aggregation and modification of the structure of biologics (*i.e.*, proteins, mAbs, etc.) can significantly affect the quality of the final biopharmaceutical product, especially because of the increased risk of immunogenicity and the decreased specificity. The excipients in the final formulation are intended to mitigate destabilizing effects (*e.g.*, aggregation, structural/conformational modifications, etc.). Here, we describe a novel high-throughput screening approach based on a microfluidic inline analytical platform and machine learning methods, to select the best formula composition in terms of type and concentration of excipients needed to reduce the aforementioned destabilizing effects. We show how to collect stability-related information in a fast and reliable way, with minimum material amount (*i.e.*, few hundreds of microliters), and how to properly structure the dataset for subsequent machine learning-based processing. This approach is taught to dramatically reduce the number of experiments needed for later fine characterization of injectables' stability.**

***Keywords*—High-throughput screening, inline analysis, thermodynamic stability prediction, biotherapeutics.**

I. Introduction

In the industrial and academic fields, there is a lack of fast and reliable screening platforms for biologically active compounds. More than 90% of the API (Active Pharmaceutical Ingredient) compositions are not stable enough to enter the successive fine-tuning steps, resulting in an increased cost of drug development [1] and a decreasing number of marketed drugs.

Compared to small pharmaceutics, proteins are larger entities with superior physical and chemical complexities. Protein degradation, which is of major concern when dealing with pharmaceutical products, can be due to many different factors, either chemical and/or physical [2]. Chemical degradation accounts for the destruction and/or formation of covalent bonds, including processes such as oxidation and hydrolysis [2]; physical degradation accounts for precipitation, aggregation and/or disaggregation, unfolding, adsorption, and denaturation processes [2].

Depending on the destabilizing factor(s) to be characterized (*e.g.*, aggregation/disaggregation, denaturation, structural/conformational changes, etc.), different analytical techniques have been developed during the years [2], [3], [4]. Those techniques can be classified in multiple ways, based on different characteristics such as the detection method (*i.e.*, microscopic, light absorption/blockage, light scattering, separation, spectroscopic), properties of particle suspension (*e.g.*, size, particle concentration, polydispersity/polymodality, turbidity, refractive index, etc.), API's attribute (*e.g.*, aggregation status, chemical modifications, structural/conformational changes, etc.), and the operational mode (*e.g.*, single particle, ensemble, separation-based) [4].

Standard off-line analytical techniques are usually not allowing for fast and real-time measurements. Moreover, they require multiple sample pre-processing steps (*i.e.*, dilution, separation, buffer exchange) that may alter the native context of the API, impacting the stability and thus leading to misleading information. Plus, there is a lack of automation because different qualified operators perform different steps at different times. For example, one of the established and vastly employed techniques for the characterization of the monomer/oligomers/aggregates is the SE-HPLC (Size Exclusion – High-Performance Liquid Chromatography) [5]. However, SE-HPLC can provide misleading results because of (1) adsorption of protein aggregates to the column matrix, (2) dissociation or formation of protein aggregates during the sample preparation and measurement, (3) incapability to resolve larger aggregates that may coelute, (4) inability of large aggregates (*i.e.*, subvisible particles) to elute, and (5) underestimation of aggregate species and levels if only UV-absorbance detector is used [5] [6]. In addition, the analytical measurement is operator-, time-, and reagents-consuming.

Nowadays, pharmaceutical formulation development relies on classical trial-and-error approaches that are laborious, time-consuming and expensive [7]; it is almost impossible to reach the optimal formulation composition, in terms of type and concentration of excipients (*e.g.*, salts, buffer agents, sugars, amino acids, surfactants, etc), with the aforementioned approaches.

Over the years, several machine learning methods and algorithms have been introduced to deal with the problem of the stability prediction of injectable biologics, to fill the gap in the traditional approaches leveraging data-driven predictions [8], [9], [10]. Obrezanova et al. [11] developed a high-throughput screening algorithm able to classify antibody molecules based on their aggregation propensity, using their aminoacidic sequence as input; protein aggregation was assessed using standard SE-HPLC method and the Oligomer Detection assay (ODA) [12] to classify the antibodies according to low and high aggregation risk. Gentiluomo et al. [13] proposed the use of interpretable artificial neuronal networks (ANNs) to predict important biophysical properties of therapeutic monoclonal antibodies such as melting temperature T_m, aggregation onset temperature T_{agg}, and the interaction parameter k_D as a function of pH and salt concentration from the aminoacidic composition. Authors exploited the ANN to find relationships between these

biophysical properties and some specific residues [13]. Yang et al. [7] applied deep learning (DL) to predict successful pharmaceutical formulations by building regression models on the disintegration time (*i.e.*, output parameter), comparing two types of dosage forms with different formulations; moreover, they evaluated the predictive performance of six machine learning algorithms. Narayanan et al. [14] demonstrated the power of the Bayesian optimization algorithm in identifying the formulation that optimizes the thermal stability (in terms of T_m) of a target protein in 25 experiments, by considering eight factors (*i.e.*, pH, sodium chloride, l-arginine, l-lysine, l-proline, trehalose, mannitol, and Tween20) as independent variables for the algorithm; notably, the number of required experiments is much lower compared with the number of experiments required by a classical trial-and-error approach.

However, the totality of the aforementioned research works complies with the lack of sufficient amount of high-quality data referred to the stability characterization of pharmaceutical formulations. This lack is mainly due to the high cost and time required for the data generation. Furthermore, injectable biologics are usually formulated at high concentration (> 100 mg/ml) to reduce the amount of drug product to be administered to patients, while maximizing the deliverable dose [15]. Dealing with stability studies of injectable biologics at such high concentrations takes with it many challenges: (1) difficulties to process highly viscous solutions, (2) dilution should be avoided, since it may add unwanted destabilizing and/or stabilizing effect on the product, (3) heterogeneity of the solutions (*e.g.*, API, excipients) may represent an obstacle for some analytical techniques.

With this work, we aim to develop a fully automated microfluidic inline analytical platform for a fast screening of the stability of injectable biologics. Plus, stability data are processed through machine learning approaches to build an in-silico predictive model. The aim of the work is schematized in Figure 1 below.

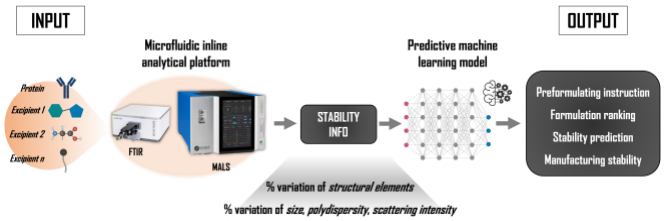

Fig. 1: Aim of the work

II. Inline Analysis – Stability Data

For our purpose, we selected two inline analytics based on different principles: a spectroscopic-based one that is ATR-FTIR (Attenuated Total Reflectance - Fourier Transformed InfraRed) spectroscopy, and a light scattering-based one that is MALS (Multi Angle Light Scattering). These two analytics were chosen considering a series of parameters: (1) the attribute measured (*e.g.*, hydrodynamic radius, gyration radius, turbidity, molecular spectra, etc.), (2) sample volume required, (3) measurement time, (4) flow rate and concentration range, (5) detection limits, and (6) availability of the technology.

Both the analytics require small amount of sample (100 microliters each) and measurement time (few seconds to few minutes, depending on the target quality), allowing for fast analysis and minimum sample consumption; plus, since they are non-destructive, the analyzed samples can be recovered and reused for further characterizations.

ATR-FTIR spectroscopy [16] allows to acquire information about the secondary structure of the protein inside the formulation, without requiring any dilution or separation. This information, extracted from the molecular spectrum, can be used to quantify the percentage change in structural elements (*i.e.*, α-helices, β-sheets, random coils, etc.) by evaluating specific region of the second derivative of the absorbance spectrum [17], [18]. For instance, intermolecular antiparallel β-sheets formation can be observed at the absorption band around 1620 cm^{-1} and this is a common feature of protein aggregation [19], [20].

MALS allows to acquire multiple information about average-weighted molecular weight (MW) and gyration radius (r_G) of the analyte in the formulation, leveraging the angular dependence of the scattered light intensity [3], [21]. The combination with QELS (Quasi Elastic Light Scattering) provides quantification of the hydrodynamic radius (r_H) of the molecule. This information can be used to quantify the percentage change of size (MW, r_G, and r_H), polydispersity, and scattering intensity that are related to aggregation and disaggregation dynamics due to components' interactions.

Inline ATR-FTIR spectroscopy and MALS are meant to be used together, given the different nature of the information they provide. Structural modifications (*e.g.*, conformational changes, loss in structural elements, etc.) are captured by the former, while components' interactions (*e.g.*, aggregation, disaggregation, API-excipient interactions, etc.) are captured by the latter. The combination of the two allows not to miss some destabilizing phenomena for every type of molecule in formulation: a change in the secondary structure does not necessarily imply an increased aggregation, and vice-versa.

The validity of inline ATR-FTIR as analytical technique for injectable biologics (*i.e.*, API plus excipients) without sample pre-processing, has been demonstrated through some preliminary studies. A drug product (DP), denoted as DP3, has been used; it is a solution in Tris 10mM (pH 7.5) containing a nanobody (at 150 mg/ml), trehalose, and Poloxamer-188 at specific concentrations. ATR-FTIR spectra were acquired by a ReactIR 702L (Mettler Toledo) with a microflow cell (Di-comp) equipped with a diamond crystal. A syringe pump (Harvard Apparatus) was used to flow the sample, at a fixed flow rate of 0.3 ml/min, inside the microflow cell. Three different spectra were acquired with a fixed number of scans per each sample of 100 and a resolution of 4 cm^{-1}: (1) untreated DP3, (2) thermally treated DP3 at 50°C for 3 minutes, and (3) thermally treated DP3 at 55°C for 3 minutes. The 2nd derivatives of the absorbance spectra were computed from the iC IR software (Mettler Toledo) with standard configuration. Results of ATR-FTIR spectroscopy are reported in Figure 2.

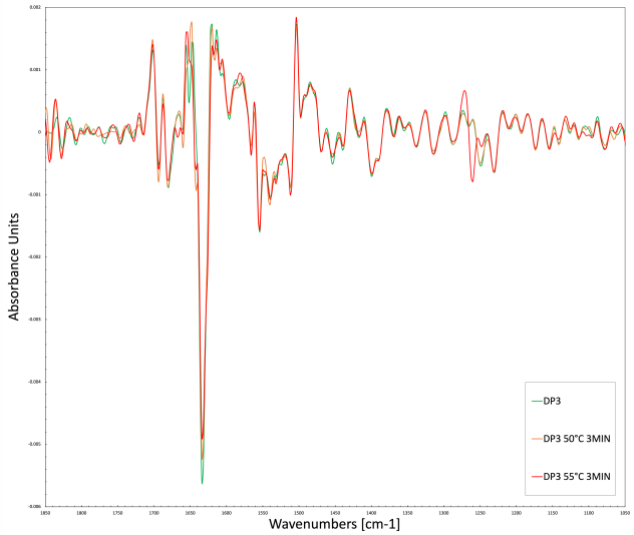

Fig. 2: 2nd derivative ATR-FTIR spectra of an injectable drug product (DP3). Untreated DP3 (in green), thermally treated DP3 at 50°C for 3 min (in yellow), and thermally treated DP3 at 55°C for 3 min (in red).

Figure 2 shows a progressive loss in the β-sheets content of the nanobody around 1630 cm^{-1} wavenumber with the increase of the thermal degree of the treatment. This technique appeared to be promising in classifying different formulations having different excipients (both type and concentration) depending on the extent of their secondary structure modifications. A greater extent (*i.e.*, a greater percentage change) of structural modifications is associated with a lower stability of the API.

III. Dataset Building

Dataset building and structuring is a crucial step, to have data properly organized to be processed through machine and/or deep learning methods. Depending on the kind of available data (*e.g.*, categorical, continuous, data range, missing values, etc.), different algorithms and pre-processing strategies may be chosen to maximize the accuracy of the in-silico model generated.

Given the analytics selected and the obtainable information, a possible way of dataset structuring is reported in Table I below.

TABLE I: Example Dataset

API	*Concentration (mg/ml)*	*pH*	*Trehalose (g/ml)*	*Arginine (mg/ml)*	*Poloxamer (mg/ml)*	*β-sheet loss (%)*	*Size change (%)*
1	*150*	*7*	*0.1*	*0*	*0.2*	*10*	*25*
1	*150*	*7*	*0.5*	*2*	*0*	*8*	*10*
1	*150*	*7*	*0.1*	*4*	*0.2*	*4*	*12*
1	*60*	*7*	*0.1*	*0*	*0.2*	*5*	*17*
1	*60*	*7*	*0.5*	*2*	*0*	*3*	*8*
1	*60*	*7*	*0.1*	*4*	*0.2*	*3*	*7*

A possible way of structuring a dataset for regression purposes. First six columns are input variables (independent variables), last two are output variables (dependent variables) evaluated through inline ATR-FTIR spectroscopy and MALS, respectively. For instance, further independent and dependent variables can be added to the dataset depending on the achievable information.

This example dataset is focusing on one API, at two concentrations, to exploit the excipients effect on the destabilization upon thermal treatment. Such dataset is well suitable for regression purposes, since the output variables (*i.e.*, β-sheet loss (%), and size change (%)) are continuous and not categorical. For classification, the output column must contain a categorical variable; therefore, a "stability-related label" (*e.g.*, stable, mildly stable, instable) should be defined. However, no uniquely defined stability thresholds are available in literature, since they strictly depend on the molecule under investigation.

For this kind of datasets (Table I), machine learning algorithms that are mostly used for regression are: (1) Multiple Linear Regression, (2) Polynomial Regression, (3) Logistic Regression, (4) Robust Regression, (5) Support Vector Regression, (6) k-Nearest Neighbors regression, (7) Decision Tree regression, (8) Random Forest regression, and (9) Gaussian process regression. Each of the previous has advantages and drawbacks, and algorithms' selection is a crucial step because their performances may vary a lot depending on the number of experimental datapoints available; the dataset splitting strategy (*e.g.*, K-Fold, stratified K-Fold, repeated K-Fold, Leave One Out, etc.) between training set and test set must be chosen accordingly. Moreover, if the number of the independent variables change, then also the algorithm's output is dramatically affected.

IV. Future Perspectives

This work paves the way for future machine- and deep-learning applications to build in-silico models capable of predicting thermodynamic stability behaviours of injectable biologics. Moreover, high amount of data can be leveraged to exploit the role of each one of the excipients in the thermodynamic stability of the API to build knowledge.

These machine learning-based computational tools can be beneficial to formulation design, since an early evaluation of the most promising formulations, in terms of type and concentration of excipients, dramatically reduces the formulation design-related costs and speeds up the overall process. In addition, an in-silico approach leveraging microfluidic inline analysis, allows to further enlarge the plethora of possible excipient(s)-API combination with less effort compared to classical trial-and-error approach [7] and minimum sample volume required (*i.e.*, few hundreds of microliters).

Further improvements may be introduced by encoding the amino-acidic sequence of the API as additional input parameter(s) to the model. Accounting for the quantity of each residue present in the primary sequence of a biologics could be a possible choice.

We envisage that this approach, characterizing the stability without pre-process the sample (*e.g.*, without separation) and getting advantage from machine learning tools, has a strong impact both in enhancing formulation development, and on a quality-by-design framework.

***Abstract*—To conduct studies on the somatosensory system, different physical stimuli, typically mechanical and thermal, are applied to *in-vivo* or *ex-vivo* samples. This paper presents a testbed able to produce both mechanical and localized hot/cold thermal stimuli in versatile conditions for studies on somatosensory functions. The paper describes the components of the testbed, which mainly includes a 3-axis positioning system, with a resolution of 0.5 μm and a total workspace of $150 \times 150 \times 150$ mm^3, a force- or position-controlled mechanical stimulator, that can deliver up to 5 N with a minimum resolution of 0.3 mN, and a thermal stimulator that can reach desired temperatures from 5 up to 60 °C. The testbed has been used for preliminary tests on a skin substitute, demonstrating the capability to mechanically and thermally stimulate the sample accurately.**

***Keywords*—Testbed, thermal and mechanical stimulation, somatosensory studies.**

I. INTRODUCTION

The somatosensory system and its underlying transduction principles have been the focus of multiple investigations. To conduct these studies, different physical stimuli, typically mechanical and thermal, have been applied on *in-vivo* (humans and animals, typically rodents), or on *ex-vivo* samples; the electrical response or the psychophysical one is then recorded and analyzed. Among the multiple purposes of the studies conducted so far (*e.g.* the characterization and classification of mechanoreceptors responding to given inputs, the analysis of inflammatory and neuropathic pain, the identification of mechanical and thermal thresholds), different methods have been employed to deliver physical stimuli of interest to a test sample. The Von Frey filaments represent the primary tools used in the literature to deliver mechanical stimuli and detect the touch threshold in humans and animals [1]–[3]. Moreover, custom solutions, mainly consisting of an automated indenter, are extensively used for generating mechanical sensations, in terms of touch and pain, on *ex-vivo* samples [4], humans and hand prostheses [5]. Thermal stimulation can be based on contact and contactless methods [3]. The use of Peltier cells represents a gold standard among the contact solutions. These devices can produce both hot and cold sensations and, due to their versatility and ease of use, they are widely employed on both humans and animal models [1], [6].

Solutions available on the market are mainly intended to deliver mechanical and (sometimes) thermal stimuli in *ex-vivo* models. The Mechanical Tester PB1000 by Nanovea is an automated indenter vertically controlled, integrated with a planar sample holder moving in two perpendicular directions. Even if it has been designed for materials mechanical characterization, it has also been used to test biological samples. The Piuma nanoindenter by Optics11 also provides accurate measurements of the micro-mechanical properties of soft samples, both in-air or liquids. These and other commercial systems are not employed for studies on somatosensory functions because: *i)* they typically do not integrate into a single platform a mechanical and thermal stimulator; *ii)* in case they include temperature-controlled stages to set pre-defined environmental conditions, they can not produce localized thermal stimuli and often only heating is included; *ii)* they are often not suitable to investigate touch and pain sensations *in-vivo*.

In this paper a testbed able to produce both mechanical and localized hot/cold thermal stimuli in *in-vivo* and *in-vitro* models is presented. This device was developed to perform a comparative analysis between an *in-vitro* skin model of human somatosensory system and an *in-vivo* animal counterpart when the same stimulation is provided. This skin model is being used as a testing sample for the validation of ultrasound-based interfaces for robotic hand prostheses developed within the SOMA European project.

II. TESTBED CHARACTERISTICS AND COMPONENTS

The functional characteristics of the developed testbed and its components will be presented in this section. As reported in Fig. 1, the testbed includes a sample holder, a positioning system, a mechanical and a thermal stimulator (not mounted simultaneously). A data acquisition system, and a custom interface with the user have also been added.

The technical specifications for the testbed design were identified based on a review of the scientific literature on the techniques used to thermally and mechanically stimulate *in-vivo* and *ex-vivo* models and on the ranges of somatosensory sensations to be elicited. For the mechanical stimulator, the dimensions of the tip have been selected to be suitable for tests on humans, small animals (rodents), and *in-vitro* skin models.

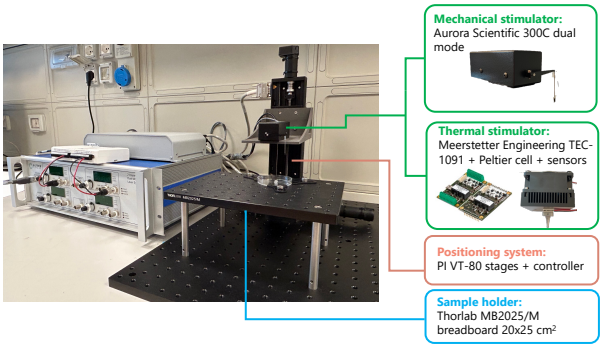

Fig. 1: Testbed main components.

For this reason, an interchangeable round tip with different sizes has been chosen in the range 0.5–3 mm in diameter. With this tip, the mechanical stimulator was required to deliver a force from 0.1 mN, corresponding to threshold recognizable as mechanical stimulation, to 1 N, to elicit pain sensation in humans and animals. Moreover, the thermal stimulator was required to include a round tip with diameter in the range 2–3 mm and generate a temperature stimulation in the range 5–60 °C, to induce a hot/cold sensation up to pain.

A. Sample holder

As a base frame, the Thorlab optical table MB6060/M (600×600 mm^2) has been selected to include all the testbed components. The sample holder was made of a second Thorlab optical table MB2025/M (200×250 mm^2) placed on 4 mounting posts (height: 100 mm).

B. Positioning system

To accurately stimulate the sample, a motorized 3-axis Cartesian positioning system is used. It includes three linear stages (PI VT-80), with DC motors controlled by one multi-axis driver (PI C-884.4DC), whose main features are reported in Table I.

TABLE I: Positioning system main characteristics.

	Linear stage PI VT-8
Stroke [mm]	150
Resolution [μm]	0.5
Maximum speed [mm/s]	20
Load capacity [N]	50

C. Mechanical stimulation

The mechanical stimulator is based on the 300C Dual Mode system device by Aurora Scientific, that has been already largely used in literature [6]. It is composed of a motor head whose indenter ends with an interchangeable tip (diameter from 0.5 to 3 mm) and it can be force- or position- controlled by means of an external analog signal. A picture is reported in Fig. 2. Two different motor heads can be mounted: one is able to deliver up to 1 N of indentation force with a resolution of 0.3 mN and the other is able to deliver up to 5 N with a resolution of 1 mN. This dual option increases versatility

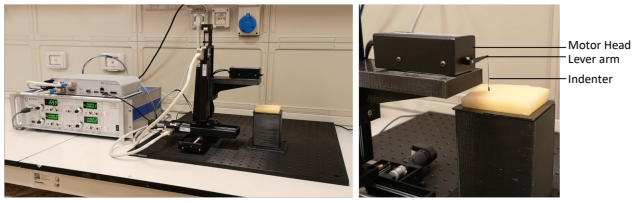

Fig. 2: 300C Dual Mode indenter by Aurora Scientific.

in the experiments since it allows to have alternatively high-range/low-resolution and low-range/high-resolution solutions. The main characteristics of the system are reported in Tab. II.

TABLE II: Mechanical stimulator main characteristics.

	Aurora Scientific 300C Dual Mode	
Maximum force [N]	1	5
Resolution [mN]	0.3	1.0
Stimulation diameter [mm]	0.5 – 3	

D. Thermal stimulation

A custom thermal stimulator was developed and is reported in Fig. 3. A Peltier cell has been employed, which is the most effective solution to generate both hot and cold stimuli. It is connected on one face to a heatsink to dissipate the heat produced when operating in cooling mode, and on the other face to a custom-made interchangeable aluminum tip. The tips have been designed in a shape that allows the highest contact with the Peltier cell on one side and a punctuate ending on the other one, to precisely stimulate the sample. They have been fabricated in two different dimensions (diameter: 2 or 3 mm). Moreover, an aluminum adapter has been fixed to the Peltier cell and consents to interchange the two tips easily. Both the tips and the adapter have been 3D-printed in aluminum. The Peltier cell was selected from Adaptiv with a surface of 15×15 mm^2, a cooling power of 8.6 W, and a 74 °C maximum temperature difference between the two faces. This device is also connected to two NTC thermal sensors: one is used as a feedback sensor to control the temperature of the tip, whereas the other one is used to monitor the temperature of the heatsink to avoid exceeding the maximum value allowed by the Peltier cell. The temperature regulation is performed by means of a ThermoElectric Cooling (TEC) controller by Meerstetter Engineering (TEC-1091). The main characteristics of the thermal stimulator are reported in Table III.

TABLE III: Thermal stimulator main characteristics.

	Thermal stimulator
Temperature range [°C]	5 - 60
Stimulation tip diameter [mm]	2, 3

E. Data acquisition system

To send analogue signals commanding desired position/force values to the mechanical stimulator, and also to acquire the analogue actual position and/or delivered force, a DAQ from National Instruments (USB-6212) was used.

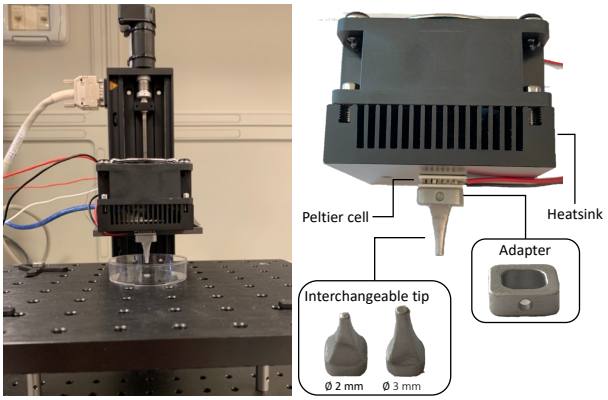

Fig. 3: Thermal stimulator main components.

Fig. 4: Mechanical stimulator custom user interface.

F. User interface

1) Positioning system: The multistage positioning system from PI came with the dedicated software PIMikroMove. It enables the experimenter to perform movements of the single stages by imposing the stroke and the desired velocity, to synchronize the movement of the three stages or to perform a pre-defined stimulation pattern by implementing a macro.

2) Thermal stimulator: For controlling the Peltier cell the software that came with the TEC-1091 controller by Meerstetter Engineering has been used. After setting the main characteristics of the Peltier cell (maximum input current, maximum difference of temperature between faces, and the direction of the current for cooling) and of the NTC thermal sensor, it is possible to set the desired temperature.

3) Mechanical stimulator: To control the mechanical stimulator, a custom interface has been developed by using NI Labview, as shown in Fig. 4. It allows the experimenter to set different stimulation profiles, also choosing between a force or position control of the indenter. Moreover, the temperature control tab has been added to control both the mechanical and thermal stimulation from a single interface. Once the temperature control tab is activated it is possible to set the desired temperature and monitor the actual temperature, the heatsink temperature, the actual current and voltage.

III. Testbed Preliminary Use

A. Experimental tests

Some preliminary *in-vitro* experiments to assess the performance of the testbed have been carried out on an artificial Skin Substitute (SS), with a diameter of 6 mm and thickness of 1 mm. The SS has been fixed with formalin 4% for 20 min and washed in PBS 3 times.

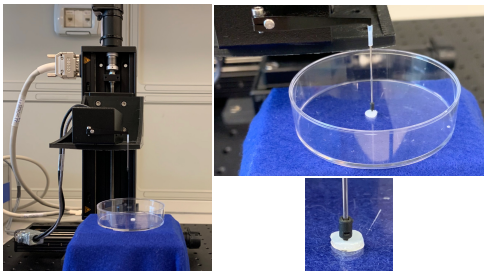

Fig. 5: *In-vitro* mechanical stimulation of the SS sample.

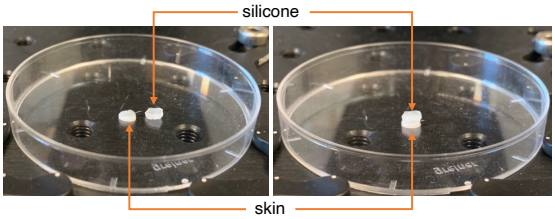

Fig. 6: *In-vitro* mechanical stimulation of the SS sample covered with a silicon layer.

1) Mechanical stimulation: In Fig. 5 the used setup is shown with a detail of the tip (diameter: 0.5 mm) in contact with the SS. The sample has been stimulated by using a triangular profile for a total (loading-unloading) duration of 20 s. After reaching the contact of the tip with the SS, by means of the positioning system, two different stimulations were performed. First, a position-based stimulation has been pursued, by applying a displacement from 0.1 to 0.7 mm with a step of 0.1 mm. Then, a force-based stimulation has been performed. In this case, a symmetric trapezoidal waveform, with a total duration of 6 s and steady-state stimulation of 2 s, has been applied with a force of 0.01, 0.02, 0.05, 0.1, 0.2, 0.5 N. However, this stimulation was not successful since the tip slept over the SS sample due to its high compliance. The issue was overcome by repeating the tests, considering the same range of forces, after adding over the SS sample a silicon layer with comparable shape and dimensions, as shown in Fig. 6.

2) Thermal stimulation: The tip (diameter: 3 mm) was brought to a predefined temperature and then placed for 10 s in contact with the sample (Fig. 5) by using the positioning system. Five randomly selected temperature values were tested in the range 5–50 °C. The temperature of the tip was continuously monitored.

B. Results

1) Mechanical stimulation: The actual displacement and delivered force when the SS was stimulated in position control mode have been recorded and are shown in Fig. 8. Desired and actual position profiles in all the conditions, *i.e.* with step displacement of 0.1 mm, are substantially superimposed thus demonstrating that it is possible to easily achieve a mechanical stimulation by using a position control mode. Fig. 8 also

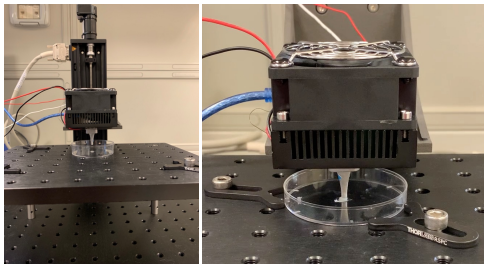

Fig. 7: Setup of the *in-vitro* thermal stimulation of SS sample.

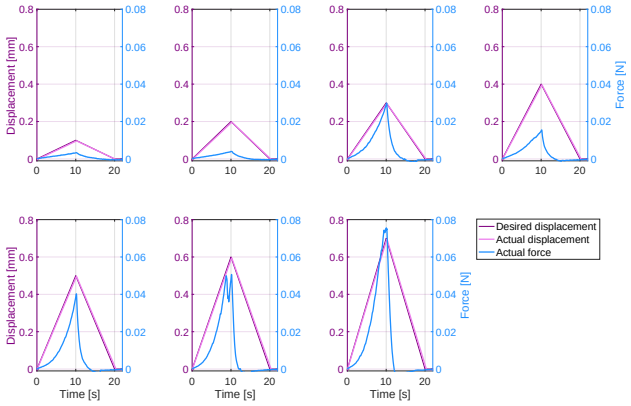

Fig. 8: Force and position data from the position-based mechanical stimulation tests.

indicates clear non-linear force-position characteristics and also a viscoelastic behavior (visible in asymmetric loading and unloading responses), more pronounced with increased displacement.

The results of the force-based stimulation applied on the compound SS-silicone sample are reported in Fig. 9. The tests were successfully performed thus demonstrating that a surface stiffer than the SS sample alone is needed to properly achieve force-based stimulation. Indeed, in this case, the actual force accurately replicates the desired one.

2) Thermal stimulation: The results of the thermal stimulation tests are shown in Fig. 10, where the desired and actual temperature measured at the contact point between the thermal tip and the SS sample are reported. It can be seen that the temperature is maintained almost constant during the stimulation period of 10 s and it is not influenced by

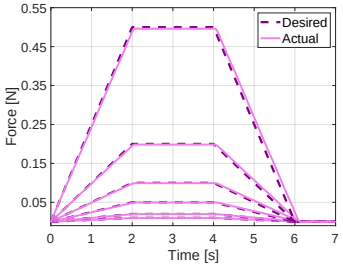

Fig. 9: Desired and actual force data from the force-based mechanical stimulation tests on the SS sample covered with the silicon layer.

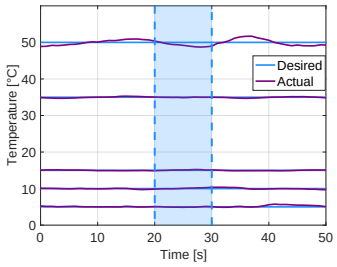

Fig. 10: Desired and actual temperature during thermal stimulation tests.

the contact with the sample, with the only exception of the test at 50 °C, which is likely influenced by the non-constant environmental conditions.

IV. Discussion and Conclusion

A new testbed for studies on somatosensory functions has been developed. It integrates a positioning system, a mechanical stimulator with interchangeable tips to be used in position- and force- controlled modes, and a thermal stimulator, able to deliver hot/cold localized stimuli on tips with two sizes. The testbed has been used in preliminary tests on a fixed SS to demonstrate the capability to produce the desired performance. Thermal and position-based stimulations were successfully obtained. Force-based stimulation suffered from the high difference between tip and sample stiffness. This limitation will be solved by including in the testbed a compliant stimulation tip. This solution will be also useful to potentially perform shear (brushing like) stimulations. Finally, in future works, the testbed will be used in *in-vitro* tests on an innervated skin model and its electrical somatosensory response will be recorded and compared with the one obtained in tests on an *in-vivo* animal model.

***Abstract*— Synthetic and Natural Lipid Bilayer (LB) systems are attracting particular interest due to their distinctive pharmacokinetic profiles and physico-chemical properties. The elastic adaptability owing to the fluidity of lipidic membranes opens exciting possibilities to engineering these structures by properly stimulating them.**

However, a lack of knowledge of the mechanical responses and the high sensitivity to small perturbations are still hindering the accurate manipulation of these complex surfaces. Microfluidic approaches seem to be a good choice to finely manipulate local environmental conditions, in such a way to precisely alter biomembranes and control the final deformative outcomes. However, to the best of our knowledge, microfluidic approaches are mostly geared at stimulating single vesicles, rather than concentrated suspensions.

In a recent work, our group patented an innovative method for the encapsulation of U87-derived exosomes with various molecules, based on the application of high hydrodynamic pressures. It seemed that the pool of forces generated from this stimulation temporarily modified lipidic membranes, allowing the transit of molecules inside exosomes, with the resulting rise of their encapsulation efficiency.

Inspired from these results, we propose the application of controlled stresses on population of lipid-based systems as a way of handling, identifying, and manipulating membrane's mechanics and dynamics, in order to improve and widen their industrial applicability.

***Keywords*—Lipid Based Systems, Microfluidics, Permeabilization, Thermodynamics.**

I. Introduction

LIPID Bilayers (LBs) are complex systems that spontaneously form due to enthalpic and entropic forces established when lipidic molecules are exposed to aqueous environments. This is a result of their amphipathic nature that induce the formation of macromolecular assemblies aimed at reducing the exposure of hydrophobic lipidic fractions to water. [1]

The combination of various lipidic-related factors drives the formation of different architectures [2]. As elegantly described by Antonietti et al. [3] the self-assembly is a two-step process in which amphiphiles first form a bilayer, then rearrange to minimize the system free energy.

However, the structures formed are far from being static and permanent assemblies.

Indeed, the fluidic nature of membranes that may mostly be related to the presence of various lipids in different amounts, has been observed to confer a dynamic structural behaviour [4, 5] .

Accordingly, shapes and compositional arrangements are continuously modified depending on thermodynamic needs and external conditions.

Fluidity of lipid bilayers can be seen as the property filling the gap between the compositional variability and the structure dynamicity, since it allows the activation of remodelling pathways, supporting the lateral diffusion of molecules along the plane of the membrane, the inter-leaflet flip-flop movements as well as bending or thickness fluctuations. Consequently, alterations of membrane properties can be detected in terms of asymmetric molecule assemblies, deformations and rafts formations [6], to name a few.

These alterations may finally be related to variable mechanical properties and physical states, that in turn impact on several biological outcomes.

However, the complex biological remodelling machinery works adaptively [7] and complies with the variations in the external conditions.

It has already been reported [8] that cells are highly regulated by forces, which they are able to transmit from the exterior to the interior and vice versa, or to neighbour cells. Consequently, sensing molecular modulators [9, 10] are activated, showing how elastic features are responsible for activities like vesicle fusion and fission [11], cellular signalling [12], compositional membrane remodelling [7], shape modifications [13].

The distinctive fluidity of the lipidic counterpart has paved the way to the exciting possibility of exposing membrane-formed structures to multiple forces, in such a way to deform their architecture temporarily or permanently, in a controlled manner.

Spanning from cells to both natural and synthetic lipid-based systems, we are investigating how these deformations can be used to temporary permeabilize biomembranes in such a way to encapsulate different types of molecules, or to trigger and modify biological remodelling pathways. We believe that the application of controlled stresses on lipidic membranes may be useful for engineering different LB systems in order to increase their delivery abilities, by directly impacting on their encapsulation, diffusion, Nano-bio-interactions, cell targeting and uptake mechanisms.

II. THEORETICAL BACKGROUND

A. Pioneering descriptions of Lipid Bilayer membranes

The detection of Lipid Bilayers emerged in the first instance from pioneering studies of cells [14-19] and laid the ground to theorizations, debates, and release of various compositional and mathematical models.
The most complete and accepted description is currently considered the Fluid Mosaic model [20], released in 1972 by Sir Singer and Nicolson.
This model highlighted the heterogeneity of bilayers made of lipidic and protein molecules and the fluidic nature of these assemblies, that are able to rearrange according to thermodynamic demands.
Starting from these pillars, further studies were devoted to melting the bundle of the biomembrane dynamics complexity, at various level of interpretation.
The peculiar mechanical properties of lipidic bilayers have been studied for years to discuss the dynamic re-shaping that could be triggered by external or internal stresses.
Mathematical investigations were firstly introduced by Helfrich [21] in 1973.

B. Helfrich-Canham 2D Model

Through a continuum-mechanical approach Helfrich discussed the dynamism as the resulting deformations established after the application of external loads.
Accordingly, the ability to withstand these loads can be related to elastic abilities of storing energy of deformations until a limit, before being discharged under bending.
It can be showed that amphipathic fluid elements are characterized by a spontaneous curvature resulting from the repulsion between hydrophobic moieties and the water environment.
To minimize the contact area, spherical configurations are realized, driven by entropic forces.
A way to identify the spontaneous curvature is through two main radii of curvatures, that can be simplified as the total curvature J and the Gaussian curvature K of the surface.
Through the representation of membranes as bidimensional elastic interfaces [22] , Helfrich applied the principles of Gibbs theory of elastic interfaces [23] to derive a mathematical description that is only based on material properties.
By introducing the main radii of curvatures, as the total curvature J and the Gaussian curvature K, the excess of internal energy U^{exc}, entropy S^{exc}, and masses of components N_i^{exc}, on a diving surface at the lipid – water interface, can be described as:

$$dU^{exc} = TdS^{exc} + \sum \mu_i dN_i{}^{exc} + \gamma dA + A\tau dJ + A\bar{k}dK \quad (1)$$

From mathematical insights described elsewhere [22], by assuming to be in a small elastic deformation regime it is possible to define elastic moduli only dependent on the monolayer internal structure. They are the stretching modulus Γ, the bending modulus k, the mixed modulus E_{AJ}

$$\Gamma = A \cdot \frac{\partial \gamma}{\partial A} \quad (2)$$

$$k = \frac{\partial \tau}{\partial J} \quad (3)$$

$$E_{AJ} = \frac{\partial \gamma}{\partial J} = \tau + A \cdot \frac{\partial \tau}{\partial A} \quad (4)$$

These material parameters can be used along with the assumptions of constant entropy (i.e. ΔS=0), constant amount of lipid molecules (ΔN_i=0) and a flat monolayer (ΔJ=J). Moreover, the dividing surface can be chosen at the neutral surface, where the overall contribution coming from the mixing modulus is equal to zero. In this way, a more compact expression for Eq. (1) can be derived:

$$dU^{exc} = \gamma dA + A\tau dJ + A\bar{k}dK + \frac{1}{2}\Gamma\frac{(\Delta A)^2}{A} + \frac{1}{2}Ak(J)^2 \quad (5)$$

This is the most general expression for the description of the elastic bending forces in bidimensional fluid systems, according to the Helfrich-Canham 2D model [24]. By integrating this expression, it is possible to obtain the deformation energy that drives the shape remodeling:

$$f = \gamma dA + \frac{1}{2}\Gamma\frac{(\Delta A)^2}{A} + \tau \cdot J + \bar{k} \cdot K + \frac{1}{2}k(J)^2 \quad (6)$$

C. 3D Mathematical description of Biomembranes

While for a bidimensional depiction it is possible to neglect some contributions, trans-monolayer stresses become extremely relevant in the 3D case. Indeed, Lipid Bilayers are characterized by lateral stress profiles [6] rising along transverse structures.
Seifert and Langer developed a continuum model [25] explicitly accounting for the bilayer architecture and capturing the major energetic driving forces and dissipative drag forces involved in the dynamics of lipid membranes.
However, a good mathematical description for this class of soft materials must consider a solid–fluid duality, from a mathematical viewpoint.
Indeed, lipid monolayers have been demonstrated to exhibit a lateral liquid-like nature and transverse solid-like. Thus, the stored energy in the transverse direction causes tilt deformations that need to be included in the thermodynamic description through the integration of both a tilt modulus and mixed moduli.
By taking into account all these facts, a tridimensional expression for the excess internal energy of biomembranes can be derived:

$$dU^{exc} = \gamma dA + A\tau dJ + A\bar{k}dK + \frac{1}{2}\Gamma\frac{(\Delta A)^2}{A} + \frac{1}{2}Ak(\Delta J)^2 + E_{AJ}\Delta A\Delta J + Am_t d\theta_t \quad (7)$$

From this formula a complex expression for the total free energy of deformation can be obtained, in terms of the 4th order elastic moduli tensor.
While relying on multiple assumptions, this model provided the first mathematical description of biomembranes, by also including a simple estimation of their dynamic behaviour.

III. ENGINEERING FLUID LIPIDIC MEMBRANES

The mechanical profile of LB systems has emerged as a unique characteristic deriving from the synergic combination of both fluidity and viscoelasticity.

It dictates the ability to respond to applied forces, in light of the material thermodynamical state, architecture and composition.
The deformed states acquired under the application of external stresses and the elastic tendency of restoring initial configurations, are the most relevant contributions that are responsible for the activation of the remodelling machinery in biomembranes.
Deeper knowledge of their functionality could be useful to engineer structures in order to reach desired outcomes.
In particular, the temporary permeabilization of membranes could be an effective approach to increase the encapsulation efficiency of different molecules in various LB systems, by overcoming issues related to the highly impermeability.
Accordingly, the use of microfluidic forces may be an effective approach to establish locally controlled conditions in such a way to predict and manage the forces exerted on single and multiple cell populations.
On the other side, optimal deformations may be designed in such a way to stimulate biological pathways and modify vesicles properties. In this way, there would be a direct implication for both the delivery and the diffusive properties in various biological environments, as well as an improved interaction at different nano-bio-interfaces.
According to the specific aspect to be investigated, LB mechanics can be translated in different aims, moving from mechanical phenotyping or biological investigations to the engineering of drug delivery vesicles.
However, it is only recently that microfluidic approaches are emerging as tools for questioning and investigating mechanical properties of various LBs.
As the primary application, examples of cellular stimulations under hydrodynamic microfluidic forces are reported in the following sections. To the best of our knowledge, different types of stimulations on cells or various LB systems have only been used at single-cell level. Thus, section B is aimed at discussing the applicability of dynamic perturbations on concentrated suspensions, by reporting our innovative approach as a case study.

A. Microfluidic hydrodynamic permeabilization of single cells.

Chung et al. [26] developed a microfluidic platform to inertially focus cells at the centre of the channel and guide them to collide at a T-junction. This hydroporator is able to apply controlled compression and shear forces on single cells, in order to generate transient membrane discontinuities on their membranes and facilitate passive diffusion of various molecules into their cytoplasm, while preserving cell viability. However, despite the high delivery performances also with large nanoparticles, they obtained non-optimized cell deformation patterns that have hampered the applicability of the platform to gene delivery and primary cells.
Two years later, another inertially-based microfluidic platform ending with a cavity on the T-junction [27] was designed.
Adding the cavity instead of the tip, they were able to exploit hydrodynamics to elongate cells and let them collide with the fluidic wall instead of the PDMS.
In this way, the combination of compressive, shear, elongational and collision forces allowed the achievement of a homogeneous deformation field.
Another interesting application of microfluidic hydrodynamics is the investigation of mechanical phenotyping [28] and properties of both adherent and suspended cells [29]. However, to the best of our knowledge all the microfluidic devices already developed that are aimed at stimulating cells are only geared to work at a single-cell level.

B. Hydrodynamic permeabilization of LBs populations.

Differently, our group recently patented an innovative approach to manipulate lipidic membranes at a large scale [30]. We used complex deformative fields deriving from the application of high hydrodynamic pressures in a Microfluidizer (Model M-110P Microfluidizer^{TM} Materials Processor, Microfluidics, Westwood, MA, USA) to stimulate a suspension of U87-derived exosomes. By including recycling cycles, the same fluidic forces were applied to a large number of vesicles, thus realizing a uniform deformative field. The purpose was to temporarily modify external lipidic membranes of multiple vesicles in order to underpin the passive encapsulation of different molecules.
Encouraging results in terms of the highly encapsulation efficiencies of multiple molecules compared to literature, while preserving structure integrity and purity, demonstrated the potential role of high dynamic hydrostatic pressure in temporarily modifying lipidic membranes.

IV. Conclusion

This work is aimed at raising concerns about the necessity of expanding the field of investigation about the mechanical properties of Lipid Bilayer (LB) systems. By quickly introducing theoretical and biological backgrounds that are useful for a deeper understanding of mechanical aspects of these structures, the realization of controlled deformative frameworks is proposed as an engineering approach to modify physico-chemical properties. For this purpose, the optimally designed microfluidic devices seem to be optimal tools to locally control the extent of the forces applied, in such a way to finely modify the deformative outcomes. While microfluidics has been demonstrated to be largely used for mechanical phenotyping or cell manipulation at a single level, there is still a lack of techniques used for LBs manipulation at a large-scale. A high throughput approach based on the use of high hydrostatic pressures on exosomes populations has been recently developed by our group and it is reported here as a model for encouraging next microfluid translations.

***Abstract*—Pudendal nerve stimulation has a proven efficacy in reducing overactive bladder symptoms in patients with, for example, spinal cord injury. Clinical neurostimulation devices provide electrical pulses to the whole nerve with tined lined electrodes. However, the low selectivity of such electrodes does not allow the specific targeting of nerve fascicles. Existing intrafascicular solutions showed higher selectivity but they can induce high nerve trauma or have an unsatisfying conductive site distribution within the cross-section of the nerve.**

Here, an existing tool is exploited for the modeling of mechanical stresses induced by the implant's micromotion, to validate the design of an innovative intrafascicular interface that selectively targets the pudendal nerve. The mechanical stresses induced by the latter are compared to currently used intrafascicular solutions. Our results indicate that the proposed innovative geometry enables the redistribution of micromotion-associated loads to less delicate parts of the interface.

***Keywords*—Pudendal neuromodulation, Bladder dysfunctions, Intra-fascicular implants, Finite elements modeling**

I. Introduction

Lower urinary tract (LUT) symptoms, including incontinence or urinary retention, affected 2.3 billion people in 2018 with negative consequences on their quality of life [1]. Since storage and elimination of urine are controlled by multiple nervous pathways, neurodegenerative diseases such as multiple sclerosis, Parkinson's disease or spinal cord injuries can affect bladder control. [2].

FDA approved sacral nerve stimulation (SNS) for the treatment of urinary urge incontinence, urgency, frequency, and refractory retention. SNS requires the placement of an implantable tined lead electrode to stimulate the sacral nerves [3]. The same technology has been proven to have higher efficacy when implanted within the pudendal nerve for pelvic pain, urgency, frequency, and bowel function [4]. However, the low selectivity of tined lead electrodes in fascicle recruitment can result in side effects, such as dorsiflexion of the toe or pelvic pain [5].

Alternative electrodes available for peripheral nerve stimulation can be classified as extra-neural and intrafascicular. The first ones are typically cuffs revolving around the nerve in a non-invasive way. Their customizable length and diameter give the possibility to target also small nerves. Hokanson studied pudendal nerve stimulation in rats with cuff diameters ranging from 200 µm to 400 µm [6]. Intrafascicular electrodes penetrate the nerve reaching nerve fascicles with higher selectivity [7]. Mathews proved selective recording of felines' pudendal nerve activity evoked by a variety of genitourinary stimuli with high-density Utah slanted electrode arrays (HD-USEA); however, the high degree of nerve damage may have been the cause of loss in neuronal signals over time [8]. Transversal intraneural multichannel electrodes (TIME) proved the higher biocompatibility in long-term applications and the ability to restore sensory feedback in upper-limb amputees [9, 10]. The limitation of TIME electrodes is the distribution of all the active sites along a cutline within the target nerve, which may result in the loss of the contribution of externally distributed fascicles within the nerve cross-section.

In this context, finite elements models (FEMs) are becoming increasingly useful as a guiding tool for the design of new electrodes prior to *in vivo* testing on animals. Akouissi proved the importance of simulating the mechanical effects of the implant's micromotions originating from connecting wires and muscle contractions on the target nerve to optimize electrode geometry and reduce foreign body reaction, which is responsible for the long-term performance of the implant [11].

Here, we used mechanical simulation to evaluate pig pudendal nerve micromotion-associated loads when implanted with an innovative peripheral nerve electrode (iPNE) geometry. The iPNE proposed is able to intersect the specificity of intrafascicular electrodes in selectively considering the fascicles and the non-invasiveness of extra-neural cuff electrodes with active sites distributed within the cross-sectional area of the nerve. The study also compares the mechanical behavior of iPNE with the already existing TIME, which proved their long-term safety in terms of mechanical interaction with nerves.

II. Materials and Methods

All experimental animal procedures were approved by the Italian Ministry of Health and were in accordance with the Italian law (D.lgs. 26/2014).

The behavior of two intrafascicular electrodes (iPNE and TIME) in the porcine pudendal nerve was simulated since LUT's gross anatomy of this animal model is comparable to the human one. The analysis followed the guidelines proposed

by Akouissi to design peripheral nerve implants, adapting the framework from a rodent's sciatic nerve to the porcine pudendal nerve [11]. The nerve simplified geometry and the two electrodes were implemented in the COMSOL 5.6 environment, with the Solid mechanics module. The FEM study was performed using a desktop PC (Windows 7 Professional, Intel Core i7-6700 CPU @ 3.4 GHz, 32 GB RAM) running the previously mentioned software.

A. 3D model of the porcine pudendal nerve

The histological evaluation of the porcine pudendal nerve was performed. The nerve sample was explanted at the ischioanal fossa level by using the transgluteal approach previously described by our group [13]. Histological image acquired with a digital optical microscope (Hirox, Japan) was then segmented using MATLAB (MathWorks, US). The exact shape of each fascicle was obtained from the segmented image. The epineurium surface was simplified into a circle with a radius of 500 µm, estimated as the mean value around the nerve. The simplified 2D geometry of the pudendal nerve was extruded in COMSOL to create a reliable three-dimensional (3D) nerve model. The extrusion length was set to 2 mm according to the boundary condition in section C.

The epineurium, internal epineurium and endoneurium are characterized by mechanical properties taken from literature and listed in Table I [13]. The pudendal nerve was considered composed of linear elastic components. The assumption of operating within the small (< 5%) strain regime allowed neglecting the viscoelastic and non-linear behaviors due to the complex interaction between cells, extracellular matrix and blood vessels.

The mesh was set as free tetrahedral, with a volume distribution increasing distally from the interface with the implants. The maximum growth rate was 1.5, while the minimum element size is 5 µm and the maximum element size was set at 400 µm. Edges and vertices have been smoothed to avoid singularities and further complexity.

TABLE I: Mechanical properties of nerve components

Element	*Poisson's ratio*	*Density [kg/m^3]*	*Young modulus [Pa]*
Epineurium	0.49	1043	100
Internal epineurium	0.49	1014	60
Endoneurium	0.49	1030	90

B. 3D model of iPNE and TIME electrodes

The iPNE implant was modeled as a cuff electrode revolving around the nerve and 5 equally spaced high-aspect ratio spines penetrating the nerve partially embedded within the cuff. The cuff was modeled as 500 µm thick and 1.6 mm long. A connector tip was modeled as a cylinder with 300 µm length and 100 µm radius and embedded in the cuff structure. The fibers were overall 550 µm long, with 350 µm inserted in the cuff and 200 µm inserted in the nerve.

The mechanical properties of the electrode's components are listed in Table II. For this preliminary study, the material chosen for the cuff and the connector tip was Polydimethylsiloxane (PDMS), such as most of the currently used extraneural interfaces [11]. Spines are supposed to be realized with 7 µm carbon fibers, thanks to the small dimension and their high tensile and compressive modulus.

The nerve-cuff and the nerve-fibers interfaces were provided with a triangular mesh with a maximum element size of 60 µm, minimum element size of 1 µm, and maximum element growth rate of 1.5. The cuff and the connector were provided with a tetrahedral mesh with a maximum element size of 300 µm, minimum element size of 5 µm, and maximum element growth rate of 1.5. The fibers were provided with a tetrahedral mesh with a maximum element size of 50 µm, minimum element size of 1 µm, and maximum element growth rate of 1.1.

The TIME implant has been modeled as a rectangular bar crossing the whole nerve, as it is shown in Figure 2 B. The dimensions of the bar are 18 µm in thickness and 545 µm in length, while the extrusion is long 1.6 mm. To reduce the effect of singularities, the edges of the TIME implant have been filleted with a radius of 9 µm. The material chosen for the TIME was Polyimide (PI), as reported in literature [11]. Other metallic elements have been neglected as they do not represent a major part of the electrode, thus they are not significant in the mechanical modeling [12].

The nerve-TIME surface perpendicular to the nerve was described with a triangular mesh having a maximum element size of 20 µm, minimum element size of 1 µm, and maximum element growth rate of 1.5. The nerve-TIME surface parallel to the nerve length was described with a triangular mesh having a maximum element size of 60 µm, minimum element size of 1 µm, and maximum element growth rate of 1.1.

TABLE II: Mechanical properties of electrode components

Element	*Poisson's ratio*	*Density [kg/m^3]*	*Young modulus [Pa]*
Cuff	0.49	965	10^6
Spines	0.3	1800 *10^3	234 *10^9
TIME	0.49	1300 *10^3	2.5 *10^9

C. Boundary conditions and solver

Three boundary conditions were imposed on the 3D models to reproduce the micromotions experienced by the nerve due to the movement of the cables linked to the implant.

Spring foundation boundary condition with elastic properties of the nerve applied to the XY surface at the two extremities of the nerve allowed to virtually extend the short simulated nerve with 6 mm on each side. This allowed to obtain results equivalent to a 14 mm nerve by modeling a shorter 2 mm long nerve with the same mechanical properties and reducing the computational complexity.

An *identity mapping pair* boundary condition linked the surface of the implants with the one of the nerve. This condition represented the worst-case scenario with the TIME and the iPNE electrodes having a complete adhesion to the

nerve. Thus, the condition pictures the stresses and the strains as fully transmitted to the nerve [12].

Prescribed displacement boundary condition simulated the micro-movements the nerve has to withstand when implanted with the two electrodes due to the presence of connecting cables. A displacement of 20 µm (under a small strain regime hypothesis) was applied to the TIME tip and to the iPNE connector tip, perpendicularly to their length.

Results were achieved in a standard stationary study performed at equilibrium. The linear direct solver was used, together with a constant Newton non-linear method with an initial damping factor of 1. The termination criterion was the residual and the procedure is tolerance based. The solution time took approximately 50 minutes.

D. Stress and displacement evaluation

The von Mises stress, called just 'stress' from now on, and the displacement generated on the nerve were evaluated as a consequence of the prescribed displacement of cables for both the iPNE and TIME electrodes implanted.

The maximum stress was evaluated at the interface nerve-implant. To compare results obtained from the two electrodes the maximum stress values were evaluated along cutlines. For the TIME electrode, the stress was evaluated at 5 µm from an in parallel to the rounded part of the implant. For the iPNE, maximum stress was evaluated by averaging the maximum stresses obtained over 5 cutlines, each of them considered at 5 µm from and in parallel to each of the spines.

Sharp changes in the geometries and material properties of the models may cause singularities, thus the evaluation of maximum stress and displacement may bring to unrealistic information. Bearing that in mind, the average stress at the interface nerve-implant was evaluated far from the entry point, where the effect of that uncertainty is not significant anymore. This distance was set to 100 µm as it is the minimum distance sufficient to avoid the effect of singularities [12]. The average stress was calculated by averaging the total stress retrieved on an XY cut plane at 100 µm from the implanted part of the electrode and dividing the obtained value by the total area of the implants. All the average stress results were normalized with respect to the maximum stress obtained in the simulations in the cut planes built at 100 µm from the implants, which is the one retrieved in the TIME model. For the TIME electrode, the average stress retrieved at 100 µm from the implantation site was normalized by dividing the TIME area. For the iPNE electrode, three different normalization areas were considered for the evaluation of the average stress retrieved at 100 µm: the array of spine constituting the iPNE electrode, the spine array together with the internal portion of the cuff, and the whole iPNE electrode surface in contact with the nerve. The internal portion of the cuff considered was limited to 200 µm since this area is supposed to withstand mostly the effect of friction. Displacement quantification followed a similar path, as the trend of the maximum displacement applied on the nerve was evaluated at intervals of 100 µm starting from the center of the implants.

III. Results

A. 3D model of the porcine pudendal nerve

Figure 1A shows the histological image of the explanted pudendal nerve. Figure 1B shows the simplified 2D geometry of the pudendal nerve implemented in COMSOL. The final 3D design of the nerve includes 19 fascicles (endoneurium) embedded in the internal epineurium, which is wrapped by the epineurium (100 µm thickness).

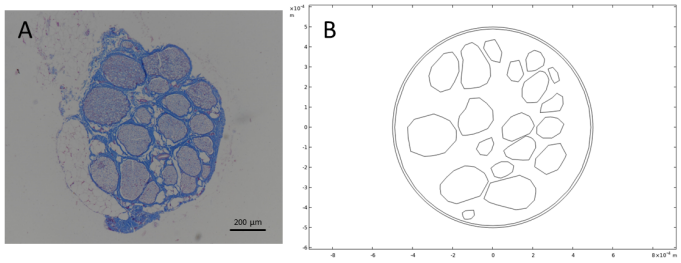

Fig. 1: A) Histological image of the pudendal nerve stained with Mallory's trichrome. B) Simplified 2D geometry of the pudendal nerve implemented in COMSOL.

B. 3D model of iPNE and TIME electrodes

The 3D model of the iPNE electrode inserted in the pudendal porcine nerve is shown in Figure 2A, while the one of the TIME is shown in Figure 2B. Both of them are pictured in their three-dimensional versions.

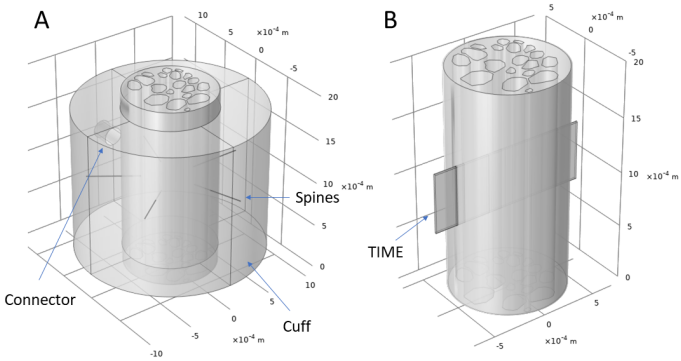

Fig. 2: A) 3D model of the iPNE and B) 3D model of the TIME with the 3D model of the pudendal nerve.

C. Stress and displacement evaluation

Figure 3A shows the maximum von Mises stress for both the TIME and iPNE electrode at the interface nerve-implant. The trend is descending in both cases. However, the stress produced from the TIME on the nerve is considerably higher (from 3 to 4 orders of magnitude) than the one resulting from the iPNE.

Figure 3B shows the stress retrieved at 100 µm from the implantation site, averaged by dividing it for the area of the

TIME, the array of spine constituting the iPNE electrode, the spine array together with the internal portion of the cuff and the whole iPNE electrode surface in contact with the nerve.

Finally, the results regarding the displacement are shown in Figure 3C. Consistently with the previous ones, even in this case, the displacement applied by the iPNE on the nerve is not only lower than the one applied by the TIME but also more consistent throughout the whole nerve length.

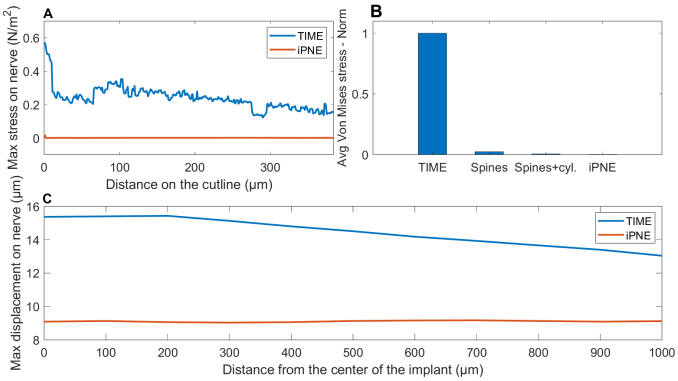

Fig. 3: A) Maximum von Mises stress on the nerve with varying distance on the cutline. B) Bar graph showing the average normalized von Mises stress at 100 µm from the implant. C) Displacement trend on the nerve with increasing distance from the center of the implant.

IV. Discussion & Conclusions

The results obtained with the FEM studies have shown promising results justifying the development of the iPNE interface as an alternative to currently used intrafascicular interfaces like the TIME.

The von Mises stress studies demonstrated that the maximum stress not only generally has a decreasing trend increasing the distance from the insertion point, coherently with the implantation of the electrodes (higher stresses will be closer to the insertion point), but it is also remarkably lower in the case of the iPNE. Moreover, the results obtained from the averaged stress study proved that even considering only the spines, which means averaging over a very small surface area, the averaged stress produced by the iPNE is orders of magnitudes lower than the one of the TIME interface.

Finally, the results regarding the displacement are in line with the previous reasoning. The displacement applied on the nerve by the iPNE is consistently lower than the one of the TIME. On top of that, the displacement enforced on the nerve is also more stable. This is a crucial point because it implies that the displacement does not twist the nerve in the case of the iPNE, rather it remains constant, shifting the twisting effect on the cuff itself.

Limitations of this work are the absence of an analysis of the different materials that could be used to construct the interface and the lack of an evaluation of the electrical selectivity performance of the iPNE. Although the properties of the design have been confirmed, new materials could be exploited to create an electrode that is more adherent to the nerve and more stable in terms of mechanical properties. Regarding selectivity, the distribution of active sites within the cross-sectional area of the nerve within the iPNE is expected to improve selectivity performance compared with placement along a straight line as in TIME, but future studies will evaluate these aspects. However, the model appears to be a reliable tool.

Development of excitatory neuronal networks derived from human induced pluripotent stem cells

G. Parodi[1], M. Chiappalone[1], and S. Martinoia[1]
[1]*Department of Informatics, Bioengineering, Robotics, and Systems Engineering (DIBRIS), University of Genova, Genova, Italy*

***Abstract*— The combination of neuronal networks derived from human induced pluripotent stem cells (h-iPSCs) with micro-electrode arrays (MEAs) opened new perspectives in the neuroscience and neuroengineering fields. In this paper, we present the electrophysiological characterization of excitatory h-iPSCs-derived neuronal networks obtained from healthy subjects. We recorded the neural activity from 35 up to 91 days *in vitro*, and we extrapolated the main features describing both firing and bursting patterns. With this work, we provide a solid baseline for future exploitation of *in vitro* human-derived experimental models in the field of personalized medicine.**

***Keywords*— *in vitro*, micro-electrode arrays, electrophysiology, spike, burst**

I. Introduction

The human brain is the most intricate system of the human body, composed by about 85 billion of neuronal cells that communicate with each other through electrical signals [1]. Over the years, understanding the processes and behaviour of the neural circuitry became of fundamental importance, as it can favorably impact the biomedical field. However, due to the complexity of such organized system, this is one of the major challenges in neuroscience, regardless of substantial advancement in *in vivo* electrophysiology investigation [2].

Thus, the intricacy of the human brain leads to the research of simplified *in vitro* models, replicating the *in vivo* neural activity and communication. Through the years, several *in vitro* models have been proposed to characterize the neuronal activity, mainly of animal origin [3], [4], [5]. However, to obtain *in vitro* systems that closely resemble the *in vivo* condition, human induced pluripotent stem cells (h-iPSCs) have been recently gaining popularity. One of the great strengths in the use of h-iPSCs is the possibility of deriving the cultures from human donor somatic cells [6], [7], this opening up new opportunities in the field of personalized medicine. Indeed, by using h-iPSCs, it is possible to create *in vitro* patient-specific systems that well mimic the activities and processes of the human brain, allowing to overcome limitations and ethical issues due to the use of animal species [8], [9]. To characterize these cultures, one of the most powerful technologies able to collect electrophysiological signals from *in vitro* networks is the micro-electrode array (MEA). MEAs can be coupled with electrogenic cells without affecting their viability and/or functionality [10], since they perform extracellular measurements. Hence, the combination of MEAs technology with neuronal networks derived from h-iPSCs can provide a reliable *in vivo*-like experimental model [11].

Despite the promising premises, these cultures have not been widely characterized from the electrophysiological point of view [12], [13], as most studies in the literature are focused on models of animal origin.

In this work, we perform a study centred on the development of *in vitro* h-iPSCs-derived neurons over a long time period, to understand the stability of our experimental model and its evolution over the time. In particular, we present the characterization of cortical excitatory h-iPSCs-derived neuronal networks obtained from healthy subjects by means of MEAs. The cultures of h-iPSCs were derived from somatic cells and gave rise to neuronal networks thanks to the overexpression of Neurogenin-2 (Ngn2). We recorded the electrophysiological activity during the spontaneous development, and we extrapolated the main features that describe the firing and bursting activity, typical of the *in vitro* populations. Our study provides a first, solid baseline in the characterization of h-iPSCs-derived neurons, necessary to identify the best experimental conditions which resemble the human *in vivo* development for applications in the personalized medicine field.

II. Materials and Methods

A. H-iPSCs cultures

The h-iPSCs cultures were maintained in E8Flex medium (Thermo Fisher Scientific) with the following supplements: E8F supplements (2%, Thermo Fisher Scientific), pen/streptomycin (1%, Sigma-Aldrich), G418 (50 µg/ml, Sigma-Aldrich), and puromycin (0.5 µg/ml, Sigma-Aldrich).

The medium was refreshed every two days. After stressful steps (e.g., thawing or splitting), to the aforementioned medium was added RevitaCell (1%, Thermo Fisher Scientific) to facilitate the recovery of the cells.

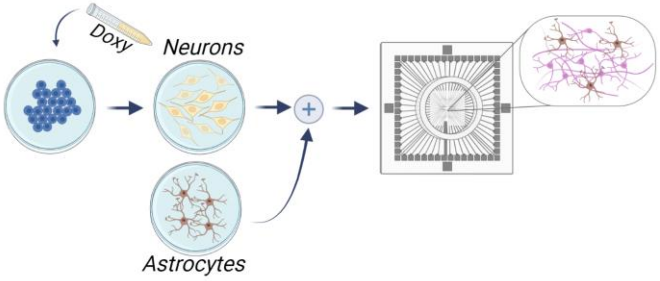

Fig. 1: Schematic representation of neuronal culture protocol. From left to right: h-iPSCs culture are induced to differentiate into neurons with doxycycline administration. Then, the early-stage neurons are co-plated with rat astrocytes on MEAs active area.

Neuronal cultures were obtained with the overexpression of Neurogenin-2 (Ngn2) [11]. The cells were induced to differentiate into excitatory cortical neurons with doxycycline (4 µg/ml, Sigma-Aldrich) treatment added to the medium (Fig. 1). The h-iPSCs cultures could be considered as early-stage neuronal cells after 3 days of doxycycline administration. The cultures were maintained at 37°C/5.5% CO_2 in incubator in stable condition.

B. Neuronal cultures

To obtain the neuronal cultures, early-stage neurons were detached with Accutase (Sigma-Aldrich). MEAs devices were previously cleaned, sterilized, and treated overnight with the following adhesion factors: poly-L-Ornithine (50 µg/ml, Sigma-Aldrich) and human laminin (20 µg/ml, BioLamina). After the detachment, excitatory neurons were co-plated on MEAs with rat astrocytes (30%) to promote neuronal development and maturation (Fig.1) [14]. The co-cultures were plated at a final density of 1200 cells/mm^2 and were maintained into Neurobasal medium with the following supplements: B27 supplements (2%, Thermo Fisher Scientific), penicillin/streptomycin (1%, Sigma-Aldrich), L-Glutamine (1%, GlutaMAX 100X, Thermo Fisher Scientific), human Brain-Derived Neurotrophic Factor (BDNF, 10 ng/ml, Sigma-Aldrich), human Neurotrophin-3 (NT-3, 10 ng/ml, Sigma-Aldrich), doxycycline (4 µg/ml, Sigma-Aldrich). After 7 days *in vitro* (DIV), Fetal Bovine Serum (FBS) was added to the abovementioned supplemented medium. After 14 DIV, doxycycline was removed from the culture medium. The medium was refreshed every two days at the 50%. The cultures on MEAs were stably maintained in the incubator (same conditions specified above) till up to 91 DIV.

C. MEA set up and data recordings

We used commercial MEAs for our study (i.e., 60 TiN electrodes on glass substrate, arranged in an 8x8 grid layout, Multi Channel Systems - MCS, Reutlingen, Germany). The electrodes were equally spaced with a 200 µm of distance and 30 µm in diameter. Electrophysiological data was acquired with the MEA2100 system (MCS, Reutlingen, Germany). The recordings were performed on 6 cultures at three different time points: DIV 42, DIV 70, and DIV 91. During each experimental session, after 10 minutes of rest out of the incubator, the electrophysiological spontaneous activity was recorded at a 10 kHz-sampling for 15 minutes (37 ℃, 5% CO_2).

D. Data analysis

Data analysis was performed using SpyCode [15] and custom-made codes developed in MATLAB (The Mathworks, Natick, MA, USA). We pre-processed the data adapting the pipeline presented in [4]. Briefly, to perform spike detection we used the precision time spike detection [16]. The threshold of noise for spike detection was set to 10 times the standard deviations, while the peak lifetime period and the refractory period were both set at 2 ms. The mean firing rate - MFR (i.e., number of spikes in the unit time) for each network was computed as the average among the firing rates of all the active channels. Channels with firing rate greater than 0.1 spikes/second were considered as active [11]. Bursts were detected using the logarithmic binning of the neuronal inter-spike interval (ISI) [17]. An event was defined bursts if the intra-burst frequency was higher than 50 spikes/second and if it was composed by at least 10 spikes. For two consecutive bursts, if the inter-burst interval (IBI) was lower than 50 ms, we merged the two bursts. Active channels with a bursting rate greater than 0.4 bursts/minute were considered as bursting channels [11]. The mean bursting rate (MBR) for each network was calculated by averaging the bursting rate of all the bursting channels. To characterize the neuronal activity, we extrapolated the IBI, defined as the time that elapses between the end of a burst and the beginning of the next one, and mean frequency intra burst (MFIB), defined as the number of spikes detected over the burst duration. We realized the raster plots by representing the spikes detected for each channel with a black dot. We computed the cumulative spike trains by merging the activity detected over all the electrodes. Subsequently, the cumulative spike trains were binned (bin = 10 ms) and all the spikes detected over all the electrodes in each bin were counted. In this way, we obtained the cumulative histogram, representing the network behavior.

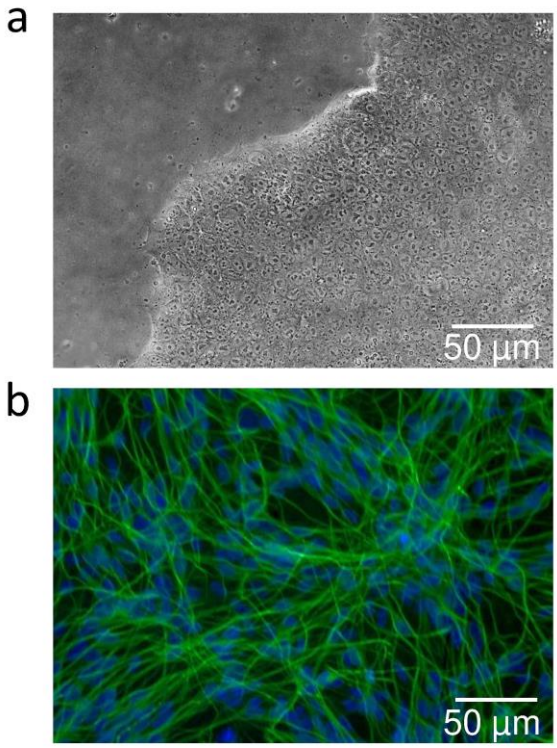

Fig.2: a) Representative h-iPSCs culture. **b)** Neuronal network image of excitatory neurons culture three days after the doxycycline administration (green: MAP2 and blue: DAPI).

E. Immunocytochemistry

The immunocytochemistry was performed on h-iPSCs-derived cultures after 3 days from the administration of doxycycline (early-stage neuronal cultures). Cells were fixed with 4% paraformaldehyde (PFA) in phosphate buffer solution (PBS) for 10 minutes at room temperature (RT) and permeabilized with 0.2% of Triton-X100 in PBS for 10 minutes at RT. We blocked unspecific binding sites with

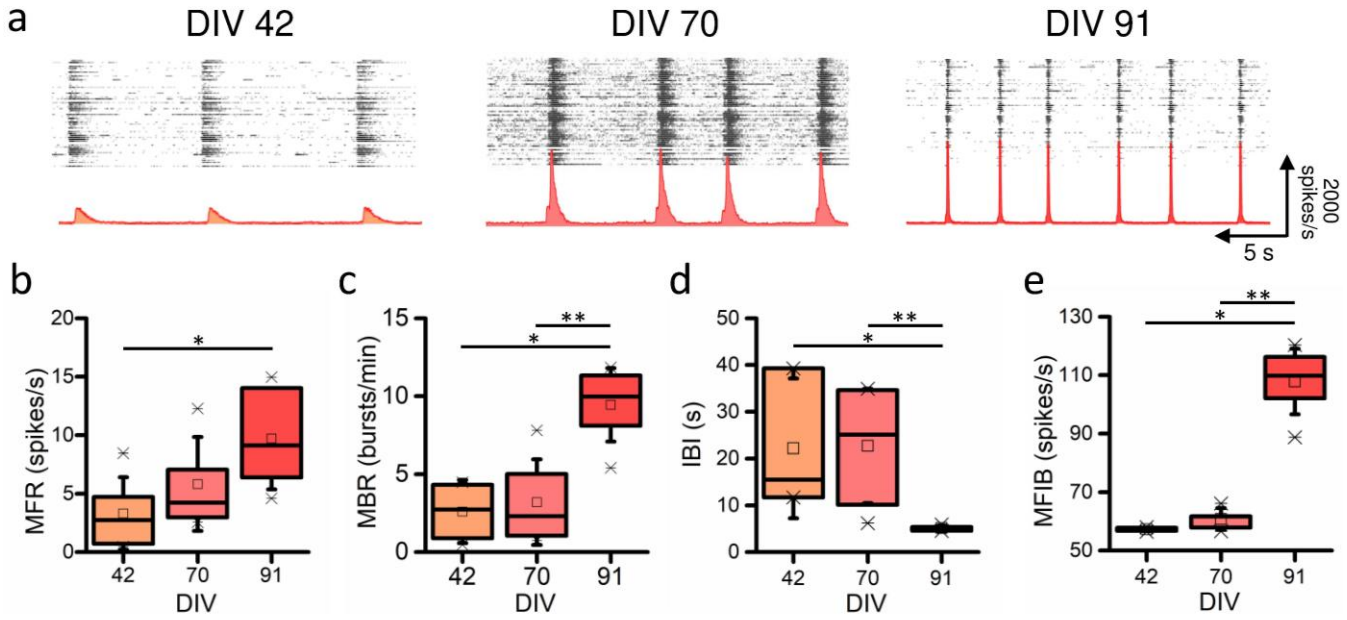

Fig. 3: Characterization during the development of excitatory neuronal networks derived from h-iPSCs. **a)** Representative electrophysiological spontaneous activity at DIV 42, 70, and 91 (from left to right). In particular, raster plots (on top), in which a black dot and a dense black band represent a detected spike and a network event, respectively, and the corresponding cumulative histograms (on bottom). **b-e)**: Box plots of the extrapolated features characteristic of the firing and bursting activity: **b)** mean firing rate (MFR); **c)** mean burst rate (MBR); **d)** inter burst interval (IBI); **e)** mean frequency intra burst (MFIB). In the box plots, the data are represented with the percentile 25-75 (box), the standard deviation (whiskers), the mean (square), the median (line), and the minimum and maximum (crosses) values.

blocking buffer solution (BBS) composed of 0.2% Triton-X100, 5% FBS in PBS for 1 hour at RT. We diluted in BBS the MAP2 primary antibody (rabbit polyclonal 1:500, Synaptic System) to label the microtubes' proteins of the neurons' cytoskeleton. Primary antibody solution was incubated overnight at 4°C. We diluted the following secondary antibodies in BBS: Alexa Fluor 488 (goat-anti rabbit, 1:700, Invitrogen) to label MAP2 primary antibody and DAPI (1:10000, Sigma Aldrich) to mark the cells' nuclei. Secondary antibodies solution was incubated for one hour at room temperature.

F. Statistical analysis

Statistical analyses were performed using MATLAB (The Mathworks, Natick, MA, USA). We exploited Kolmogorov-Smirnov normality test to assess the normal distribution of the data. As data were not normally distributed, we performed a non-parametric Kruskal-Wallis test. Statistical significance levels were set at $p < 0.05$. Asterisks over the plots show statistically significant differences. All values in the text are reported with mean ± standard deviation, unless otherwise indicated.

III. Results

The electrophysiological activity of h-iPSCs-derived neurons were monitored during their spontaneous development.

The acquired images of the cells indicated that the obtained cultures were characterized by compacted colonies with well-defined edges. Uniform and circular cellular morphologies among colonies and low levels of differentiated cells in the cultures were qualitatively observed (Fig. 2a). After the induction of the overexpression of Ngn2 with doxycycline administration, we performed immuno-cytochemistry to monitor the cell differentiation into neurons. In Fig. 2b, a neuronal network image is reported in which the excitatory neurons (green, MAP2) and the cells' nuclei (blue, DAPI) were labelled. The cultures qualitatively showed a high differentiation yield after 3 days from the administration of doxycycline.

We then recorded the electrophysiological activity of our cultures at DIV 42, 70, and 91. In Fig. 3a, we report the raster plots (top panels) and the respective cumulative histograms (bottom panels) of one representative culture at the different time points. Qualitatively, we can observe an increase of the activity along the development (Fig. 2a, top), during which more evident bursts are displayed. The increase in the number of network events and in the amplitude of the same was paralleled by a reduction of their duration (Fig. 2a, bottom). This implies that the neuronal cultures were characterized by a more packed and organized activity at DIV 91 with respect to the previous temporal steps. To quantify these differences, we computed a set of firing and bursting-related features (i.e., MFR, MBR, IBI, and MFIB).

The firing pattern showed an increasing MFR (Fig. 2b) with significantly statistical differences between DIV 42 and DIV 91 ($MFR_{DIV42} = 3.3 \pm 3.1$; $MFR_{DIV70} = 5.82 \pm 4.01$; $MFR_{DIV91} = 9.70 \pm 4.32$; 42 vs 91: $p = 0.025$). Subsequently, we investigated how the bursting activity evolved during the weeks. We observed a similar result: MBR demonstrated a relevant increase during the weeks (Fig. 2c, $MBR_{DIV42} = 2.60 \pm 2.02$; $MBR_{DIV70} = 3.20 \pm 2.75$; $MBR_{DIV91} = 9.43 \pm 2.36$; 42

vs 91: p = 0.01; 70 vs 91: p = 0.006). With the increasing MBR, a parallel and reasonable decrease of the IBI (Fig. 2d) was found (IBI_{DIV42} = 22.16 ± 14.94; IBI_{DIV70} = 22.67 ± 12.22; IBI_{DIV91} = 5.10 ± 0.57; 42 vs 91: p = 0.025; 70 vs 91: p = 0.006). Finally, since the aforementioned parameters were related only to the occurrence of the events, we were interested in understanding whether also the organization of the spikes intra burst was affected by variation during the development. Thus, we considered the MFIB, and we determined the range values of the feature to describe the neuronal network phenotype (Fig. 2e). MFIB showed significantly statistical differences between the DIV 91 with respect to both DIV 42 and DIV 70, supporting what observed in the raster plots and the cumulative histograms ($MFIB_{DIV42}$ = 57.25 ± 0.68; $MFIB_{DIV70}$ = 60.80 ± 3.76; $MFIB_{DIV91}$ = 107.84 ± 11.26; 42 vs 91: p = 0.01; 70 vs 91: p = 0.006). To conclude, multiple features describing both firing and bursting patterns suggested an increasing and more organized activity during the weeks *in vitro*.

IV. Conclusion

In the present work, we performed the electrophysiological characterization of h-iPSCs-derived excitatory neuronal networks over a long-period of time (until DIV 91) to quantify both firing and bursting patterns. During the first monitored weeks (from DIV 42 to DIV 70), the cultures maintained stable firing and bursting parameters. Later in the development, at DIV 91, the MFR, MBR, IBI, and MFIB exhibited a significant variation, according to the maturation stage of the networks. Thus, the presented results showed that neuronal networks derived from h-iPSCs self-organize into functional neuronal networks, modifying both firing and bursting patterns. Our findings, even if preliminary, provides an indication that the developmental profile of h-iPSCs-derived neurons is consistent with what observed in animal models [18]. Additionally, our experimental model presents a not negligible strength: being of human origin, it resembles more faithfully the *in vivo* condition, overcoming the problems due to the translation of species and ethical issues due to the use of animal models. Nevertheless, further studies are necessary to confirm the developmental profile, by for example performing more frequent recordings. Moreover, a substantial improvement might consist in the introduction of different neuronal types (e.g., inhibitory neurons) leading to a more physiological model which better resembles the *in vivo* conditions.

To conclude, we provided the characterization of excitatory neuronal networks that can be exploited as a reference to analyze the behavior of Ngn2-induced cultures. As a future perspective, our study can be relevant in the field of personalized medicine, to compare healthy phenotypes with patient-specific models and to facilitate the performance of targeted pharmacological tests.

Acknowledgement

The authors wish to thank University of Twente, in particular Dr. Monica Frega, to kindly supply the h-iPSCs cultures and Dr. Mariateresa Tedesco for gently providing rat astrocytes.

***Abstract* — The protein stability in protein-based therapeutic injectables (typically highly concentrated and viscous (HCV) solutions) is essential, as its lack determines mild to severe immune response in patients. Commonly, protein stabilization is attempted by adding stabilizers to the biomolecule solutions that are consequently studied by being exposed to physico-chemical solicitations to induce protein destabilization. Standard protocols to study protein HCV solutions rely on batch approaches, that exhibit poor controllability and are time- and reagent-consuming. Because of this and due to the rheological complexity of these fluids, there is still poor scientific knowledge about the correlation between protein stability in HCV systems and destabilization factors. Also, just a little is known about the role and the interaction of stabilizing agents with biomolecule in solution. Here a novel miniaturized approach based on microfluidics to study protein behavior in HCV systems is proposed. While requiring minimum solution volumes to be processed, the automated microfluidic platform can stimulate HCV protein solutions, offering fine controllability of stimulating environment in a wide viscosity range and in a broad spectrum of thermal and mechanical stimuli. As proof of concept, some results from light scattering-based analysis comparing stimulated and unstimulated HCV BSA solutions are presented.**

I. Introduction

The study of biomolecules (lipids, carbohydrates, nucleic acids, oligonucleotides, proteins, peptides) covers a focal role and aims to broaden their potential utilizations in many fields, ranging from the industrial, to biological and biomedical sector. Protein-based therapeutics have been shown to be encouraging for the treatment of many diseases, performing much better than synthetic small-molecule drugs thanks to their high specificity and physicochemical properties [1]. Despite their potentials, protein-based injectables manifest some drawbacks mainly related to immunogenicity, determining either drug inefficacy or, in worse cases, harmful side effects in candidate patients. The phenomenon has been shown to lie in biomolecule instabilities occurring in the injectable solutions that cause the proteins to degrade or aggregate [2]-[5]. In fact, protein stability (both conformational and colloidal) is threatened by several factors, including *solution conditions* (ionic strength, pH), *temperature, mechanical stress, light* and *exposure to chemicals*, that are surely encountered throughout the biomolecule lifecycle, from the manufacturing to the transportation and patient injection [6]-[11]. With the aim to shield it against the overmentioned factors, the protein is typically solubilized with additives (sugars, amino acids, surfactants etc.), yielding to highly concentrated and viscous (HCV) systems, properly named *formulations*. These solutions are typically studied by subjecting them to physico-chemical stimulations (thermal, mechanical, photonic and chemical stress) and then analyzed through several spectroscopic, spectrometric, optical or chromatographic techniques to assess their impact on protein physical state (aggregation, fragmentation, degradation etc.) [12]-[17]. Studies on biomolecule stability in formulations are mainly conducted through time- and reagent-consuming batchwise protocols, that provide poor controllability of process parameters, low-throughput exploration of stress conditions and inadequate versatility in terms of stress combination. In addition, the use of *offline analysis techniques* includes long preparative phases (*e.g.,* high dilution), causing the stressed formulation to be analyzed in a context by far different from the original stimulated solution.

Because of the limitations posed by current approaches along with the challenging chemical and rheological features of the fluids in question, there exist a prominent lack of scientific knowledge about the correlation between physico-chemical stimulating factors and protein behavior. Also, a considerable gap is still present in the comprehension of the physical and chemical interactions among stabilizers and proteins in HCV formulation.

Here the *proof of concept* of the application of a novel microfluidic-based approach to study protein stability in HCV systems is presented. The automated microfluidic platform applies physico-chemical stimulations to HCV protein solutions in broad thermal and mechanical solicitation ranges. It manages an *ample fluid viscosity interval* offering *superb controllability* of the stimulating environment in terms of *intensity*, *stimulus duration* and *reproducibility*.

II. Materials and methods

A. Materials

Harvard syringe pumps, model 11 Elite, were employed to inject the formulations into the microfluidic platform. Automated valves, a Peltier cell, an aluminum heat sink, thermocouples and dedicated controllers were obtained from LabSmith microfluidics. The two-position three-port automated valves (part number AV201-T116) serve either as simple on/off or as switchers to create preferential pathways for the processed fluids. The 2x2 cm Peltier cell (part number uTE02-132020; max T 130°C; ΔT between faces 67°C; 13 W) was used as heating source. The heat sink (part number HS-2020) is placed on top of the cold side of the Peltier cell for fine temperature control as it provides the contribution to a

proper thermal module mass. Thermocouples (part number uTS01-STD-20) are used for real-time temperature control. The mentioned parts and the controllers are connected by flexible cable to enable electric signal transmission for their control. A miniaturized peristaltic pump (part number 3200243) was purchased from Dolomite microfluidics to realize the fluid recirculation. Nominally, it guarantees a non-tunable stable 0,45 ml/min flow rate with a 3V supply. For sake of completeness, the actual experienced miniaturized peristaltic pump flow rate was about 800 µl/min. Polymethyl methacrylate (PMMA) was processed through a Minitech CNC mini-mill/GX to build up the customized microfluidic chip. All the microfluidic parts, were interconnected through FEP tubing (0.8 mm ID, 1.6 mm OD).
Bovine Serum Albumin (BSA) was bought by Merck (product code A2153) and solubilized in phosphate buffered saline (PBS) 10 mM pH 7,4 (Sigma-Aldrich, product code P4417).
MilliQ water was used to prepare the buffer solution and to wash the microfluidic platform.

B. Methods

1) Microfluidic platform development

Considering the high concentration and viscosity of fluids being processed through the microfluidic plant, the sizing of the latter (microfluidic chip shape and dimension, inlet/outlet bore of valves, tubing diameter and length) was properly conducted through precise calculations and numerical simulations aiming to minimize the pressure drops.
For the thermal line setup, some microfluidic parts (automated two-position three-port valves, Peltier cell, heat sink, miniaturized peristaltic pump, 0.8 mm ID - 1.6 mm OD FEP tubing) were carefully selected from the market, verifying their geometrical and operational features to suit the purposes of the present work. Plus, the microfluidic chip was designed, optimized through numerical simulations and fabricated through a Minitech CNC mini-mill/GX machine. A feasibility study was conducted to define the process parameters and their impact on the temperature control. The explored variables were: *target temperature*, *heating voltage ramp* and *tolerance*. All other variables (*fluid flow rate* and *Peltier Cell operating voltage window*) were kept constant throughout this study (800 µl/min and ± 3.5 V, respectively).
Also, numerical simulations were carried out to characterize the and heat transfer kinetics into the microfluidic chip.
The same approach was used to build the mechanical stress microfluidic line. Automated programmable elements (valves, miniaturized pumping device) and tubing were properly chosen to promote versatility and ability to manage HCV fluids. In addition, A PMMA customized microfluidic chip was appropriately designed, optimized through numerical simulations and fabricated to have a controlled and defined shear rate.
The ability of the platform to manage HCV fluids was assessed by processing different protein solutions with variable viscosity: *low* [1; 4] mPa*s, *moderate* [4; 7] mPa*s and *high* [7; 15] mPa*s. According to literature study and data collected from pharma industries, the overmentioned fluid property thresholds are exhaustively representative of typical viscosity of injectable biologics.

2) Preparation of HCV protein solutions

The protein solutions having different viscosity values were prepared combining BSA and sucrose. For low viscosity (1-4 mPa*s) formulations, [0; 100] mg/ml of BSA and sucrose were dissolved in PBS. To obtain moderately viscous (4-7 mPa*s) solutions, [125; 175] mg/ml of the same components were solubilized in PBS. In addition, [200; 300] mg/ml of BSA and sucrose were solubilized in PBS in order to prepare the high viscosity (7-15 mPa*s) fluids. The system subjected to thermal and mechanical stress was a HCV BSA solution (≥300 mg/ml in PBS).
The overmentioned solutions were all filtered with a 0,22 µm syringe filter to remove any impurity and stored at 5 ± 3 °C.

3) Thermal stimulation of protein solution

The microfluidic platform was programmed to offer a 60°C stable environment and stimulate the HCV BSA solution for 5 min.

4) Mechanical stimulation of protein solution

The platform was programmed to recirculate the HCV BSA solution for 15 min while undergoing 8000 s^{-1} max shear rate intensity.

5) Protein stability analysis in HCV solutions

Nanoparticle tracking analysis (NTA) were performed to compare untreated and treated protein solutions. Both stimulated and unstimulated HCV BSA fluid systems were diluted 1000 times in PBS before being analyzed. The particle (aggregation body) concentration was identified for the thermally and mechanically treated and untreated fluids.

III. RESULTS

A. Microfluidic platform setup and rheological window

The microfluidic platform is composed of a syringe pump connected to the thermal and mechanical stress modules.
In particular, the thermal line presents some automated and programmable two-position three-port valves to create preferential pathways for the processed fluids (forward or backward directions). Moreover, a Peltier cell is in touch with a heat sink on the cold side and a customized PMMA microfluidic chip on the hot one. In addition, a miniaturized peristaltic pump enables the recirculation of the fluid to control the duration of the stimulation. The microfluidic parts of the thermal stress line are all linked through 0.8 mm ID, 1.6 OD FEP tubes. The overall volume of this module is around 300 µl.
The microfluidic mechanical stress line exhibits the same valve configuration of the thermal stress. Similarly to the latter, the automated valves are linked to a customized PMMA microfluidic chip. Furthermore, a miniaturized peristaltic pump is connected to achieve the fluid recirculation throughout the chip. As for the thermal stress, the recirculation enables a fine control on the extent of the stimulation. The components of the mechanical stress module are all connected through 0.8 mm ID, 1.6 mm OD FEP tubes and the overall volume of the mechanical module is slightly less than 300 µl.
The microfluidic platform was properly designed and developed to manage HCV fluids, precisely in viscosity ranges typical of injectable protein-based therapeutics. As matter of fact, the microfluidic plant can be used to process fluids whose *initial viscosity* ranges from 1 to 15 mPa*s. It must be said that this upper value is not a categorical limit of the platform. Indeed, while being stimulated, the rheological properties of

the HCV protein formulation can deeply change: typically, the fluids experience a considerable increase in the viscosity, reaching values far higher than 15 mPa*s. This behavior was also detected during the thermal stimulation of the HCV BSA solution and the platform did not show any tendency to clogging.

1) Thermal stress operational range and temperature control

Preliminary experiments conducted in a feasibility study clarified the influence of the process parameters, *i.e.* target temperature, heating voltage ramp and tolerance. Concisely, the following conclusions can be drawn:

1. the higher the target temperature, the longer the stabilization time (for a fluctuation-free thermal environment);
2. at the same target temperature, the higher the heating voltage ramp, the wider the temperature oscillations of the system;
3. at the same target temperature, the smaller the tolerance, the broader the system oscillations.

Based on the knowledge acquired in preliminary experiments, a combination of process parameters for an excellent temperature control in the range [50; 80] °C was defined (TABLE I).

TABLE I: COMBINATION OF PROCESS PARAMETERS FOR FINE TEMPERATURE CONTROL IN [50;80] °C

Process parameters	Value
Fluid flow rate	800 µl/min
Peltier Cell operating voltage window	± 3.5 V
Heating voltage ramp	0.001 V/s
Tolerance	± 1.5 °C

A typical stimulation temperature trend can be divided into three phases: the first is intended to reach the target temperature. This phase is characterized by the same process parameters reported in the TABLE I, except for the heating voltage ramp, that is set to 0.005 V/s to minimize the time needed for the thermal module to reach the target temperature. The second phase is needed to stabilize the temperature around the target; the third is the actual thermal stimulation. The second and third phases present the same parameter configuration reported in TABLE I.

TABLE II reports the equilibration time (extent of the second phases) at different target temperatures. In general, the higher the latter, the longer the stabilization time. The only dissonant voice is observed for 70°C that requires the largest equilibration time. In spite of this, the reported values seem to be reproducible.

TABLE II: THERMAL STRESS LINE EQUILIBRATION TIME AT DIFFERENT TARGET TEMPERATURE

Target Temperature (°C)	Equilibration time (s)
50	140
60	180
70	320
80	190

Once equilibrated, the thermal line is ready to dive into the third phase for a stable stimulation. In TABLE III the average temperature and standard deviation at different targets are reported over 2, 5 and 10 min of stimulation.

TABLE III: Average temperature and standard deviation for different targets

Target Temperature (°C)	2 min	5 min	10 min
50	49.0 ± 2.2	48.6 ± 1.6	48.5 ± 1.6
60	61.2 ± 0.1	61.4 ± 0.2	60.6 ± 0.9
70	70.4 ± 1.1	70.5 ± 1.2	70.6 ± 1.3
80	79.5 ± 0.9	78.2 ± 0.9	80.2 ± 1.9

2) Mechanical stress operational range and control

For the mechanical stress implementation, the fluid-solid interface offered by the microfluidic channel walls can be readily exploited to apply shear stress to the HCV protein solutions. Considering the candidate fluids spanning a broad viscosity range, the convenient parameter to design and develop the mechanical stress module is the *shear rate* (s^{-1}). In fact, unlike the shear stress, the shear rate is by definition insensitive to the fluid rheological properties (*e.g.*, viscosity). In particular, for a Newtonian fluid flow in a pipe, the shear stress is the multiplication between the shear rate and the liquid dynamic viscosity. Thus, with the same shear rate, solutions with different viscosity experience different shear stress. Guaranteeing a constant flow rate assures the processed fluids being subjected to the same shear rate regardless of their viscosity.

While keeping a fixed flow rate, diverse chip geometries (specifically, different cross sections) can be employed to control the shear rate range the fluid undergoes. According to this strategy, different squared cross-section straight channels were designed and fabricated to reach up to 20000 s^{-1} at 800 µl/min flow rate.

B. *Protein instability induced by the microfluidic platform*

The ability of the platform to induce a destabilization on a model HCV fluid was preliminarily proved by subjecting a BSA solution (≥300 mg/ml) to thermal and mechanical stress according to the protocols described in *Methods* (paragraphs 3 and 4). The treated solutions were compared to untreated ones through NTA. In *figure 1* and *2* the thermal and mechanical NTA analysis are respectively reported. Evidently, the stimulated solutions (orange curves) present an important increase in aggregation concentration with respect to unstimulated fluids (red curves), thus assessing the effectiveness of the microfluidic platform solicitations.

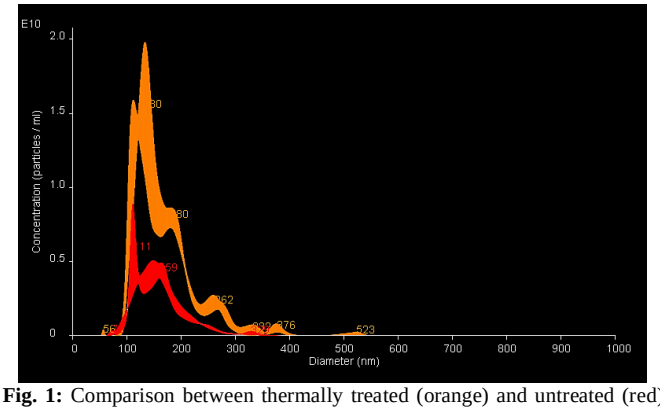

Fig. 1: Comparison between thermally treated (orange) and untreated (red) HCV BSA solution. The solution underwent 60°C thermal stimulation for 5

min. The concentration of aggregations is noticeably higher in the stimulated solution (orange).

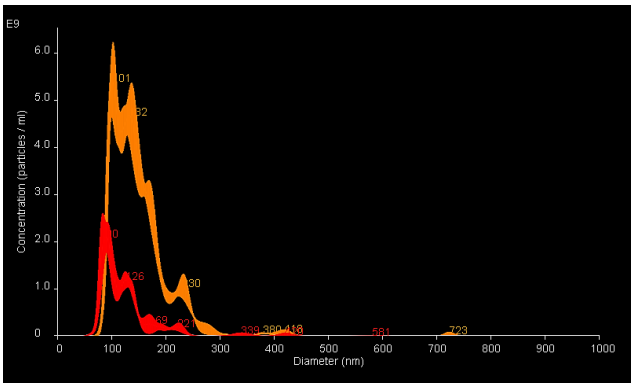

Fig. 2: Comparison between mechanically treated (orange) and untreated (red) HCV BSA solution. The HCV solution underwent 8000^{s-1} for 15 min. The concentration of aggregations is remarkably higher in the solicited solution (orange).

IV. Conclusion

In this work a novel miniaturized and automated approach based on microfluidics to study protein stability in challenging liquid systems is presented. The platform is properly design and sized to manage HCV fluids, with minimized pressure drop and absent tendency to clogging. Whilst it may seem trivial, such a step represents a noticeable achievement, as, at small scales, the control of pressure drops becomes tedious. The capability to manage high viscosity guarantees the process continuity, avoiding setbacks. This achievement resulted from matching data acquired from the pharma industry repertoire (chemical, physical and rheological properties of typical solutions), sound scientific knowledge and advanced engineering solutions.

To the current status, the proposed miniaturized approach is already a good option to address the expensiveness limitation posed by conventional technological approaches, with equal or superior versatility. In fact, minuscule solution volumes are required, thus providing a strong cost reduction compared to classical batch protocols. In addition, the automation of the process can facilitate the conduction of the stimulation, ensuring its reproducibility, reliability and easy exploration of a broad solicitation range while paying minimum effort.

The typical features of the microfluidics (*e.g.*, small volume and high predictability of transport phenomena), along with the automation of the platform and the potential integration of other technologies, such as sophisticated programmable pumping systems and real time inline analysis techniques, pave the way to a paradigm shift in the study of complex HCV protein systems. In fact, the vast screening of different environment conditions and composition of protein solutions through the microfluidic platform may help address the scientific gap of knowledge, clarifying the relation between physico-chemical environments and protein behavior in HCV solutions. Moreover, the microfluidic plant is intended to point out the influence of stabilizing agents on biomolecule stability. In other words, the platform may have a role in industrial contexts, promoting a *quality by design approach* in the setting of large scale processes (*e.g.*, development of protein-based therapeutics).

***Abstract*— Stroke is one of the main causes of long-term disability worldwide. Recently, an activity-dependent intracortical microstimulation technique demonstrated the capability of closed loop approaches to better entrain network activity with respect to standard random stimulation. This was demonstrated at the pre-clinical level, in rodent models following an ischemic lesion in the primary motor cortex. At the clinical level, stimulation-based therapy still relies on standardized protocols with not so convincing results. A possible explanation for these inconsistencies is the lack of tailored, personalized stimulation protocols. In this study, we aimed at investigating the changes in the electrophysiological activity occurring in a pre-clinical model of focal lesion and the subsequent effect of a personalized, open-loop stimulation therapy. We adopted anesthetized Long-Evans rats undergoing a focal ischemic injury in the caudal forelimb area (i.e., CFA). Microelectrode arrays were inserted in the ipsilesional rostral forelimb area (i.e., RFA) to record spike activity and in the somatosensory cortex (i.e., S1) also to deliver intracortical microstimulation. We found that the ischemic injury in CFA led to an overall decrease of the spiking activity both in RFA and S1. A neurostimulation treatment with tailored open loop microstimulation tended to increase the firing activity in both RFA and S1. Further studies will be necessary to confirm these preliminary findings, which can lead to design novel electroceutical therapies for stroke rehabilitation.**

I. INTRODUCTION

NOWADAYS non-communicable diseases represent the 80% of the top ten causes of death worldwide. Among these disorders, stroke is the second leading cause of death and disability [1]. Current assistive technology is limited and only a minority of survivors are able to achieve functional independence in simple activities of daily living. Thus, understanding the impact of a lesion on the brain networks and promoting functional and behavioural recovery has become a global priority in healthcare.

The standard-of-care for post-stroke rehabilitation is physical therapy, but its effects are often limited or incomplete [2]. To this end, research is exploring innovative approaches, such as ‘electroceutical’. Electroceutical provides an ‘electrical’ rather than ‘pharmacological’ treatment based on stimulation of the target organ/tissue. Electrical-based therapies have sparked interest among researchers, industries and funding agents since a while [3], [4], been successfully employed for treating neurological diseases, such as depression and epilepsy [5].

Recent studies have shown how brain stimulation could enhance functions after stroke in both animals and patients [6]. These studies have used electrical stimulation patterns that are ‘adapted’ (i.e., personalized) to the intrinsic dynamics of the networks under examination, primarily through two different modalities, i.e., open loop and closed loop. By using personalized stimulation is possible to: (i) promote both plasticity and motor recovery, as in the case of stroke or traumatic brain injury –TBI [7]; (ii) block the pathological activity and promote the physiological one within the damaged tissue, as in the case of Parkinson's disease [8] or epilepsy [9]; (iii) ‘entrain’ the network under examination and facilitate motor responses [10], [11]. Currently, at the clinical level, stimulation-based therapy relies on standardized protocols with not always convincing results [12]-[14]. A possible explanation for these inconsistent outcomes is the lack of a stimulation protocol ‘tailored’ on the intrinsic dynamics of the target system.

In this study, we aimed at investigating possible changes in electrophysiological activity induced by a focal lesion and the subsequent effect of a personalized, open loop stimulation protocol, with the idea to be further translated to clinics.

We capitalized on the work of Guggenmos [7] and our own works for the experimental design [15]-[18]. Briefly, we used anesthetized Long Evans rats implanted in the Rostral Forelimb Area (i.e., RFA, equivalent of the pre-motor cortex in the rat) and in the Somatosensory cortex (i.e., S1). A lesion was performed in the equivalent of motor cortex (i.e., CFA) by means of a local injection of endothelin-1 [19]. Differently from our previous studies, here we evaluated the effect of the lesion on a large dataset and we designed a novel personalised stimulation protocol by following an open-loop paradigm, inspired by the literature [20]. Specifically, we implemented a ‘repeated stimulation’, where trains of extracellular voltage-pulses were delivered, reproducing exactly the pattern and timing of spikes detected at one selected electrode during the ‘pre-lesion’ spontaneous activity. We found that the lesion had a clear-cut effect on decreasing the spontaneous activity at the two monitored locations. Moreover, the open-loop (i.e., repeated stimulation) protocol showed a tendency to increase the level of spiking activity.

II. Material and Methods

A. Animals

The Italian Ministry of Health and Animal Care (Italy: authorization n. 509/2020-PR) approved all experiments. Twenty-seven adult, male Long-Evans rats (weight: 300-400g; age: 4-5 months; Charles River Laboratories, Calco, LC, Italy), divided into two main categories, i.e. No lesion (Naive; n=14) and Lesion (n=13), were used in this study. To preliminary test the effects of a personalized stimulation treatment, we randomly assigned four animals of the lesion group to a third group (Lesion-Open Loop; n=4).

B. Surgical Procedure

Prior to surgery, the rats were anesthetized with gaseous isoflurane within a sealed vaporizer chamber. The anesthetization was followed by injections of ketamine (80-100 mg/kg IP) and xylazine (5-10 mg/kg). Anesthesia was maintained throughout the entire procedure with repeated bolus injections of ketamine (10-100 mg/kg/hr IP or IM) as needed. The rat was secured in the stereotaxic frame and placed on a homeostatically controlled heating blanket to maintain temperature. A midline skin incision was made spanning rostro-caudally between ~6 mm rostral to bregma and ~5 mm distal to the atlanto-occipital junction exposing the skull surface. The muscles of the neck overlying the cisterna magna or between the upper vertebrae were reflected, and a small puncture was made in the spinal dura to allow cerebrospinal fluid drainage and to control brain edema after craniotomy. In the lesion group (i.e., Lesion), six 0.7-mm diameter holes were drilled into the skull over the dominant hemisphere (contralateral to the preferred forelimb) as follows: +2.5, +1.5, +0.5 AP +2.5, +3.5 ML from bregma, corresponding to the CFA of the motor cortex (Fig. 1A). Burr holes (3 mm diameter) exposing RFA and S1 were made at +3.5, +2.5 and –1.25, +4.25 AP, ML [21]. Ischemic injury was induced through Endothelin-1 injection (ET-1; 0.3 µg ET-1 dissolved in 1 µl saline or 1 mg ET-1 dissolved in 3.33 ml saline; Merk Life Science S.r.l., Italy), ~ 1.5 mm below the pial surface at each of the 6 holes over CFA [19]. The spread of ET-1 with this procedure is confined to an area of 0.5 mm diameter; injections were placed to produce a continuous CFA infarct while leaving RFA and S1 intact [22].

C. Experimental protocol

For this study, we made use of three experimental groups: (i) Control (i.e., Naïve, animals who did not receive any lesion), (ii) Lesion (i.e., animals who did receive the lesion) and (iii) Lesion-Open Loop (i.e., a subset of the Lesion group which underwent a session of intracortical therapeutic stimulation), as schematically reported in Fig. 1B. In the Control group, the experimental timeline consisted of 2 phases of 20-min of spontaneous recordings before (i.e., PreL, light blue) and after (i.e., PoL, aqua green) the 'no lesion' period, which lasted approximately 1 hour. In the Lesion group, the experimental timeline consisted of the same 2 phases of 20-min of spontaneous recordings before (i.e., PreL, light blue) and after (i.e., PoL, aqua green) the 'lesion' period. Additionally, four animals of the Lesion group (i.e., Lesion-Open Loop) received 1 hour of stimulation (i.e., Stim, yellow) and were recorded for 20-min of spontaneous activity after the stimulation (i.e., PoS, blue).

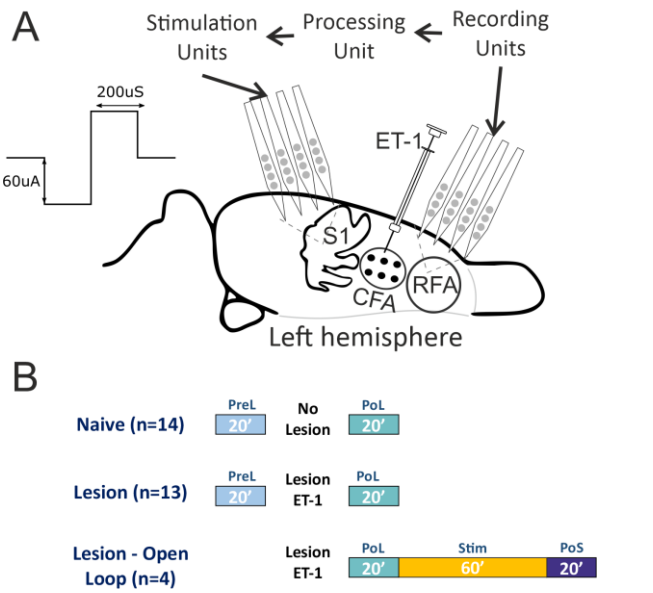

Fig. 1: Experimental protocol. A) Neural activity was recorded by means of Multi-Electrode Arrays-MEAs (four-shank, sixteen-contact site electrode, NeuroNexus) using a commercial data acquisition system (Intan Technologies). The electrophysiological activity was recorded simultaneously at two locations: the Rostral Forelimb Area (RFA) and the Somatosensory cortex (S1). For the stimulation session, the pulse was always designed to be a single squared 60 µA biphasic, cathodal-leading pulse (200 µs positive, 200 µs negative). The lesion was performed by means of a focal injection of endothelin-1 in the Caudal Forelimb Area (see Methods). B) Experimental timeline for the three groups (for details, see Methods).

D. Recording/Stimulation paradigms

As detailed in Fig. 1A, the cell activity was recorded in RFA using a four-shank, sixteen-contact site electrode, placed at a depth of 1500 µm (1-1.5 MΩ impedance, A4x4-3mm-100-125-703-A16, NeuroNexus). The stimulation was applied through a single contact on a four-shank, sixteen-contact electrode with an impedance of ~ 200 kΩ (A4x4-3mm-100-125-177-A16, NeuroNexus). In all the experiments, the stimulation pulse was designed to be a single squared 60 µA biphasic, cathodal-leading pulse (200 µs positive, 200 µs negative). The personalized Open Loop stimulation was created following a 'replay' and 'repeat' strategy. The stimulation pattern exactly reproduced the first 10-min of the healthy spontaneous activity recorded before the lesion (i.e., PreL1) on a selected channel in RFA (replay), and was delivered, using the INTAN RHS Stim/Recording System (http://www.intantech.com), by looping it six times over the course of an hour (repeat) [20].

E. Data Processing

All the analysis were performed in Matlab (The MathWorks, Natick, MA, USA). First, data were filtered using a 4th order elliptic bandpass filter in the range of 300-3000 Hz to remove low frequency components within the signal. A spike discrimination approach was used to detect spikes from the filtered data. This consisted of a power based spike detection

algorithm, named Stationary Wavelet based Teager Energy Operator (SWTTEO) [23]. The SWTTEO includes two levels of Stationary Wavelet Transform (SWT) followed by the use of the Teager Energy Operator (TEO). The TEO outputs are then smoothed and summed, and their combination is thresholded. No sorting method was applied to the detected spikes. Spikes were then analysed in terms of mean firing rate (MFR), i.e. we computed the average number of spikes within the unit time (s) in each recorded phase. We discarded those electrodes whose firing rate was less than 0.01 spikes/s [15].

For better efficiency in the data processing step, data were organized in blocks of 10-min recordings each. In total, for the experimental groups, we have six blocks: PreL1, PreL2, PoL1, PoL2, PoS1 and PoS2.

F. Statistical analysis

Statistical analysis was performed in Matlab (The MathWorks, Natick, MA, USA). First, we tested the normality of the data with the Kolmogorov-Smirnov test. Since data failed the test, we applied a non-parametric test, the Friedman test, to identify significant differences among firing rates at different experimental phases. P-values <0.05 were considered as significant and corrected for multiple comparisons when relevant.

III. Results

A. The ischemic lesion decreased the level of firing

We investigated how a focal ischemic lesion affected the firing activity at two distal areas (i.e., RFA and S1). Fig. 2A1-B1 shows some raster plots of a representative animal in the Lesion group. Here, the baseline activity (i.e., Pre Lesion, PreL) is characterized by a random and slight synchronous spiking in both RFA and S1. Immediately after the lesion (i.e., PoL), a significant decrease in the activity in both RFA and S1 is observed (Fig. 2A2-B2). The quantitative analysis of the inter-phase MFR confirmed these qualitative results. Both RFA (Fig. 2C) and S1 (Fig. 2D) are characterized by an overall significant decrease in the MFR from the PreL (PreL1 and PreL2) to the PoL (PoL1 and PoL2) phase. Interestingly, this is not true for the Naïve group, where the MFR remained constant over time (Fig. 2E-F).

B. Open loop stimulation increased the level of firing

We evaluated the effects of the repeated stimulation on the level of firing of both RFA and S1 in the Lesion-Open Loop group. The baseline activity in the pre stimulation phase (i.e., PoL) was characterized by a random spiking with sparse synchronous events (Fig. 3A1-B1). As shown in the representative raster plot (Fig. 3A2-B2), after the stimulation, in the PoS period, we observed an overall increase of spiking activity in both RFA and S1. Even if the statistical analysis did not show any significant change, in Fig. 3C-D, we can observe that the MFR values and their median are tended to increase after the stimulation phase in both RFA (Fig. 3C) and S1 (Fig. 3D). Moreover, in both areas we observed a change in the data distribution, tending from a unimodal (Fig. 3C, PoL1-PoL2) to a bimodal shape in RFA (Fig. 3C, PoS1-PoS2) and to a more pronounced bimodal distribution in S1 (Fig. 3D, PoS1-PoS2 vs. PoL1-PoL2). This suggests that the Open Loop repeated stimulation was able to elicit a change in the firing rate in the two considered areas, with a tendency to increase it.

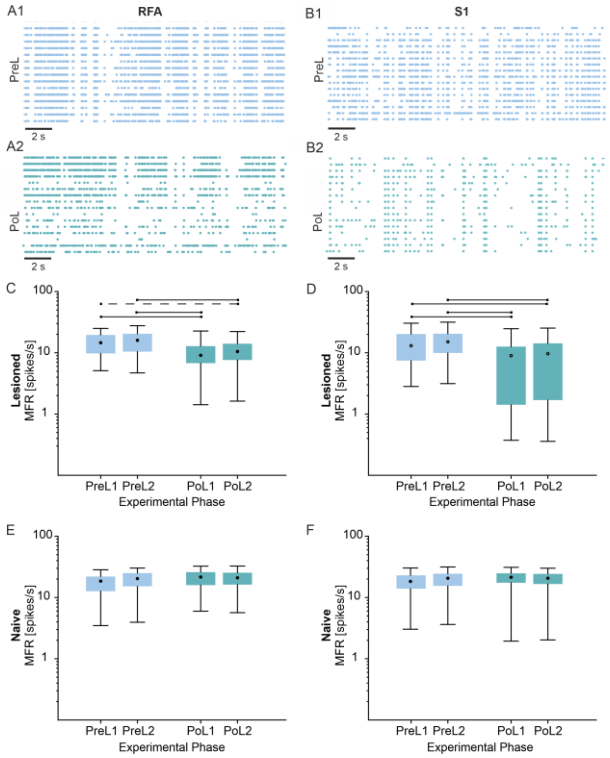

Fig. 2: Firing rate analysis of the lesion effects. (A,C,E) Activity in RFA. (B,D,F) Activity in S1. (A, B) Spike rasters (dotted graphs, one row per single channel during 10 s period before (i.e., PreL, top) and after (i.e., PoL, bottom) the lesion, in a single representative animal of the lesion group (i.e., Lesion). (C, D) Distribution of the Mean Firing Rate (MFR, spikes/s) for the Lesion group. (E, F) Distribution of the Mean Firing Rate (MFR, spikes/s) for the Naïve group. In both groups, each phase was split in 10 min windows (i.e., PreL1, PreL2, PoL1 and PoL2). Data is summarized in box plots, where the central black dot indicates the median; the box limits indicate the 25th and 75th percentiles. Whiskers represent the 5th and the 95th percentiles. Dashed line: p<5·10-3; solid line: p<5·10-5, Friedman nonparametric test.

IV. Conclusion

This study describes the impact of a lesion in the motor area and the effect of the subsequent personalized stimulation on the spiking activity of two cortical areas (RFA and S1) in the brain of anesthetized rats. We found that an ischemic lesion in the motor cortex induces a significant decrease of the firing level in both RFA and S1. These findings support and make stronger our previous outcomes [15]-[18], obtained for a smaller and less consistent dataset, where we observed a change in the spiking activity. Moreover, we showed that a personalized open-loop protocol tends to increase firing activity. These preliminary results are in line with the effects induced by a different type of personalized stimulation [15], i.e. the closed-loop one (ADS). We can conclude that non-periodic, tailored stimulation might be the key to restore the firing pattern in the damaged brain [9], in line with recent findings in healthy humans [10], [11]. Additional experiments are now necessary to confirm this preliminary finding, which can open up the possibility of translating the personalized electroceutical therapy to the clinical level.

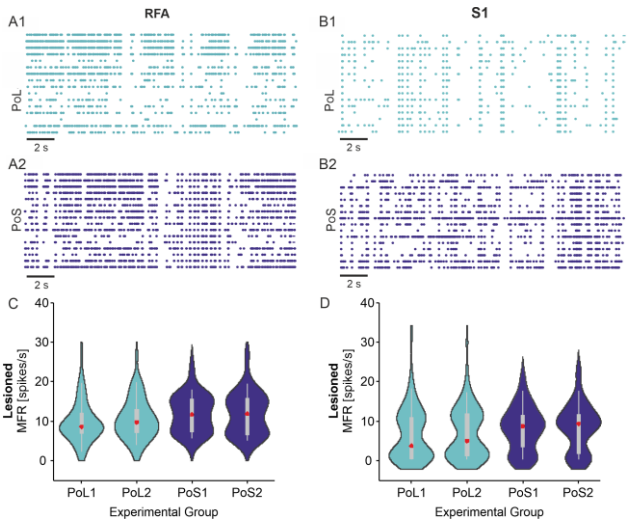

Fig. 3: Firing rate before and after stimulation. (A, C) activity in RFA. (B, D) activity in S1. (A, B) Spike rasters (dotted graphs, one row per channel during 10 s period before (i.e., PoL, top) and after (i.e., PoS, bottom) the stimulation in a single representative animal of the Lesion-OL group. (C, D) Distribution of the Mean Firing Rate (MFR, spikes/s) for each phase split into 10 min window (i.e., PoL1, PoL2, PoS1 and PoS2). Data is represented as violin plots, where the outlines illustrate probability density, i.e. the width of the shaded area represents the proportion of the data located there. Inside, we reported the box plots (grey) where the box represents the 25th and the 75th percentile values, the red dot the median value and the whiskers denote the 5th and the 95th percentile values.

***Abstract*—Angiopep-2 is a 19 amino acid synthetic peptide that demonstrated the ability to shuttle active agents across the BBB in clinics by the interaction with LRP-1 receptors. The combination of such peptide with properly designed drug delivery systems can strongly improve the outcome of patients with brain tumours, a pathology in which the standard of care is scarcely effective because of poor transport and resistance. In this work, we engineered theranostic crosslinked hyaluronic acid nanoparticles (Thera-cHANPs), co-encapsulating Gd-DTPA with boosted relaxivity and the chemotherapeutic drug Irinotecan (CPT-11), with Angiopep-2, to produce Thera-ANG-cHANPs. Thera-ANG-cHANPs demonstrated stability in the biological environment, boosted uptake by patient derived Glioblastoma cells and, as consequence of improved transport, a boosted therapeutic effect exerted with a lower dose of drug in a reduced time window.**

***Keywords*—Angiopep-2; Glioblastoma (GBM); Nanoparticles; Hydrodenticity.**

I. INTRODUCTION

Angiopeps (ANGs) are a family of synthetic peptides that selectively target Low-density Lipoprotein Receptor Related Protein 1 (LRP-1). [1, 2]. Those receptors are relevant for the targeted transport across the Blood Brain Barrier (BBB) since they are highly overexpressed at the endothelial layer of the Neurovascular Unit, being also present in a greater extent with respect to other receptors (e.g. Transferrin and Insulin receptors) [3]. Demeule et al., demonstrated that one specific ANG peptide, Angiopep-2 (TFFYGGSRGKRNNFKTEEY) bears 10-folds higher transcytosis capacities at the BBB in vivo with respect to the endogenous substrates of LRP1 receptors, such as aprotinin [4]. Moreover, Angiopep-2 confirmed its shuttling ability into the Central Nervous System (CNS) in clinical settings, determining successful brain tumour accumulation of the drug paclitaxel, when formulated as a drug-peptide conjugate (ANG1005) in patients with recurrent gliomas [5]. Indeed, further evidence proved that LRP1 receptors are also overexpressed at glioma cell membrane, and thus that Angiopep-2 bears dual targeting ability, probably because of the marked proliferating phenotype characterizing cells of higher grade tumours, such as Glioblastomas (GBMs) [6] [7, 8].

GBM is the most aggressive and incurable CNS malignancy, with very poor patient prognosis[9]. Clinical protocols for diagnosis and therapy are constantly revised and updated based on the developing knowledge around tumour genotyping and stratification. The latest guidelines have been released in 2017 by the European Association of Neuroncology (EANO) [10]. They identify the tumour burden by T1-enhanced regions in MRI and confirm the Stupp protocol, based on chemo-radio-combinatorial therapy, as standard of care. However, Gadolinium (Gd)-based contrast agents are not able to cross the BBB and can accumulate only in the regions of the tumour where it is disrupted. Moreover, the only approved chemotherapeutic drug, Temozolomide (TMZ) has been proved to be ineffective in more than 50% of patients, in details those affected by the methylation of the O [6]-methylguanine-DNA methyltransferase (MGMT) promoter [11]. For all the aforementioned reasons, the use of Angioepep-2 engineered formulations constitutes a huge opportunity to improve GBM standard of care and expand it both for diagnosis and therapy, repurposing strongly effective active agents that are currently excluded because of poor CNS accumulation.

Hyaluronic Acid (HA) demonstrated the ability of boosting the relaxivity of Gd-based CAs through the properties of Hydrodenticity[12, 13]. In particular, when encapsulated in properly crosslinked HA nanoparticles, it is packed in gado-meshes, domains of packed water that is determining the boosting Gd-DTPA relaxivity up to 12-fold as a consequence of the improved hydration degree of the metal chelate [12-14]. Secondly, the camptothecin prodrug Irinotecan (CPT-11), approved for the treatment of colorectal cancer since 1996, has been recently proposed for the treatment of Glioblastoma as valuable alternative to the poorly effective TMZ. Despite some encouraging results, its poor serum stability and CNS penetration are still posing limitations to its approval for GBM treatment. Based on these observations, we designed Angiopep-2 engineered theranostic crosslinked HA NPs (Thera-ANG-cHANPs) encapsulating both Gd-DTPA with boosted relaxometric properties and the camptothecin drug Irinotecan for an earlier diagnosis and more effective therapy of GBM [14]. In this regard, the present study aims at highlighting the improved interaction of Thera-ANG-cHANPs with a relevant model of patient derived glioblastoma cells and its potential implication on GBM theranostics.

II. RESULTS

Table 1 reports the main methodologies applied for the production and in-vitro testing of Thera-ANG-cHANPs. The use of patient tumour material for cell culture establishment was approved by the 600 institutional review board of the ErasmusMC and obtained with patient's informed consent. Ethical Commette: MEC-2013-090.

Table 1. Main methodologies applied for Thera-ANG-cHANPs production and testing

	TECHNIQUE	*METHODOLOGY*
NP Production	Microfluidic Hydrodynamic Flow Focusing (HFF)	Nanoprecipitation in a quartz X-junction chip. Solvent phase: HA 0.05% w/V; Gd-DTPA 0.1% w/V: CPT-11: 0.025% w/V + EtOH 10% V/V. Non-solvent phase: Acetone; Divinyl sulfone 4% V/V. Process parameters: Middle Flow rate 30 µL/min Side Flow rate 110 µL/min
Angiopep-2 Conjugation	NH_2-COOH chemical crosslinking	EDC (0.02M) and NHS (0.006M) activation and 50 µg Angiopep-2 per mL of NPs. BCA assay kit for peptide quantification
NP physicochemical properties	Morphology: TEM Average Size: DLS	TEM observation of 5 µL of sample on copper grids; DLS measurement of 1 mL sample by Zetasizer Nano (Malvern)
NP relaxivity	1T MRI	Spin-echo sequence (repetition times 550, 880, 1400, 2000 ms, echo time 80 ms) and T1 signals calculated using MLE method to fit saturation recovery curves (a*exp(-TR/T1)+c). FOV 80-mm, a 96 × 96 matrix, and 2 mm slice thickness
Active Agents Encapsulation	ICP-MS Uv-VIS	Gd-DTPA: ICP-MS CPT-11: Abs 368 nm
Cell uptake	Flow cytometry (FACS)	Cell culture: U87 MG: Dulbecco's modified Eagle's medium (DMEM), 10% FBS, 1% penicillin/streptomycin, 1% L-glutamine; PDX: (DMEM)–537 F12 with 1% penicillin/streptomycin, B27, human epidermal growth factor (EGF; 5 538 µg/mL), human basic fibroblast growth factor (FGF; 5 µg/mL), and heparin (5 539 mg/mL). Seeding density: 50000 cells/well .

The theranostic design of Thera-ANG-cHANPs is schematically presented in Figure 1a.

The following sections present the rational for particle testing and the achieved results.

A. Impact of Angiopep-2 conjugation on LRP1 targeting ability

The targeting ability of Thera-ANG-cHANPs entirely depends on Angiopep-2 interaction with the receptor LRP1. For this reason, as a first step, a molecular docking simulation between the peptide and the LRP-1 portion responsible for the ligand binding (the double complement type repeats CR56) is performed. It allows to characterize the peptide/receptor binding in terms of energy, binding modes and, most importantly, know about both peptide and receptor amino acids involved, to assess the impact of peptide conjugation to NPs on its interaction with the LRP1, if any. As presented in Figure 1b, the binding is characterized by a quite high binding energy, -5.67 kcal/mol. Moreover, it appears that a specific region of the CR56 is involved. The analysis of the amino acids reveals that this LRP1 region comprises the Asp959, reported as the residue involved in the Receptor Associated Protein (RAP) binding, directly connected to the recycling of the receptors from the endosomes to the cell surface, thus to its transcytosis capacity [15, 16]. Moreover, all the residues of Angiopep-2 result to be involved in the binding with equal probability, allowing to conclude that a chemical crosslinking of the peptide on NP surface, preventing some amino acids from the binding with LRP1, should not negatively impact on its overall targeting ability.

B. ANG-cHANPs: production and characterization

Microfluidic production of crosslinked Hyaluronic Acid Nanoparticles (cHANPs) encapsulating multiple agents is a consolidated process[14, 17-19]. Briefly, by implementing a nanoprecipitation process in an X-junction chip through a hydrodynamic flow focusing regime, a highly uniform population of nanoparticles with tightly controlled features is produced. For the theranostic design, a co-solvation strategy is implemented allowing to maximize encapsulation of the poorly soluble CPT-11 without perturbing HA precipitation and crosslinking, and Gd-DTPA encapsulation. In optimal process conditions, a uniform population of spherical particles with mean size of 106.5 ± 46 nm is achieved. Encapsulation efficiencies (EE%) of Thera-cHANPs are 30% (80µM) and 18% (151µM) for Gd-DTPA and CPT-11, respectively.

After production, Angiopep-2 is conjugated to -COOH groups of HA exposed onto NP surface to produce engineered Thera-ANG-cHANPs. Briefly, after -COOH activation by EDC/NHS, Angiopep-2 is put in contact with Thera-cHANPs (50 µg per mL of NPs). After 4h, excess peptide is purified and particle size, morphology, and relaxometric properties are characterized. Dynamic Light Scattering (DLS) reveals a particle population of increased mean size (368 ± 61 nm). Neverthless, as showed by Transmission Electron Microscopy (TEM) observation in Figure 1c, particle morphology is preserved, and Angiopep-2 is successfully and uniformly conjugated to the polymer, as further confirmed by the BCA assay, measuring 32 µg/mL of Angiopep-2 in the purified sample. The increase in NP size might be due to polymer chain sliding consequent to interaction with the peptide causing water imbibition and hydrogel swelling.

Relaxometric properties of NPs are evaluated under a preclinical 1T MRI. Figure 1d present the T1 maps as measured for increasing concentration of Gd-DTPA encapsulated in NPs showing, as expected, T1 shortening as Gd-DTPA concentration increases. Figure 1e reports fitting of mean T1 values for longitudinal relaxivity evaluation. This analysis reveals a $r_1 = 13.08\, mM^{-1}s^{-1}$ for Thera-ANG-cHANPs that is 3.45 times higher than free Gd-DTPA ($r_1 = 4\, mM^{-1}s^{-1}$). This result suggests that the Hydrodenticity

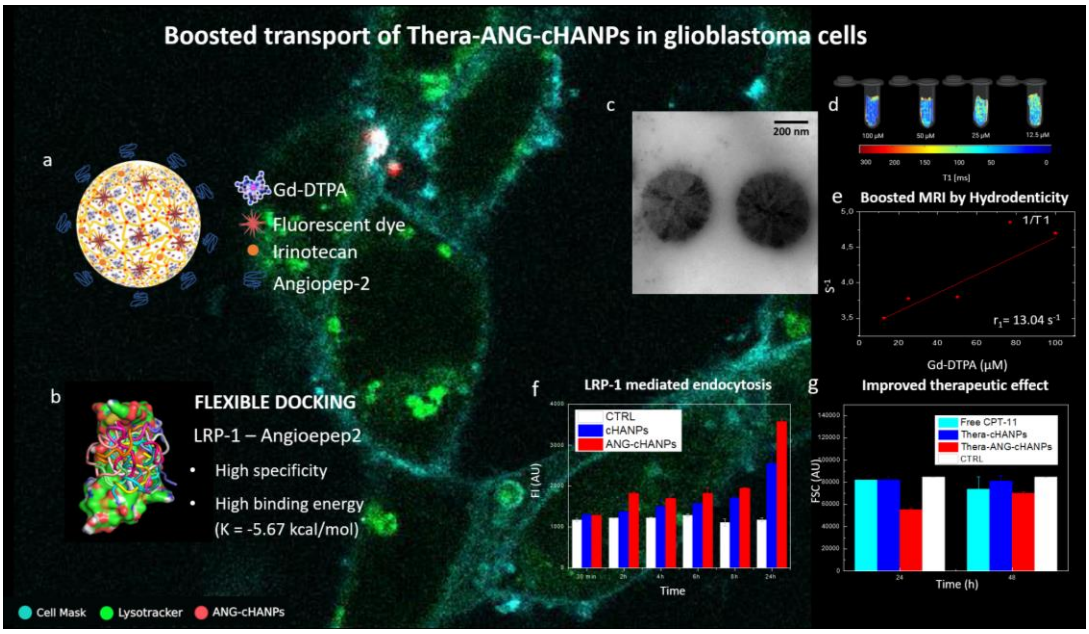

Fig. 1: Thera-ANG-cHANPs for boosted theranostics of Glioblastoma cells; a) Schematic representation of Thera-ANG-cHANPs architecture; b) Flexible Molecular Docking between Angiopep-2 and LRP-1 receptor; c) Transmission Electron Microscopy (TEM) of ANG-cHANPs; d) T1-map of NPs at 1T MRI; e) Longitudinal relaxivity estimation by T1 measurement; f) Uptake of ANG-cHANPs vs cHANPs by Flow Cytometry (FACS); g) Cytotoxicity of Thera-ANG-cHANPs vs free-CPT-11 and bare Thera-cHANPs by Forward Scattering Measurement in FACS.

boosting is preserved, as consequence of preserved hydrogel network.

C. 2.3 Boosted ANG-cHANPs transport into glioma cells

The interaction of Thera-ANG-cHANPs with glioma cells is evaluated by Flow Cytometry measurements, a single cell analysis technique that additionally allows to interrogate a statistically relevant cell population. NIR emitting cHANPs and ANG-cHANPs are produced by encapsulating the standard dye ATTO 633 ($\lambda_{ex/em}$ = 633/652 nm) to reduce the signal overlapping with cell autofluorescence, mostly present in the Vis spectrum. NP uptake is evaluated in a patient derived (PDX) cell population, as relevant model of human glioblastoma.

To quantify NP uptake, cells are seeded in 48-well plates at a density of 50000 cells/well and let adhere for 24h. Afterwards, cells are exposed to bare or engineered NPs (50 μg/mL). At selected time points, cells are washed three times with PBS for removal of non-internalized particles, detached by trypsinization and uptake is measured by flow cytometry. The analysis of the fluorescence at 650 nm is presented in Figure 1f comparing the uptake of bare cHANPs with engineered ANG-cHANPs over time. At the analysis of cHANPs internalization profile a linear increase in fluorescence over time can be observed. Differently, ANG-cHANPs show higher value of fluorescence, as indication of higher amount of internalized particles and also a sharper, exponential increase of signal after 24h of contact. As widely reported in literature, this behaviour is proper of energy dependent mechanisms which are not saturated over time as the gradient of concentration of the moving specie is vanishing across the cell membrane[20-22]. For this reason, it is possible to conclude that Angiopep-2 is mediating the boosted uptake of NPs by human derived glioma cells. Similar results are achieved in the standard U87-MG cell line (data not shown).

To investigate the possible implications of such improved transport properties, Thera-ANG-cHANPs are tested on U87-MG cells for their therapeutic potential. The cytotoxicity induced by encapsulated CPT-11 is compared to cell death caused by free CPT-11 at the same concentration (10 μM), both evaluated through the Forward Scattering Signal (FSC) measured by Flow cytometry that is widely recognized as indication of cell viability[22]. Results are presented in figure 1g. Cytotoxicity is measured at 24h and 48h since CPT-11 is a topoisomerase II inhibitor, and for this reason, is exerting its therapeutic effect at cell replication. At the analysis of the results, it is clear that free CPT-11 is producing slight or no effect on U87 cells, even after 48h of contact, as bare cHANPs. This result is not surprising if considering that the tested dose of 10 μM is 10-folds lower than the measured ED50 for CPT-11 in many cell lines. Differently, Thera-ANG-cHANPs are producing a strong reduction in cell viability already after 24h of contact, consolidating this result at 48h. In light of these results, it is possible to conclude that as a consequence of the boosted particle accumulation in U87 cells, a lower dose of CPT-11 resulted highly effective in a reduced time window.

III. CONCLUSION

GBM is characterized by several biological barriers that are very different in nature (physical, chemical, biological and mechanical) and highly dynamic among tumoral stages. They strongly limit the effectiveness of the standard of care and

vanish most of the efforts that literature is posing to design alternative but complex diagnostic and therapeutic approaches. To significantly impact on GBM diagnosis and therapy a deeper understanding of the cross-talk of active agents with disease-specific biological barrier is needed. In this sense, Thera-ANG-cHANPs are designed starting from approved materials and active agents, that already proved their effectiveness in clinics. The effort in this case is devoted to the understanding of the impact of their combination and the evaluation of nano-bio-interactions that arise at the cellular level between Thera-ANG-cHANPs and a relevant human model of Glioma.

***Abstract*— Nanoparticles offered unique properties respect to their bulk counterpart that make them promising vehicles for diagnosis and therapy in cancer. However, only the 0.7 % of administered NPs effectively reach the tumour site. This limited efficacy is mainly due to filtration exerted on NPs by the biological barriers, encountered in their *in vivo* journey. To improve these nano-bio interactions, we present an optima design of hybrid nanovector, Lipid-Polymer NPs, through an innovative microfluidic process defined as coupled Hydrodynamic Flow Focusing (cHFF). We co-entrapped in the NPs, Gd-DTPA and Atto 633 for MRI and optical imaging, while the Gd-DTPA and Irinotecan for theranostics.**

***Keywords*—Microfluidics, LNPs, lipid-polymer, theranostics**

I. INTRODUCTION

Nanoparticles are promising vehicles for the delivery of therapeutic and diagnostic probes to the disease site[1].

Despite the huge effort made in manipulating the NPs properties to reach the tumour site, the majority of them still accumulate in off-target sites, with only 0.7 % of administered dose in tumour tissue[2, 3]. Indeed, the administered NPs during their journey to tumour site encountered several barriers, that filtered them out[4]. These unsuccessful data reported for current NPs, stand out the need for the development of optimal design carriers. Recently, hybrid NPs emerged as next generation vehicles offering unique properties from the integration of materials that improves the carrier stability upon the nano-bio interactions[5, 6]. Among these hybrid vectors, lipid-polymer NPs, made up of a polymer core enveloped by the lipid component, offered multifaced properties such as boosted structural stability, high cargo loading, improved deformability, prolonged blood circulation and enhanced cell/tissue interaction[3, 5-9]. The conventional manufacturing techniques for the production of lipid-polymer NPs rely on the addition of pre-formed polymer nanoparticles during the liposome formation or to pre-formed liposomes, requiring post-processing steps to improve the size and homogeneity of the formulation[10]. Due to the impact exerted by the physiochemical properties of NPs[3, 4], such as size, shape, charge and elasticity, on their in vivo fate, microfluidic processes have been designed for their production[11, 12]. Indeed, the microfluidics ability of controlling the fluids in the microscale range allows the fine tuning of the properties of the end-carrier. The complexity of guiding two mechanisms of NPs formation in microfluidics has led to the development of several strategies for the synthesis of hybrid NPs. First, the on-chip production of liposomes was combined to off-chip polymerization of the interiors of NPs to obtain hydrogel core[13]. Then, the hydrodynamic flow focusing in combination with passive mixing structures[14] and controlled microvortices[15] were exploited for the production of lipid-polymer NPs. Sun et al.[16] developed two-stage microfluidic chip for the synthesis of mono-disperse lipid-poly (lactic-co-glycolic acid) NPs.

In this framework, we present an innovative one-step microfluidic process, coupled Hydrodynamic flow focusing for the production of Lipid-Polymer NPs (LiPoNs)[17]. The engineered process allows to manipulate the diffusion of species and manage both the mechanisms of nanoparticle formation, nanoprecipitation and self-assembly, to obtain hybrid nanovectors. In particular, the LiPoNs are made up of a chitosan core covered by a lipid bilayer, to integrate the structural stability and cargo loading offered by the chitosan matrix with the biomimetic properties of lipid component. These multifaced nanostructures were exploited for multimodal imaging and theranostics applications. Even though the MRI is the most clinically applied modality, the Gadolinium-free contrast agents CAs suffer from transmetalation, nephrotoxic effects and abnormal brain deposition[18, 19]. Therefore, we selected the Gd-DTPA as Gadolinium-based Contrast agents (CAs) for MRI imaging and we combined an optical probe to increase sensitivity of MRI imaging [20]. We proved the ability of LiPoNs to co-entrap a model drug with the Irinotecan HCl, a chemotherapy already approved for several cancers[21].

II. MATERIALS AND METHODS

L-α-Phosphatidylcholine from soybean (SPC) and cholesterol (Chol); Chitosan (CH, 50-190 kDa); Diethylenetriaminepentaacetic acid gadolinium (III) dihydrogen salt hydrate (Gd-DTPA); Atto 633 (ex/em = 633/657 nm) have been purchased from Sigma-Aldrich (St. Louis, MO, USA). Irinotecan HCl Trihydrate (IRI) was purchased by Selleckchem Chemicals (Huston, TX, USA). As solvents, we used Acetic acid glacial (AcOH, ROMIL pure chemistry,Cambridge, UK), Ethanol (etOH, puriss. p.a., absolute, Carlo Erba Reagents, Italy) and filtered MilliQ water (Milli-Q Plus, Q-POD®, Merck KGaA, Darmstadt, Germany) and the phosphate-buffered saline (PBS, tablet, Sigma-Aldrich). The human glioblastoma cell line U87 MG (ATCC, Manassas, VA, USA) were cultured in Dulbecco Modified Eagle medium-high glucose (DMEM), 10 % v/v fetal bovine serum (FBS, Sigma Aldrich, St. Louis, MO, USA), 2 mM L-glutamine and 1 % v/v Antibiotic Solution liquid (Thermo Fisher Scientific, Waltham, USA). The methods used for the production, purification, characterization of LiPoNs are reported in table I.

TABLE I: METHODS

Methods	*Description*
Microfluidic set-up	A quartz microfluidic device (22.5 mm long;15 mm wide; 4 mm thick) with 5 parallel inputs (45 °) and one output purchased from Dolomite Centre Ltd. The chip is compatible with the H interface 7-way for FEP tubing connections (1/16 x 0.25 mm- 0.8 x 0.25 mm). All the channels have a cross section of 160µmx150µm.
coupled HFF production	The side phases are composed of etOH/Water solution (65/35% v/v) containing 0.0072% w/v of Lipids (mass ratio 8:1-SPC:Chol). The middle phase is made of an aqueous solution of 0.01% w/v of CH and 1% v/v of AcOH. The Gd-DTPA, Atto633 and Irinotecan HCl are added at 0.4 % w/v, 24 µg/ml and 145 µg/ml to the middle solution. A flow rate ratio of 0.073 (the Volume Flow Rate of the middle channel-3 µL/min and the Volume Flow Rate of the side channel-41 µL/min), was used. The process was carried out 40 min (its multiples), collected in 3.5 ml (its multiples) of water and stirred 40 min.
Purification and concentration	Mild solvent gradient dialysis (Dialysis Membrane Pre-wetted RC Tubing, MWCO = 25-50 kDa) is performed with the external phase of PBS diluted in water (1:1) for 1 h. The Rotary Evaporator (BUCHI Italia s.r.l, Cornaredo, Italy) at a vacuum pressure of 20 mbar at 25 °C was used to concentrate the sample.
Characterization	8 µL of the sample (osmium tetroxide smoke 1% v/v overnight) was observed at Transmission Electron Microscope after dried (TEM, FEI,Hillsboro, OR, USA). Dynamic light scattering (DLS) was used to determine nanoparticle size (Zetasizer). The zeta potential of NPs were determined with a Zetasizer Nano ZS (Malvern Panalytical, UK). Changes in the relaxation time (T1) were evaluated at 1.5 Tesla and 37°C by Minispec Bench Top Relaxometer (Bruker Corporation). The Multiplate Reader Photometer Enspire Perkin- Elmer Inc. (Waltham, MA, USA) was used to quantify the encapsulation efficiency (EE %) of compounds loading.
Cellular uptake	5x 10^4 U87 MG cells/well are seeded in 48-well plate and incubated for 24 h. Atto633-Gd-DTPA LiPoNs (lipid conc.60 µg/mL) were added to the cells at different time points. The cells were washed with PBS, trypsinized and analyzed by flow cytometry using a BD FACSCelesta Cell Analyzer (BD Biosciences, Franklin Lakes, NJ, USA). A total of 10,000 events were recorded for each sample, the cells were gated using Forward Scattering Area (FSC) and Side Scattering Area (SSC). For the FI distribution, the cells were excited at 561 nm and the fluorescence emitted by Atto 633 (PE_Cy5_A, Filter 688/33) was collected. Live cells were imaged with a Leica Microsystems TCS SP5 Laser Scanning Confocal Microscope (Wetzlar, Germany) with a 60xOil objective (HeNe 633 nm laser).

III. RESULTS AND DISCUSSION

Generally, in the hydrodynamic flow focusing process, the nanoparticles are produced by injecting the lipid or polymer material in the main stream dissolved in a solvent phase that is focused by a non-solvent phase flowing through side streams[22-24]. Here an innovative hydrodynamic flow focusing approach is presented for the production of hybrid Lipid-Polymer NPs (LiPoNs). The coupled hydrodynamic flow focusing (cHFF) is implemented by injecting the chitosan dissolved in acid solution in the middle stream while the lipids, dissolved in an ethanol/water solution, are injected from the side streams (Fig.1). The cHFF features govern the competition of two solvent extractions and consequently coordinate the relative kinetics of nuclei and the growth of two phenomena, self-assembly and nanoprecipitation[17]. In this way, each material is not only involved in its own thermodynamic process but mutually influences the other one.

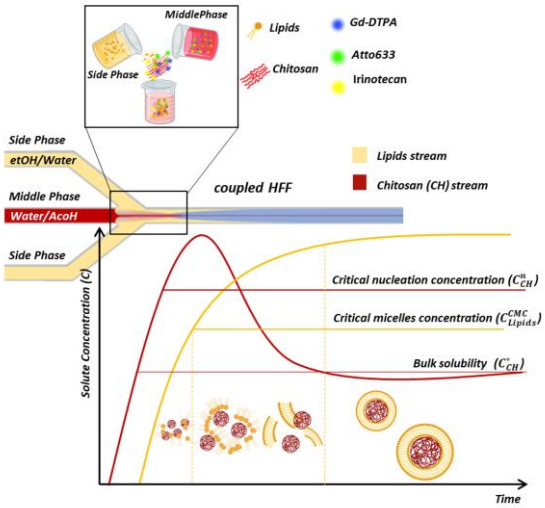

Fig. 1: Sketch of nanoprecipitation and self-assembly processes implemented in the coupled Hydrodynamic flow focusing. Some graphic elements were created with BioRender.com.

As schematized in Fig.1, in the focusing region there is the rapid extraction of acetic acid that leads to the formation of chitosan nuclei. Simultaneously, the increase in the microenvironmental polarity, due to the ethanol extraction, induces the formation of lipid bilayer fragments. Then, these bilayer fragments cover the polymer precipitate stabilizing the whole LiPoNs complex. We investigated this coupled phenomenon to obtain stable LiPoNs, by varying the process parameters, such as the solvent non-solvent ratio, the solute concentration and the flow rates. Following this study, the value of FR^2 equal to 0.073, (obtained at a middle flow rate of 3 µL/min, a side flow rate of 41 µL/min), a chitosan concentration of 0.01% w/v (dissolved in acetic solution 1% v/v-middle phase) and a Lipid concentration of 0.0072% w/v (dissolved in etOH/Water-65/35% v/v-side phase), were selected as optimal process conditions. A monodisperse population of nanoparticles is obtained as shown in Fig.2a,b. They displayed an average size around 80 nm (Fig. 2b,c).

This multimaterial nanostructure was exploited for the loading of different active agents for both multimodal imaging (Gd-DTPA- Atto633) and theranostics purposes (Gd-DTPA-Irinotecan).

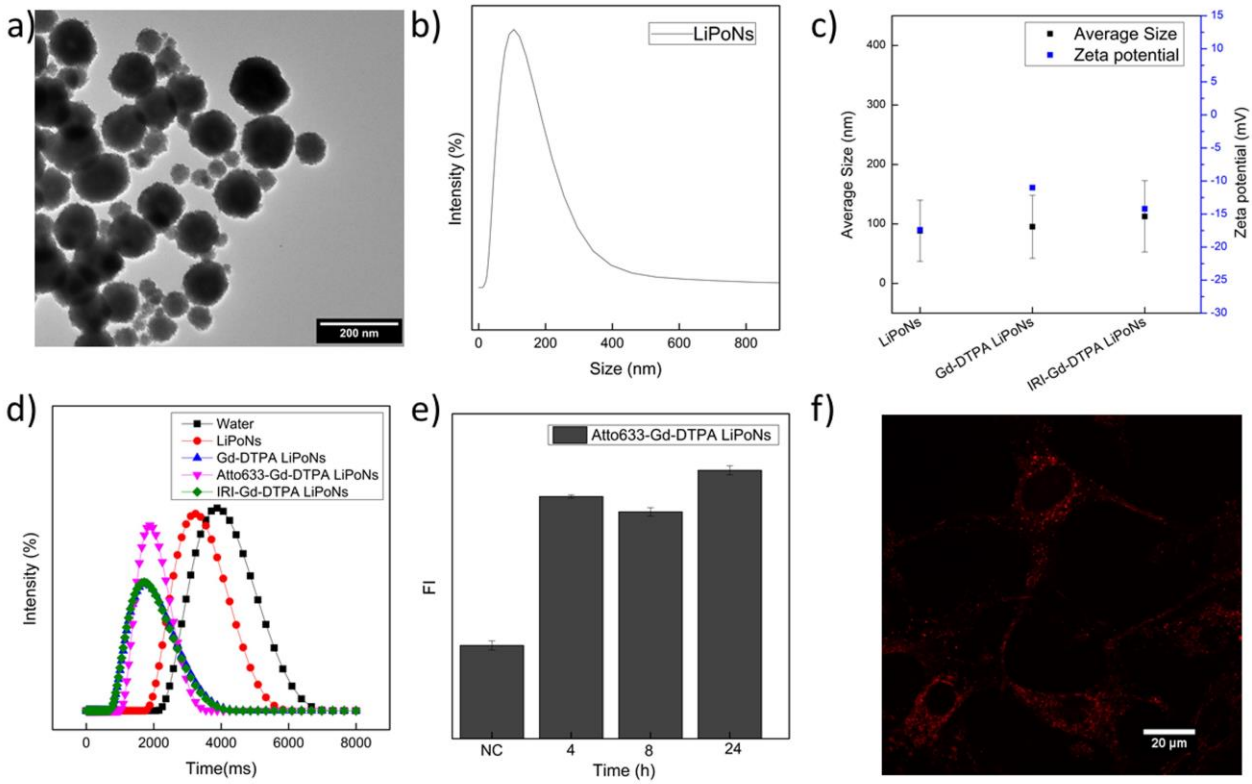

Fig. 2: Morphological characterization, size distribution, multimodal properties and cellular uptake of Lipid-Polymer NPs. **a**) TEM image (stained with osmium smoke), **b**) particle size distribution of LiPoNs, **c**) size and zeta potential of different LiPoNs formulations, **d**) in vitro MRI. Comparison of longitudinal relaxation time of LiPoNs formulations, **e**) Fluorescent intensity (FI) of U87 MG cells exposed to multimodal imaging LiPoNs (lipid conc. 60 µg/mL) and **f**) Confocal image of U87 MG cells upon 24 h of incubation with LiPoNs.

The cargos were dissolved in the chitosan solution and injected in the middle stream, forcing their loading in the chitosan matrix. We evaluated the effect of compound loading on nanoparticles size by DLS analysis (Fig.2c).

A slightly increase in the LiPoNs size is reported for the co-loading of Irinotecan and Gd-DTPA up to 113 nm (Fig.2c). Moreover, the lipid bilayer coverage conferred to the formulations a negative zeta potential ranging from -17 mV to -11 mV, according to the formulations (Fig.2c).

The slightly negative charge of LiPoNs combined with an average size around 100 nm strongly improve the nano-biointeractions that these carriers will encounter during their transport across multiple barriers *in vivo*. Yamamoto et al.[25] reported a long circulation time and lower accumulation in spleen and liver for neutral and anionic NPs, mainly due to lower absorption of serum proteins. Regarding the size, spherical nanoparticles with a size around 100 nm have the higher delivery efficacy in tumour due to their long half-live and reduced off-target accumulation[4, 11].

The optical and diagnostic properties of LiPoNs formulations were tested. The in vitro longitudinal relaxation time T1 was measured at 37 °C and 1.5 T in a the Minispec Bench Top Relaxometer (Bruker Corporation). The Gd-DTPA LiPoNs displayed a T1 of 1680 ms confirming the loading of the CA. All the formulations displayed diagnostic properties as reported in Fig. 2d.

The encapsulation efficacy (EE %) of Gd-DTPA was above 60 %, while the co-entrapment efficacy was in the range of 55-36 % for the Atto633 and Irinotecan.

To assess the delivery capability of LiPoNs, we studied their cellular uptake kinetics by fluorescence-activated cell sorting (FACs) and confocal microscope imaging. We interrogated U87 MG cells, upon incubation with Atto633-Gd-DTPA LiPoNs (lipid conc.: 60 µg/ml) at 4,8, and 24 h. No cytotoxic effects on cells were detected due to the high biocompatibility of materials that made up the LiPoNs[26-28]. The fluorescence intensity (FI) of the cells rapidly increased at 4 h and remained almost unchanged until 24 h, with a little increase in the last point of acquisition. Live cell imaging of U87 MG cells at 24 h upon the addition of LiPoNs confirmed their presence within the cells. We hypnotized that the LiPoNs uptake mainly occurred in the first 4 hours. These findings are in agreement with previous studies on the cellular internalization of lipid-based formulations, to which an energy-dependent mechanism has been associated[29-31]. Recently, Guo et al. [8]reported the impact exerted by the elasticity of NPs in mediated different cellular uptakes. By crosslinking the polymer core of the nanolipogels and consequently increasing their stiffness, they observed a shit from fusion to endocytosis in their cell internalisation pathway. Therefore, our un-crosslinked core in LiPoNs could confer a moderate elasticity to nanoparticles that could mediate the cellular uptake of both fusion and endocytosis pathways. However, this hypothesis requires further investigations because any differences in nanoparticle formulation (head group of lipids, cholesterol addition, protein corona absorption) and the physiochemical properties (size, shape, charge and elasticity) affect the NPs-cells

interaction[32].

IV. Conclusion

We proposed a one-step microfluidic process for the production of Lipid-Polymer NPs with an average size of 100 nm and a slightly negative charge. Their material configuration, where a chitosan core is covered by a lipid bilayer, can potentially stabilize the compound loading during the nano-bio interactions making them promising vehicles for cancer treatment. The chitosan matrix in the nanostructure acts as a reservoir, for the entrapment of active cargos, while the lipid material enables the cell-tissue interactions. The LiPoNs showed a higher cell internalization in first 4 hours. This ability of LiPoNs of presenting and delivery stable cargo could be connected to the fluidity or elasticity that characterized these hybrid vectors. These results support the concept that the microfluidics by controlling the material conformation and their extent, the component concentrations, solvent displacement, the amount of water entrapped between the polymer and lipid shell, provides hybrid NPs with well-defined properties to fill the lack of knowledge between synthetic identities and their nano-bio interactions.

***Abstract*— Single-cell analysis and manipulation is recognized as a central task for developing novel precision medicine approaches. Label-free technologies are especially attractive due to their potential for reduced costs and suitability to cell-therapy applications. Here, we present the development of a label-free microfluidic system for single-cell sorting based on cell electrical phenotype.**

***Keywords*—Microfluidics, Impedance cytometry, Single-cell analysis, Cell sorting.**

I. Introduction

THE cell is the fundamental unit of life. Accordingly, understanding cell function in health and disease is critical to diagnosis and treatment. The heterogeneity displayed by cellular systems motivates the need for robust approaches for single-cell analysis and separation [1]–[4], to enable disease diagnostics based on cellular markers and to control cellular compositions for cell therapy applications [5]. Among other technologies, label-free approaches are especially attractive [6], since they reduce the costs associated with sample preparation and their non-invasiveness allows cell reuse after analysis.

Electric fields offer tremendous opportunities for label-free analysis and manipulation of biological cells, by means of versatile, effective, and yet simple sensing and actuation features. Microfluidic impedance cytometry [7] is increasingly used for the high-throughput label-free electrical characterization of single-cells flowing through microchannels with integrated electrodes. Electrical fingerprints obtained via impedance cytometry can provide information on cell size, morphology [8], deformability [9], viability [10], [11], and phenotype [12]. Adding a single-cell sorting functionality to impedance cytometry systems represents an attractive opportunity [13], [14]. This requires the development of tailored approaches for the online processing of impedance signals, coupled with a suitable microfluidic cell sorter.

In this work, we propose an electrical microfluidic system for impedance-based single-cell sorting. The conceptual design of the system is shown in **Fig.1**. A suspension of cells flows through a microfluidic channel (sample flow). Sheath flows are used to laterally focus the sample flow along the channel axis. The electrical phenotype of individual flowing cells is characterized by means of a sensing region comprising three coplanar electrodes: a multifrequency AC voltage is applied to the central electrode and the differential current from the lateral electrodes is measured ($I_{\mathrm{diff}} = I_2 - I_1$). That current is processed online as follows: (i) first, lock-in

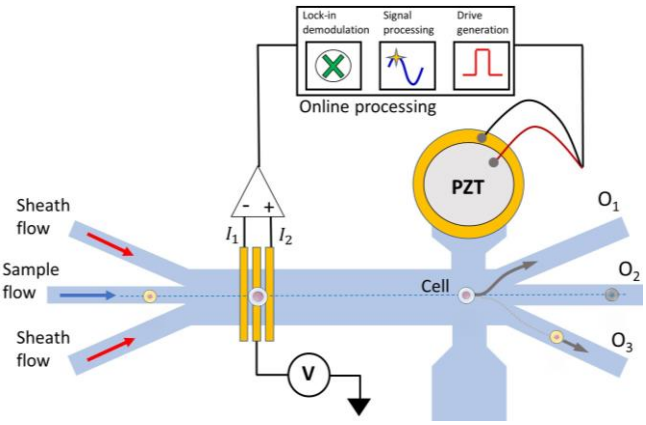

Fig. 1: Schematic representation of the label-free microfluidic system for impedance-based single-cell sorting.

demodulation provides the current traces at each applied frequency; (ii) then, those traces are processed (event detection and feature extraction) and the electrical phenotype of each detected cell is characterized; (iii) according to the cell electrical phenotype, a sorting decision is possibly made (i.e., sort to outlet O_1 or O_3), and a suited electrical signal is generated to drive a piezoelectric (PZT) actuator [15], [16]. Upon activation, the fluid displacement induced by the PZT actuator deflects the cells towards the desired outlet, whereas unsorted cells are collected at the central outlet (O_2).

The electrical sensing feature of the system has been extensively described in previous works (cf. e.g., [17]–[19]). The present work focuses on the development of the actuation feature and of the associated signal processing.

II. Materials and Methods

A. Microfluidic chip

As shown in **Fig. 2(a)**, the main channel of the microfluidic device is 150 μm wide, while the width of the three collection channels is 50 μm. Channels height is 40 μm. Two lateral regions are designed on the sides of the sorting region. The corresponding nozzles are 100 μm in width, with a distance from the diverging junction of about 50 μm. One of the lateral regions houses the actuator, that consists of a cylindrical chamber of 13 mm in diameter and 5 mm in height above which a circular ceramic transducer (lead zirconate titanate) is bonded. The PZT element has a diameter of 15 mm and a thickness of 110 μm, while its metal substrate (stainless-steel or brass) is 20 mm in diameter and 100 μm thick.

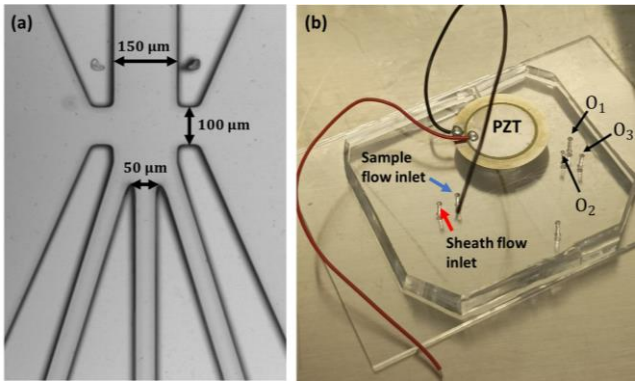

Fig. 2: (a) Microscopy image of the sorting region of the device, with indication of relevant dimensions. (b) Device photograph.

Fig. 2(b) shows a photograph of the device, with indication of the sample inlet, the common inlet of the two sheath flows, and the collection outlets. The fluidic layout is realized in a polydimethylsiloxane (PDMS, Dow Corning) block, fabricated by soft-lithography methods, and sealed to a 56 mm x 75 mm glass slide. The PZT disc is coated by a MPTS (3 mercaptopropyl trimethoxy silane) solution and then oxygen plasma-activated together with the assembled chip.

B. Numerical modelling of fluid flow and particle tracking

To analyse the fluid flow and the particles displacement induced by the PZT actuation, a 3D virtual microfluidic device is realized. The geometric model consists of the main channel, the sorting region, and the three collection channels. The overall length of the computational domain is 800 µm.

The fluid flow is modelled using the incompressible Navier-Stokes equations:

$$\rho\frac{\partial \boldsymbol{u}}{\partial t}+\rho(\boldsymbol{u}\cdot\nabla)\boldsymbol{u}=-\nabla p+\mu\nabla^2\boldsymbol{u}, \qquad (1)$$

where ρ is the fluid density, $\boldsymbol{u}$ the fluid velocity, p the fluid pressure, and μ the fluid dynamic viscosity. Boundary conditions are as follows: a laminar inflow condition at the inlet of the computational domain (average velocity $u_{av} =$ 3 cm/s), a pressure condition at the outlets ($p = 0$ Pa), and a no-slip condition on the device walls.

The movement of the particles is modelled using the Khan and Richardson's model [20]:

$$\boldsymbol{F}=\frac{\pi}{4}d^2\rho|\boldsymbol{u_r}|\boldsymbol{u_r}\left(1.84{Re_p}^{-0.31}+0.293{Re_p}^{0.06}\right)^{3.45}, \qquad (2)$$

where $\boldsymbol{F}$ is the particle drag force, d is the particle diameter, $\boldsymbol{u_r}$ is the relative velocity of the fluid with respect to the particle, and Re_p is the particle Reynold's number ($Re_p = |\boldsymbol{u_r}|d\rho/\mu$).

To mimic the PZT actuation, an inlet flow condition with applied pressure (p_{PZT}) is imposed in the sorting region, on the lateral aperture of the main channel [15]. Sinusoidal or pulse pressure conditions are considered. In the sinusoidal case, the following expression is used [15]: $p_{PZT} = p_A \sin(2\pi f t) + p_0$, where p_A is the amplitude, f is the frequency, and p_0 is the hydrodynamic pressure established by the flow. Typical values are: $p_A = 1500$ Pa, $f = 250$ Hz, and $P_0 = 630$ Pa. In the pulse actuation case, typical parameters are as follows: pulse duration $t_{OFF} - t_{ON}$ =5 ms, pulse amplitude $p_{ON} - p_{OFF} =$ 1500 Pa.

The model is implemented in COMSOL Multiphysics (Laminar Flow physics interface). The finite element mesh consists of fine unstructured triangular elements at the inlets, and coarse unstructured tetrahedral elements in the remaining geometry. Both are calibrated for fluid dynamics. The number of elements and the number of degrees of freedom typically considered are about 30000 and 26000, respectively. PARDISO solver is employed.

C. Online signal processing

As reported previously [17], [18], the lock-in demodulation is performed using the HF2IS impedance spectroscope (Zurich Instruments), which also generates the stimulation voltage applied to the centrale electrode of the sensing region. The demodulated signals (real and imaginary components at each frequency) are sent in real-time to a workstation, where they are processed with a custom Matlab script. The latter script implements the event detection using the routine findpeaks.m and extracts the corresponding event features (i.e., the particle velocity, and the electrical diameter and phase at each frequency, computed from the peak amplitudes [7]). According to the event features, a sorting decision is possibly made. In this case, instructions are sent to the HF2IS that accordingly generates the PZT drive signal at an auxiliary output connected to the PZT actuator. While the present implementation of the online signal processing is versatile and straightforward, its throughput is limited by the communication delay between the HF2IS and the workstation (~20 ms). Faster implementations are presently under development based on Field Programmable Gate Arrays (FPGAs).

III. Results and Discussion

A. Numerical characterization of piezoelectric actuation

Numerical simulations were carried out to investigate the effect of the PZT-actuation features (i.e., sinusoidal pressure amplitude and frequency; pressure pulse amplitude and duration). Water was used as the suspension fluid ($\rho = 1000$ kg/m^3, $\mu = 1.002 \cdot 10^{-3}$ Pa·s) and polystyrene beads as the particles (density $\rho_p = 1050$ kg/m^3). Different particle sizes and particle entrance positions were considered.

As an example, **Fig. 3** shows the effect of particle off-centring along the x axis (transverse direction to the main channel), which may arise due to imperfections of the sheath-flow focusing system. In the figure, different particle trajectories are shown, relevant to variable entrance position x_0 of a 5 µm bead. As the off-centring increases, the probability that the particle is deflected in the collection channel opposite to the boundary where the PZT actuation is applied decreases. The figure also shows a reduction in the length of the particle path (for fixed simulation time). In fact, as the off-centring increases the particle velocity decreases, due to the laminar flow velocity profile [21].

B. Experimental characterization of the PZT actuation

Fig. 4(a)-(b) show an experimental example of particle deflection (5 µm polystyrene bead) obtained with a sinusoidal voltage stimulation applied to the PZT transducer (10 V, 100 Hz). **Fig. 4(c)** shows an example of the time behaviour of the rotation angle (θ) of the sample stream, upon a 5 V sinusoidal

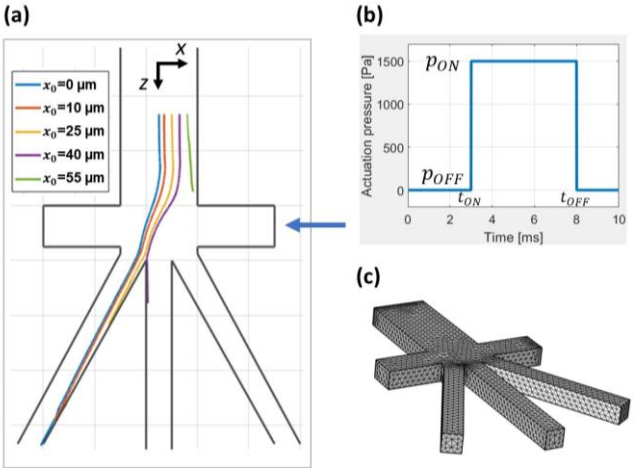

Fig. 3: Cell sorting parametric analysis with different particle's initial positions (a) under pulse pressure applied to the sorting region (b). (c) Typical computational mesh.

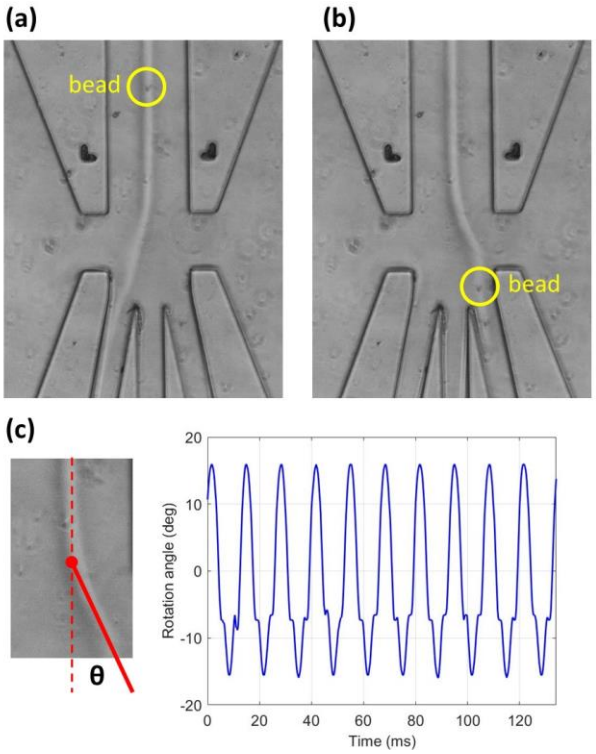

Fig. 4: (a)-(b) Microscopy snapshots showing an example of particle deviation (5 µm bead, sinusoidal PZT actuation, 10 V at 100 Hz). In panel (a) the bead (inside the yellow circle) is approaching the sorting region; in panel (b) the bead is entering the right outlet channel, due to sample flow displacement induced by the PZT actuation. (c) Rotation angle (θ) of the sample flow upon sinusoidal actuation (5 V, 75 Hz).

stimulation at 75 Hz. The angle θ was extracted from high-speed video recordings using a custom Matlab script. Oscillations with amplitude of about 16 degrees at a frequency of 75 Hz were found.

C. Online particle detection and generation of drive signal

Fig. 5(a) shows an example of online processing of the differential current I_{diff}. Two event signals are detected in the demodulated signal, corresponding to particle passages in the electrical sensing region. Particle velocity is computed from the signal peak-to-peak time. The time it takes for the particle to move from the sensing region to the actuation region (t_{SA})

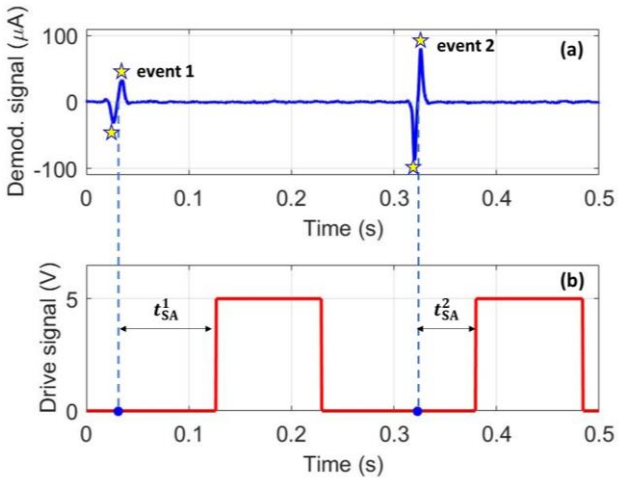

Fig. 5: (a) Example of event detection in the demodulated signal (0.5 MHz frequency channel, in phase component). (b) Corresponding drive signal.

is accordingly estimated and used to define the drive signal for the PZT actuator (**Fig. 5(b)**). It can be noticed that, due to different particle velocities, event 1 is slower than event 2 (i.e., particle 2 is closer to the channel axis - where the maximum velocity is achieved - than particle 1). Accordingly, t_{SA}^1 is larger than t_{SA}^2.

IV. Conclusion

We presented preliminary results toward the development of a label-free impedance-based microfluidic system for single-cell sorting. Specifically, we presented a numerical and experimental characterization of the PZT actuation system as well as a simple approach to online signal processing. Future activities will be dedicated to the testing and optimization of the overall system in relevant application scenarios. As a perspective, machine learning approaches tailored to impedance cytometry signals will be implemented [11], [22], [23], aiming at online cell characterization and sorting of complex samples (e.g., heterogeneous cell populations).

***Abstract*—This study focuses on the assessment of the feasibility of using magnetoelectric nanoparticles for the stimulation of peripheral nerves. The analysis was performed by computational techniques, paring electromagnetic simulation and neuronal dynamic simulation. Results suggest the feasibility of the proposed technique, highlighting the high spatial resolution achievable by such nanomaterials.**

***Keywords*—Magnetoelectric nanoparticles, electrical nerve stimulation, numerical techniques.**

I. Introduction

Motor nerve stimulation is the application of safe levels of electric current for medical purpose. The electrical stimulation elicits muscle contraction using electric pulses over the peripheral sensory-motor system, contributing to recovery functions, strengthening atrophied muscles and relieve pain [1]–[3]. In the last decades, a fast evolution in motor nerve stimulation has been possible thanks to the increasing interest in new stimulation techniques. This technology had a rapid development in prosthetic technologies to achieve sensory feedback control with desirable high spatial and temporal resolution. Particularly, the technological rapid expansion is leading to less invasive but with higher selectivity stimulating approaches. Stimulating electrodes could be surface, percutaneous or implantable (cuff or epimysial ones) [2], [3].

Recently, magnetoelectric (ME) materials could represent an innovative tool to penetrate this field, overcoming actual stimulation approaches drawbacks. Among different ME devices, ME nanoparticles (MENPs) are particularly promising. They comprise a ferromagnetic core and a piezoelectric shell. When subjected to variation of the applied magnetic field ΔH, at the interface between the two ferroic phases there is the transmission of magnetostrictive stresses generated in the magnetic phase to the piezoelectric one, which in turn changes polarization ΔP and associated electric field ΔE [4]. This behavior is quantified by magnetoelectric coefficient $\alpha = \Delta P / \Delta H$ [5]. The progress in nanoengineering of ME materials opened the path to the development of less invasive devices without any wire connections, enabling cells to react at micro and nano scales. So far, few studies have explored the possibility of using the ME nanoparticles to such purposes, however there are some experimental and theoretical evidence that underly its efficacy for nervous system stimulation [6]–[11].

For example, some studies evidence the activation of neural pathways following the brain stimulation thought the ME effect [6], [12]. A low-intensity field generates AC signals at the same frequency as the activity of a healthy nerve charge, and the vibration of a ME nanoparticle leads to the activation of neurons around it with the same frequency, that is, to their stimulation non-invasively. In this scenario, computational approaches offer a unique tool for the evaluation of electric quantities within human tissues and allow to deep investigate physical phenomena behind the stimulation effect, thus representing an essential method for the advancement towards clinical application [13] .

In this work, we aim to prove the feasibility of using MENPs as tools for electric stimulation of peripheral nerves throughout computational approaches. We report the simulation settings of our computational approach, and we discuss the presented results.

II. Material and Methods

The methodology used to assess the feasibility of using MENPs for the stimulation of peripheral nerves consists of two simulation approaches. The first one involves the estimation of the electric field (**E**) distributions elicited by the MENPs localized in biological tissue, while the second one consists of the assessment, by dynamic model of nerve behaviour, of the electric response of a peripheral nerve model localized near the MENPs to such distribution. All the simulation steps have been implemented using Sim4life platform (by ZMT Zurich Med Tech AG, Zurich, Switzerland, www.zurichmedtech.com) as reported in the followings.

A. MENPs Model and electromagnetic stimulation settings

Due to their core and shell chemical compositions, MENPs are characterized by strong coupling between magnetic and electric fields, the so-called magneto-electric (ME) effect. The electric potential on each MENP surface was found to exhibit a dipole distribution aligned along the direction of the low-amplitude magnetic field used for stimulating the ME effect. A wide range of dimension of the MENPs is reporting in literature, with size varying between 30 and 600 nm [5], [6], [9], [14], depending on the synthetization method used. The potential generated by the MENP, and so its magnetoelectric coefficient, is influenced by both the MENP dimension, the material composition and on the frequency of the magnetic fields used to elicit the magneto-electric effect [5], [15].

In this study, we hypothesized that the MENPs could be approximated by dipoles with dimension equal to 80 nm. The geometric structure of the MENP is shown in Fig. 1 and consists of two conductive surfaces separated by an insulating layer, with the dielectric properties of the techotane material. A potential of +/- 0.5 V has been assigned over the two surfaces by using Dirichlet boundary conditions, with a total

charge of 1 V, as for typical implanted electrodes [16]. The biological material surrounding the MENP was fat. The dielectric properties of all the materials were assigned according to literature data [17] at the MENP stimulating frequency.

Focusing on the stimulus shape delivered by the MENP, a sinusoidal pulse of amplitude equal to 1 V has been chosen, at the frequency of 100 Hz which is in the frequency range for neural stimulation, as reported in literature [18].

The electrostatic approximation was used to solve Maxwell equations to estimate the electric field distribution, which is the input of the following neural simulation. Dirichlet boundary conditions in which V = 0 defined the potential on the borders of the computational domain.

MENPs were placed at different distances from the line representing the nerve, equal to 5 um, 10 um, 20 um and 30 um.

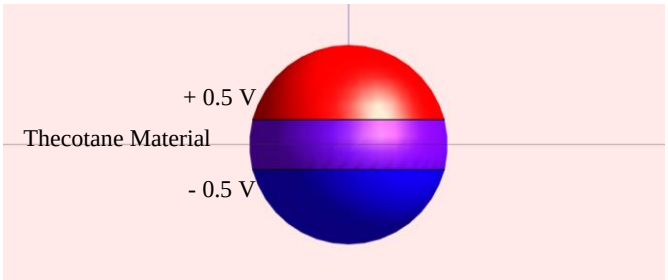

Fig. 1: MENP model in Sim4Life

B. Nerve Model

A neuronal fiber of 1000 um length and diameter equal to 5.7 um has been defined as simplified model of the peripheral nerve within NEURON environment implemented in Sim4Life.

In Sim4Life, NEURON is available as a solver library developed to simulate the effect of electromagnetic fields on neuronal dynamics and for studying interaction mechanisms. Moreover, the platform offers the possibility to directly couple the results of EM simulations with the neuronal dynamics solver. [19]. NEURON provides a powerful and flexible environment for implementing biologically realistic models of electrical and chemical signalling in neurons and networks of neurons. It has two main aims: testing the hypothesis about the mechanisms that governs electrical and chemical signals (to calculate the ionic concentrations) and efficiently simulating the mechanisms, so how nervous system functions develop from these mechanisms (by the computation of the extracellular potential next to the nerve membrane). [20]

In NEURON it is possible to define the time-response of a neuronal membrane, so basically there are different models of transmembrane dynamics. Among all, the one chosen for the simulation has been the MOTOR MRG model, thanks to its great physiological accuracy which designs it as the most realistic to represent human axons [21].

The MOTOR model allows to gain insights into the biophysical mechanisms of the fluctuation of the axonal excitability, by modelling the recovery cycle of the axon.

MOTOR models are computer-based double cable models of mammalian nerve fibers with an explicit representation of the nodes of Ranvier, paranodal, and internodal sections of the axon, and a finite impedance myelin sheath. Linear and nonlinear membrane dynamics represent the electrical behavior of the axon. Parameters associated with the kinetics of the channels were selected to enable the models to reproduce a wide range of experimental data. In the model, the nodes consist of parallel combination of nonlinear fast Na, persistent Na, slow K conductances, linear leakage conductance and membrane capacitance. Whereas the paranodal and internodal compartments comprise two layers, each including a linear conductance in parallel with the membrane capacitance. [22]

The titration mechanism implemented in the software was used to estimate the minimum pulse amplitude able to elicit and action potential. Titration consists of stimulating the axon with a series of increasing amplitude stimuli, to identify the threshold above which an action potential is generated. The equation used to find the final threshold current is: $IT(t) = I * T * a(t)$, where I is the current from the EM field, a(t) is the modulating pulse and T is the titration factor, which is varied until a response is detected [16].

The time pulse used to stimulate the nerve was simulated as a sinusoid with amplitude equal to the one obtained by the electromagnetic simulation, frequency equal to 100 Hz, and duration and time step equal to 200 ms and 0.0025 ms, respectively.

III. RESULTS

The analysis of results will be presented by considering separately the resulting electric field distribution on the nerve, the titration factor as estimation of the amplitude of the stimulus needed to elicit the action potential, and the neuron response for the different considered distances between the MENP and the nerve fiber.

The distribution of the **E** field has been studied everywhere around the MENP. We focused on a slice view over the YZ plane, which comprises the nerve along its full length. Between all the possible YZ planes, we chose to study the overall field distribution on the plane which holds the maximum RMS of **E** amplitude (V/m), as reported in Fig 2, for the case of 5 um distance. The colormap in Fig. 2 ranges between 0 and 10 V/m.

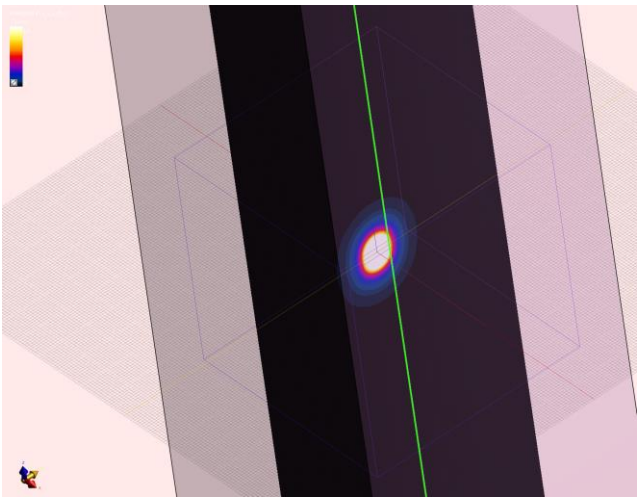

Fig. 2: View of the RMS of E amplitude. Visualization on the YZ plane, particularly the plan with maximum RMS E amplitude. The green line corresponds to the position of the neuron, and it's the line along with the E field is analysed. The MENP is placed at the centre of the white oval. This is the case with 5 um of MENP – neuron distance.

In Fig. 3, the overall field of the RMS of **E** along the neuron length is reported for all the MENP – neuron distances. In all the four different simulations, a similar bell shape of the distribution over the neuron length has been shown. What changed was the width of the bell and its maximum amplitude. In fact, it was noticed that increasing the MENP – neuron distance, the bell shape was wider. Conversely, by increasing the MENP – neuron distance, the maximum amplitude of the E field substantially decreased. The bell width was quantified at the 10% of the bell's maximum amplitude. The maximum values of the bell shape distributions were 10.35 V/m, 1.18 V/m, 0.14 V/m and 0.056 V/m and the bell width were 22 um, 52 um, 82 um and 104 um for the distances 5 um, 10 um, 20 um and 30 um, respectively.

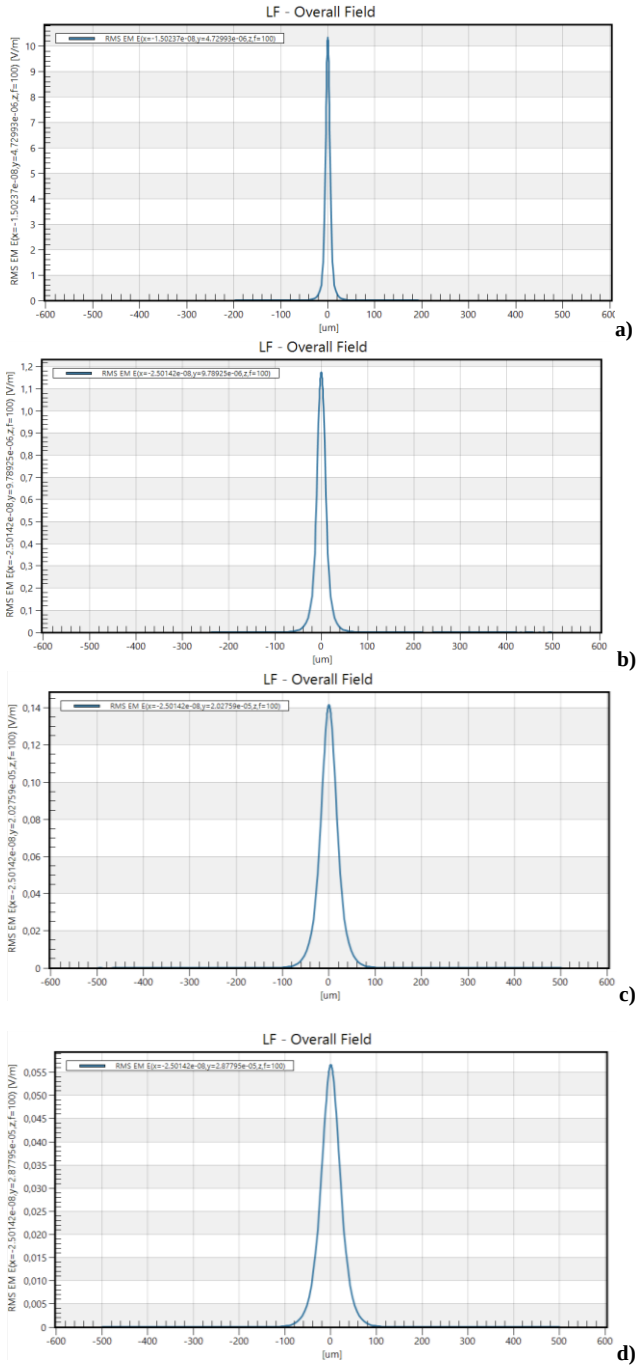

Fig. 3: Overall field of the RMS of E analysed along the neuron, for the different of MENP – neuron distances: a) 5 um, b) 10 um, c) 20 um and d) 30 um. For the sake of readability, we kept different scales in the plots.

TABLE I: TITRATION FACTOR

Distance [um]	*Time of first spike [ms]*	*Titration factor*
5	4.685	936
10	4.9275	3744
20	4.855	6240
30	4.2375	6784

The titration factor was set to define the stimulus amplitude of the MENP that causes the response of the neuron.

In Table I, the time of the first spike in ms and the relative titration factor are reported, differentiated by the corresponding MENP – neuron distance. As well expected, increasing the distance, the titration factor increases, so a bigger stimulus amplitude is necessary to stimulate the neuron.

The response of the neuron in terms of transmembrane potential, has the characteristic shape of an action potential, as shown in Fig. 4 for the distance of 5 um. When considering different distances between MENP and the nerve, negligible in the shape of the action potential were observed.

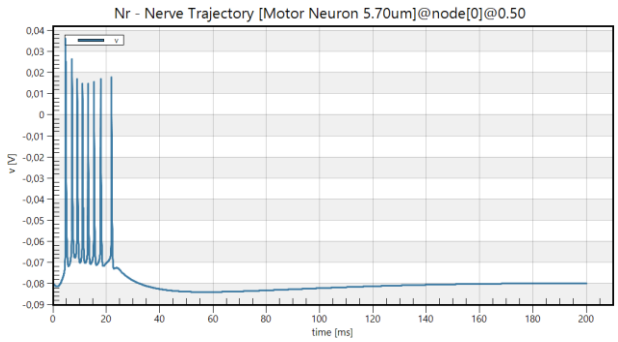

Fig. 4: Nerve response, in terms of transmembrane potential (V) during the stimulation, in the case of 5 um of MENP – neuron distance.

IV. Discussion and Conclusion

In summary, the computational approaches have proven the feasibility of using MENPs as tools for electric stimulation of peripheral nerves and have demonstrated how the MENP – axon distance influences over the EM field distribution and the axon response. In fact, the results showed that the distance between the MENP and the axon impacts the amplitude of the peak of the EM field distribution but not the shape of the distribution itself. Moreover, the overall field analysed along the neuron has shown how a punctual stimulation is feasible with MENP, allowing a very high spatial resolution. Particularly, increasing the MENP – neuron distance, the bell width of the RMS of E at the 10% of the maximum amplitude increases as well. So, the spatial resolution decreases by increasing the distance. We have confirmed the MENP capability to induce an action potential to the nerve and we have characterized the response of the nerve itself, considering the different distances. Finally, the titration factor gives information about the amplitude needed for the stimulus of the MENP. As expected, results confirmed how the titration factor increases by increasing the MENP – axon distance. The values are such to suggest that a single MENP is not able to stimulate the nerve itself, but previous experimental evidences and computational studies [10] in which MENPs have been

modelled as agglomerates [10], [11] have shown the plausibility of MENPs stimulation. Future work is needed to address the summation effects of MENPs distributions.

In conclusion, MENPs are a powerful tool for the stimulation of peripheral nerve, but a lot is still to be understood about their functioning.

***Abstract* — Biological barriers in our body, like the intestinal epithelium or the blood-brain-barrier, are devoted to the selective transport of molecules across different organs. There is growing evidence that altered permeability of such barriers play a pathogenic role in disease.**

Transwell®-like inserts based tools are the gold standard for culturing and modelling the biological barriers *in vitro*. They allow reproducing the transport mechanisms of specific molecules across semi-permeable supports in bi-compartmental wells but do not allow a dynamic culture of the cells. Trans Endothelial/epithelial Electrical Resistance (TEER) measurement is a label-free assay that is conventionally used to asses barrier integrity by measuring ionic current exchanges across the cellular layer. Conventional TEER electrodes are dependent on operator handling and usually do not allow continuous real-time monitoring. In the present work, we have developed and tested an Integrated TEER Electrode (ITE) inside an innovative millifluidic device for dynamic culture of Transwell®-like inserts based biological barrier models, able to perform suitable TEER measurements and guarantee real-time monitoring of barrier functions over time.

***Keywords*— TEER, biosensor, bioreactor, biological barriers, in vitro.**

I. INTRODUCTION

BIOLOGICAL barriers serve the natural protective function inside the body. From skin, to intestinal barrier, to blood brain barrier, they are involved in controlling the passage of exogenous molecules, cells and microorganisms as well as the absorption of important solutes for the homeostasis of specific organs [1].

The impairment of their function due to microbial action or inflammatory process is demonstrating to be involved in the onset of pathological conditions [2]. Therefore, studying the biological barriers is important to understand their physiopathology and to assess molecules toxicities and drug efficacy. Conventional *in vitro* models consist in bi-compartmental wells, such as Transwell®-like inserts based systems, that generate an apical and a basal chamber separated by a semi-permeable membrane that can host cells and form a biological barrier [3]. In particular, epithelial and endothelial cells, that form the barrier cellular monolayers, express adhesion protein forming Tight Junctions (TJs) that contribute to the overall barrier permeability [4].

Trans-Endothelial/epithelial Electrical Resistance (TEER) measurement is one of the widely used assays to characterize barrier integrity depending on the physiological status of the TJs. TEER measurement returns indirect information on TJs expression and barrier tightness by measuring the resistance of cells to the flow of ionic currents through the cell monolayer. The most widely used TEER measuring systems exploit chopstick electrodes in the four-points measurement configuration to avoid charging of the cell layer and the electrodes [5] (**Fig. 1**). This consists in a couple of current injecting electrodes and a couple of voltage measuring electrodes. The recorded resistance include the contribution of the cellular layer, the porous membrane, the culture medium and the medium/electrode interface [6].

Recently, advanced cell culture tools have been developed to improve the reliability of barriers in *in vitro* models against pathophysiological conditions in the human body. Indeed, flow perfusion and 3D environment demonstrated to dictate barrier morphology and transport properties. Examples are miniaturised bioreactors based on the use of semi-permeable porous membranes or cell culture inserts [7], and the so-called micro-physiological systems exploiting microfluidics and microfabrication [8]. In all these cases, measuring TEER inside the device in non-invasive, reproducible and reliable manner is a strong requirement when modelling biological barriers.

The existing advanced cell culture fluid dynamic systems are based on the use of commercial permeable supports, with limited possibility of monitoring TEER without the need of interrupting the experiment or accessing the system from the outside [9] [10]. On the other hand, minimally invasive electrodes are often difficult to integrate inside bioreactors while maintaining easy assembling procedures and handling [6]. Moreover, popular micro-fluidic organ-on-a-chip devices have small volumes to host planar and uniform electrodes and require complex clean-room procedures to be suitably manufactured [11].

To overcome these limitations, we coupled conventional technology for patterning thin conductive films, to on-bench low-cost 3D printing. We propose the integration of planar electrodes within an innovative 3D printed millifluidic bioreactor, named MINERVA 2.0, which can host Transwell®-like inserts for advanced *in vitro* modelling of biological barriers [12].

We applied Physical Vapor Deposition (PVD), which is generally used to sputter films on flat substrates, to the complex 3D geometry of the bioreactor by exploiting 3D printed masks to generate conductive lanes on the walls of the device. In this way, electrodes do not interfere with flow direction or cell culture procedures, and allow the electric signal to travel outside the device without the need of inserting wires across the bioreactor.

Our integrated TEER electrodes (ITEs)-device represents a useful tool to detect barriers functionality, possibly altered by drug toxicity and absorption process. In this work, we present the design and the fabrication strategy of our innovative ITE-MINERVA 2.0 device and its assessment in recording real-time TEER on a cell-based gut epithelium barrier *in vitro* model.

II. Materials and Methods

ITEs design and manufacturing

3D models of the electrodes were designed in Solidworks (Dassault Systèmes SolidWorks Corporation, Waltham, MA, USA) in order to be hosted on both sides of our MINERVA 2.0 device, that consists of two 3D-printed components fitting a commercially available Transwell®-like insert, creating two hemi-chambers (apical and basal) interfaced through the Transwell®-like insert membrane. Silicon tubings connected to the system allow for flow perfusion. A transparent glass slide is hosted on the basal chamber to allow cell culture monitoring by optical or confocal microscopy.

The conductive films were sputtered both on the glass coverslip (basal component), and the apical component of the bioreactor. The sputtering process was performed by PVD (Leybold-Heraeus LH Z400). 50 nm thick Au electrodes with 100 nm Ti as adhesion layer were sputtered on both sides of a glass coverslip while 100 nm thick Au electrodes were sputtered directly on the apical component of the ITE-device.

Numerical analysis

The electrodes were designed in Solidworks and then imported into COMSOL Multiphysics (COMSOL Inc., Burlington, MA, USA). Finally, a discrete triangle elements mesh was built by exploiting the 'physics controlled' method with an average side dimension of 0,2 mm in the region of interest. The "electric current" physics was used to simulate electrical current distribution through the system. The sensitivity was then calculated at each point of the cellular layer as in Eq. (1),

$$S = \frac{J_1 \cdot J_2}{I^2} \cdot A^2 \quad (1)$$

where I is the magnitude of the applied current, J_1 and J_2 are the current densities across the cellular layer for the two pairs of electrodes, A is the area of the cellular layer. Boundary conditions included i) a ground domain at one of the 'current' electrodes; ii) 10 μA current injection at the other 'current' electrode; iii) and zero electric potential [V] as initial condition.

TEER measurement

All the resistance measurements were performed by using EVOM3 (WPI). To perform the measurements in Transwell®-like tissue culture inserts, we used the STX2 chopstick electrode set (WPI). Measurements with the ITEs were performed by connecting the sensorized bioreactor with EVOM3 by mean of an electrode adapter.

ITEs functional characterization

To confirm that the system was able to discriminate between different resistances, we assembled three different sensorized devices, each one hosting a Transwell®-like insert (Greiner Bio-One ThinCert™ tissue culture insert) with porosity 0.0025, using Dulbecco's Modified Eagle's Medium (DMEM) with 20% Fetal Bovine Serum (FBS) at room temperature, and we made nine measurements for each device. Then we disassembled the three devices and we made the same process with the culture inserts with porosity 0.015 and 0.125. As control, we performed the measurements on the same membranes by using conventional STX2 electrodes (WPI).

CaCo2 cell culture

CaCo2 gut epithelial cells (ATCC) were cultured until reaching the confluence at P31. CaCo2 were then seeded at a cell density of 50.000 cells/cm^2 on the Transwell®-like insert (Greiner Bio-One ThinCert™), and incubated at 37 °C with 5% CO_2.

ITEs biological assessment

CaCo2 were seeded on the cell culture inserts, assembled into the sensorized devices after being maintained in multiwell plate for 2 weeks. After 90 min, a 5 mM EDTA solution was injected inside the devices that were kept at 37 °C and 5% CO_2. TEER values were recorded every 30 min.

Statistical analysis

Results are presented as mean ± SD. Statistical test one-way ANOVA (GraphPad Prism 8) was used to assess the significance of the results (p value < 0.05).

III. Results

ITEs design and manufacturing

We have designed integrated electrodes to be hosted on both chambers of our MINERVA 2.0 millifluidic bioreactor (**Fig. 2**). The ITE-MINERVA 2.0 device is composed of "plug and play" components that fit the conventional Transwell®-like inserts generating a bi-compartimental bioreactor consisting in an apical chamber hosting the cellular barrier model, and an optically accessible basal chamber. In order to perform four points TEER measurement, we designed the ITEs so that each chamber can host a couple of electrodes (one for current injection and one for voltage measurement).

The design of the electrodes was chosen according to the results of the numerical simulations (**Fig. 3**).

Both the qualitative diagrams of the sensitivity and the numerical parameter highlighted the low uniformity of the

current density using the conventional STX2, while the symmetrical-ITEs (and the concentric-ITEs, not reported in the figure) have shown much more homogeneity and sensitivity next to the ideal value 1.

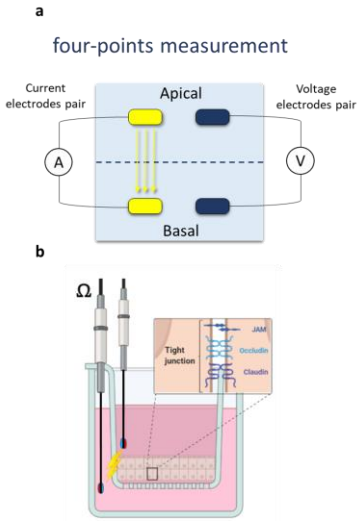

Fig. 1: Schematic representation of conventional approaches for TEER measurement. **a)** four-points TEER measurement **b)** conventional chopstick TEER electrodes.

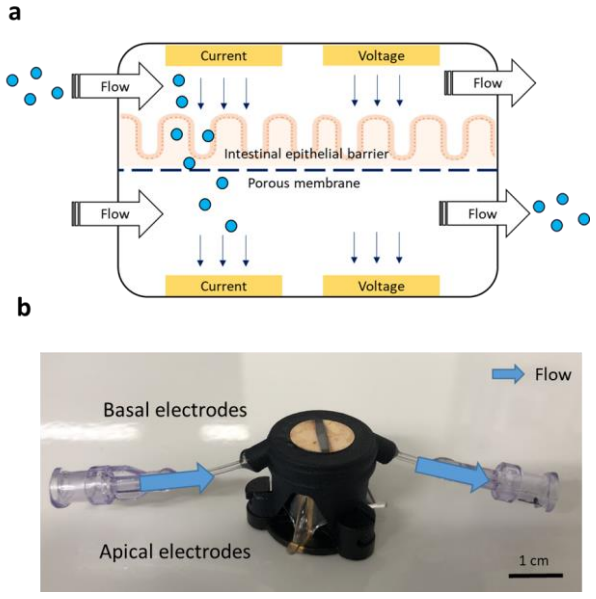

Fig. 2: ITE-MINERVA 2.0 device set-up. **a)** Schematic representation of the bi-compartmental flow chamber of the bioreactor hosting the electrodes in the four-points measurements configuration. **b)** The sensorized device.

ITEs discriminate membrane permeability with higher reproducibility than conventional electrodes.

We assessed the capability of ITEs to measure the resistance of the Transwell®-like insert membranes. The average value recorded by three devices was 25,6 ohm (SD ± 1,47). The values recorded by each device had a SD below 1,97 if compared to those measured by the STX2: 236,7 ohm (SD ± 20,87). The absolute resistance values recorded by our system differ of one order of magnitude if compared to conventional STX2. This might be due to different intrinsic characteristics of the two systems. The ITE-MINERVA 2.0 device was able to continuously detect the same resistance value over a long period proving to be suitable for real-time TEER monitoring. Finally, in order to functionally assess the sensorized bioreactor, we ensured that it was able to discriminate different resistance values of porous membranes with different porosity and permeability.

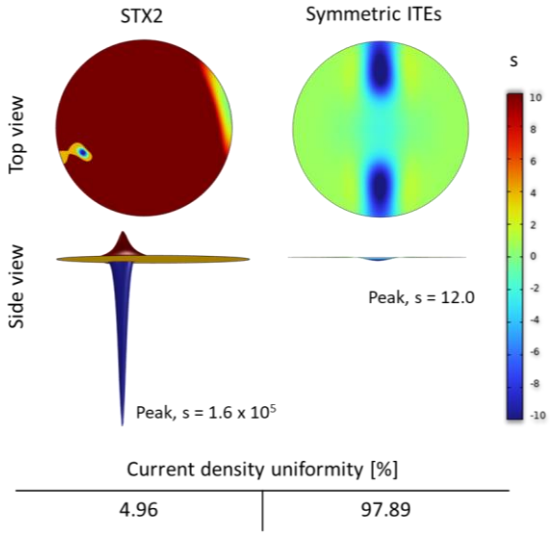

Fig. 3: Numerical simulation of current density uniformity inside the ITE-MINERVA 2.0 device. Colour map of the predicted sensitivity [s] distribution at the level of the cell culture membrane (top view and side view) comparing simulated resistance measurements by conventional STX2 with the ITEs.

ITEs detected real-time changes of CaCo2 barrier permeability

To demonstrate that the ITE-MINERVA 2.0 device is suitable to monitor barrier functionality, we measured changes in CaCo2 layer permeability due to exposure to EDTA, which is known to influence barrier integrity [13]. We recorded TEER every 30 min in each device hosting CaCo2 layers.
We injected EDTA solution (5 mM) inside the fluidic device at time point 100 min. We detected a sudden 35,6% (SD ± 3,6) average decrease of TEER value at time point 130 min.
The signal then stabilized with a slight decrease in the next three time points reaching a final drop of 62.1% (SD ± 1,1) at 210 min with respect to the initial values.
Thanks to the optical accessibility of the device we were able to assess gut epithelium cell response in concomitance with the TEER measurements by optical microscopy observations which revealed a change in cell morphology due to EDTA exposure: CaCo2 appeared rounded and separated if compared to control, where cells still displayed cuboidal shape and formed a tight layer. Future assessment should include immunostaining analysis to assess the expression of membranes protein involved in the tight junctions formation.

IV. Conclusion

In the present work we described the development of integrated electrodes for TEER monitoring inside an innovative millifluidic device for advanced cell culture *in vitro* models [14]. Our ITE-MINERVA 2.0 device showed to be potentially applicable to Transwell®-like inserts based models of biological barriers for advanced toxicity and drug screening experiments. Furthermore, our developed ITEs showed to be suitable to measure TEER in real-time and non-invasively representing a useful tool to be applied to biological barriers investigation, such as blood-brain barrier and gut epithelium.

***Abstract*—Microelectrode arrays (MEAs) represent one of the most important technologies for the study of electrogenic cells such as neurons and cardiomyocytes. The current standard commercial devices are expensive tools that researchers reuse extensively, with the downside of degrading the quality of recordings over time. Therefore, a low-cost fabrication process is needed to produce disposable and, possibly, biodegradable MEAs. Here we present a preliminary feasibility study of the fabrication of Poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) microelectrodes on extremely low-cost, parchment paper, through ink-jet printing. To this aim, alkyd resin (AR) was used to improve the superficial proprieties of pristine cellulose paper. The rheological behaviour of ink formulations and the optimal printing parameters have been investigated, and preliminary tests showed resistivity values below those of current commercial gold MEA, in agreement with previous studies on PEDOT:PSS printed electrodes. Our results suggest that AR-treated cellulose paper could be employed to produce low-cost, flexible, and low-environmental impact devices, thus representing an interesting alternative in the field of cellular electrophysiology.**

***Keywords*—MEA, inkjet, PEDOT:PSS, paper.**

I. Introduction

MICROELECTRODE arrays (MEAs) are typically used to record the activity of electrogenic cells (e.g., neurons and cardiac cells) and their use ranges from the implantation in living organisms for *in vivo* studies, to the coupling with cells and tissues *in vitro*, allowing a large variety of applications, from the study of cell mechanisms to the study of pharmacological toxicity [1].

The structure of these devices consists of a two-dimensional spatial array of metal electrodes, with sizes in the range of 10 to 100 µm, that are fabricated relying on expensive materials (e.g., noble metals for electrodes), on the use of chemical compounds that may be harmful to the environment, and on high maintenance facilities and instrumentation (such as microfabrication setups in clean rooms). *In vitro* MEAs, for example, typically have a (rigid) glass substrate over which is built an integrated array of photoetched microelectrodes, each one insulated from the other, and composed of (or coated with) conductive materials such as indium-tin oxide, palladium, platinum, or gold. Thus, MEA systems represent costly pieces of equipment for a lab and, in the effort of reducing the expense of employing such technology, researchers typically reuse the devices as much as possible, which results in their inevitable wear and in the degradation of the quality of the recordings, especially in biological applications [2]. Nonetheless, this approach can also increase the risk of cross-contamination between samples, when there is no guarantee of full sterilization of the devices after their use. A solution could be to use disposable MEAs, which should be low-cost, and, possibly biodegradable. This approach would have the additional social benefit of making this technology more accessible.

Adopting flexible substrates instead of standard rigid ones is a widely studied option to stabilize contact impedance, which is affected by the mechanical mismatch between the device and cells [3, 4], and in literature many examples of soft electronics devices make use of plastics such as polyimide (PI) [2, 5] and polyethylene naphthalate (PEN) [6-8]. Biodegradable materials, which are attractive for their capacity to dissolve in a controlled manner when in contact with living organisms (e.g., bacteria and fungi) [9], can also be employed for this task: silk fibroin (SF), chitosan, and cellulose (like commercial cellulose fiber paper or the more sophisticated cellulose nanofiber paper [10]), are some examples. Indeed, although paper has already been used as a substrate for printed electronic devices [11], its use in the bioelectronics field is limited. Using a buffer layer on top of paper is usually required to smoothen its surface and, consequentially, render it suitable for the deposition of adequately conductive structures. For example, alkyd resin (AR), which is a biodegradable transparent resin, commonly employed as a binder in paints and coatings, can be used to impregnate cellulose paper to make its surface smoother and increase its optical transmittance [12], which could favour the use of inverted microscopy setups for optical cell analysis.

Biodegradable and biocompatible conductive polymers, such as PEDOT:PSS, which is a mixture of poly(3,4-ethylenedioxythiophene) (PEDOT) and polystyrene sulfonate (PSS), can be patterned on flexible substrates to build high-conductivity microelectrodes via ink-jet printing, a versatile, noncontact, mask-free, and low-cost technology, characterized by a reduced waste of materials and scaling potential benefits [13]. Furthermore, the addition of ethylene glycol (EG) increases the conductivity of PEDOT:PSS layers, by means of electron-phonon decoupling [14], and reduces the occurrence of nozzle clogging, thanks to its high boiling point (197 °C) and to the reduction of solid content in the final solution. Moreover, ink-jet printing allows high-resolution pattering and has shown to be suitable as a fabrication method for MEAs [2].

Here we present a preliminary feasibility study of the fabrication of MEAs on cellulose paper by means of ink-jet printing. We developed and optimized a substrate preparation process, evaluated the effect of ethylene glycol (EG) addition to waterborne PEDOT:PSS dispersions on their rheological

and conductive characteristics, and optimized the ink-jet printing process.

II. Materials and Methods

All printing substrates were obtained from flexible, biodegradable, and compostable sheets of commercial parchment paper, whose thickness was estimated to be around 100 µm. To improve the characteristics of the paper substrates (i.e., wettability, roughness, and optical transmittance), two different methods have been explored: application of a fast-drying, low viscous, long oil AR (Kremer Pigmente); coating of the paper with a layer of Parylene C through chemical vapor deposition (CVD) with a Labcoater 2 SCS PDS 2010 (Specialty Coating Systems).

To increase the surface free energy of the substrates and, therefore, optimize the printing process, two different methods have been explored: oxygen plasma (Colibrì, Gambetti) and UV ozone treatments.

The conductive structures were deposited using a drop-on-demand ink-jet printer (DMP 2850, Fujifilm) under ambient conditions (Fig. 1).

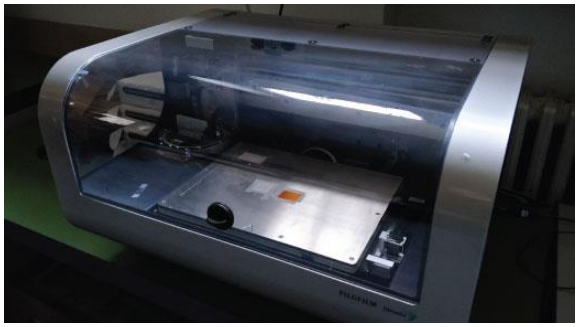

Fig. 1: The DMP 2850 ink-jet printer setup. Samples are loaded onto the printer plate that can be heated up to 60°C.

Starting from a commercial waterborne dispersion of PEDOT:PSS (Heraeus Clevios™ P Jet HC V2), various dilutions with ethylene glycol (EG) have been tested to find a formulation of rheological characteristics compatible with those of the ink-jet printer cartridge (Samba, 2.4 pL drop volume). The solutions were stirred for 30 minutes and filtered (0.20 µm average pore size, Sartorius GmbH) prior to their injection into the cartridge liquid reservoir for printing. The viscosity and shear stress of the inks has been measured using the MCR301 rheometer. The optimal printing parameters (printing height, waveform, drop spacing, and hot plate temperature) have been found after numerous trials and tuning by inspecting the printed test structures with both an upright microscope (Olympus BX-51) equipped with 4x and 10x objectives and the printer camera (for dimensional quantification), and by measuring their resistance with a multimeter.

III. Results

A. *Substrate preparation process*

The cellulose paper substrates where prepared following two different methods: bathing and spin coating. In the first method, the substrates were dipped in an alkyd resin (AR) solution (with varying solid content, by addition of acetone) for 30 minutes and air-dried under a fume hood for two days, resulting in smoother, mechanically resistant, and more transparent samples (Fig. 2). Higher solid content solutions gave thicker and smoother substrates, probably due to their slower drying times. For this reason, the pristine 65% solid content solution has been chosen.

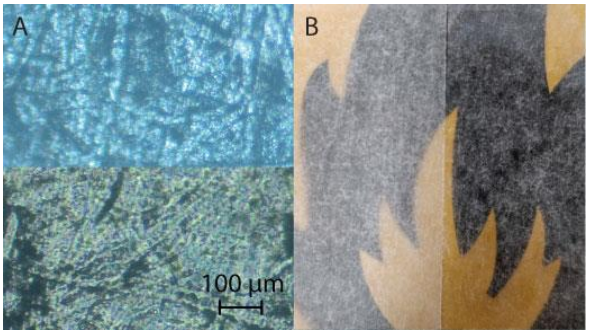

Fig. 2: Pristine vs. AR-treated cellulose paper. A) Optical microscope image of the untreated (top) and AR-treated (bottom) cellulose paper. B) Side-by-side picture of pristine (left) and AR-treated (right) substrates: the application of AR increases the optical transmittance of paper as can be qualitatively assessed by visual inspection.

Instead, the optimal spin coating parameters for 6x6 cm^2 sheets, have been evaluated by optical inspection and are 300 rpm for 60 seconds spinning after the deposition by pipette of 2 mL AR solution. Although this method requires a two-step drying process to coat both sides of the substrates, it gives thinner and more uniform layers in the macroscale.

B. *Rheological study of ink conductive formulations*

The optimal conductive ink formulation has been selected after the rheological characterization of various PEDOT:PSS and EG solutions. The viscosity and shear stress of the inks have been measured up to 2000 1/s shear rate both at 23°C and 50°C, which are the bounds of the range of operation of the printer cartridge. Adding EG to the pristine PEDOT:PSS dispersion, obtaining a 0.33 wt% EG solution (1/3 EG), gives a fluid compatible with the requirement of being in the 4 to 8 mPa·s range of viscosities (Fig. 3).

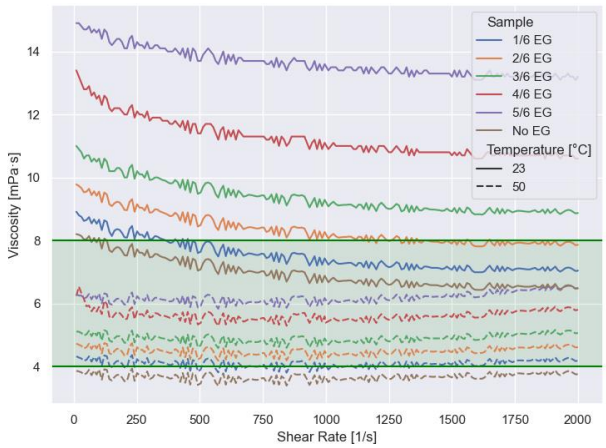

Fig. 3: Rheological behaviour of the pristine PEDOT:PSS dispersion and of different ink formulations, from 1/6 to 5/6 of EG content in weight.

C. *Optimization of the ink-jet printing process*

Being ARs highly hydrophobic, it was necessary to increase the surface free energy of the treated substrates, and, therefore, optimize the printing process. The effect of these methods has been assessed by inspecting the printed patterns with the microscope.

The use of Plasma O_2 on AR substrates at 100 W for 1-minute gives appropriate printing resolutions (around 50 µm) and continuity of structures (Fig. 4).

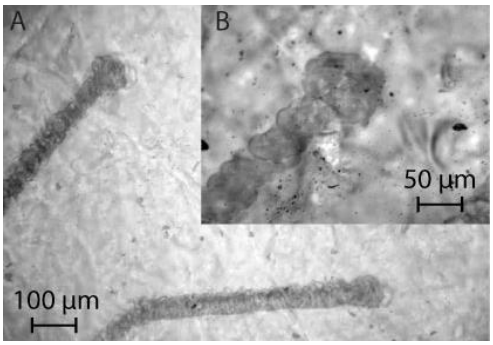

Fig. 4: Optical microscope images of PEDOT:PSS electrodes printed on cellulose paper treated with AR after oxygen plasma activation. A) Two microelectrodes. B) Zoom-in picture of one microelectrode.

A set of printing parameters (drop-spacing, printing height, plate temperature, and waveform) has been selected from previous studies and after numerous tests, by measure of achieved resolution, uniformity of layers, fidelity with the designed geometries, and conductivity of printed structures.

The resistance of printed test structures (20 µm drop-spacing) on paper treated with AR have shown values comparable with those reported in literature for PEDOT:PSS ink-jet printed electrodes, namely an average of 50.45 kΩ (7 printed layers, N = 4) for a 1.6 cm conductor line of 100 µm to 50 µm of width (Fig. 5), which is below the value observed on commercial gold-electrodes MEAs (160 kΩ) [2].

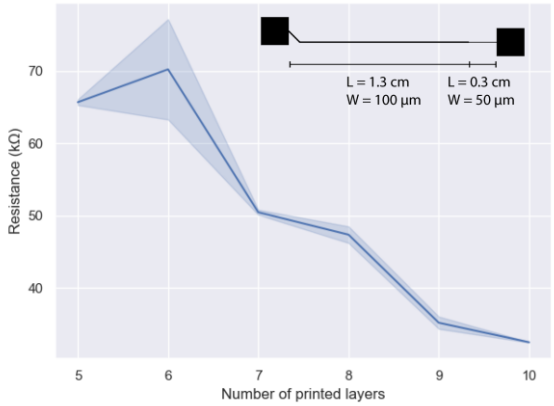

Fig. 5: Measured resistance of PEDOT:PSS lines vs. number of printed layers on AR-treated paper with the 1/3 EG ink. On the upper right the printed design geometry, which mimics the microelectrode dimensional features of MEAs.

IV. Conclusions

In this work we demonstrate the feasibility of fabricating PEDOT:PSS microelectrodes on paper-based substrates, as a starting point for the development of low-cost, disposable, and biodegradable MEAs for electrophysiological applications.

PEDOT:PSS has been selected as the only conductive element for its greater mechanical flexibility and optical transmittance, in comparison with metallic conductors, which are more brittle, and show larger mechanical mismatch with biological matter [4].

Although the effect of AR on the optical and mechanical proprieties of cellulose paper has already been demonstrated in literature [12], quantitative studies must be carried out to prove its effect on thicker sheets (as those used in this work).

Moreover, a passivation layer is required to electrically insulate the electrodes in the final device. A biodegradable option we are considering is chitosan, which has been demonstrated to be a good alternative for green dielectric films and is ink-jet printable [15, 16]. A non-biodegradable alterative is SU-8, which has already been shown to be suitable for MEA fabrication [2].

Although each individual component of the design is reported as biocompatible in literature [17, 18], work is in progress to confirm the compatibility of these multi-layered biodegradable structures with cell growth.

***Abstract*— A key challenge in neuroscience is understanding how a neural network's structure affects its activity. A simple and controllable environment like the in vitro neural network remains a powerful tool for studying physiological and pathological behaviors. Thanks to innovative printing techniques, the control of the biopolymer deposition are improved. Inkjet printing has gained much attention among patterning techniques because of its high resolution and direct-write approach, which enables the production of patterned substrates. Controlled deposition of an adhesion factor on the surface of the microelectrode array (MEA) makes it possible to guide the development of a neuronal network on a substrate that can record its activity, allowing the geometry of the network to be related to its activity. However, the inks commonly used can guide only the structure of a neural network, neglecting the functionality part. In this work, we synthesize a photosensitive ink that can be printed with a commercial inkjet printer, where thanks to its photothermal properties, we can modulate the neural activity. The photosensitive pattern printed on the MEA substrate allows a device to control the neural network geometry, record and modulate its activity. This work aims to provide an easy, versatile, fast and low-cost tool for studying the recurring relationship between the structure and function of neuronal networks.**

***Keywords*— neural network micropattering, inkjet printing, chitosan, gold nanorods.**

I. Introduction

In the past few decades, MEAs have been effectively used to investigate the correlation between the functional activity of neural networks and their structural organization thanks to their versatility and large recording area [1,2]. Different fabrication methods are possible to obtain engineered networks, involving physical and/or chemical approaches to guide cell adhesion and growth [3,4]. Among all the technological developments, inkjet printing has gained much attention thanks to its low cost, scalability, non-invasiveness, and versatility properties, which allow the localized deposition of ink micro-droplets without contacting the printing substrate [5]. We recently demonstrated that the cationic polysaccharide chitosan could efficiently promote cell adhesion and neural network maturation [6,7]. Furthermore, we have demonstrated how it is possible to control its deposition to direct the geometry of a neural network [8]. However, to better understand the relationship between structure and function of a neural network, the control of the neural activity and the control of the neural network geometry are both important [9–11]. MEAs can stimulate the neuronal network, but the electrical stimulation leads to membrane depolarization and, thus, excitation of activity. At the same time, it has been shown how neuronal activity can be inhibited using the thermoplasmonic effect of gold nanorods (GNRs) [12–15]. In this work, we combined the plasmonic properties of GNRs with the bioactive and rheological of the chitosan to realize a photosensitive ink that can be printed using a commercial inkjet printer to realized a photosensitive pattern. The patterned substrate helps control both the structure and the activity of a neural network giving a useful tools to study the recurrent relationship between its structure and function.

II. Methods

A. Photosensitive ink synthesis and characterization

We synthesized GNRs using a seed-mediated method [16]. Briefly, we prepare the seed solution by mixing 3 mL of 0.2 M Cetyltrimethylammonium bromide (CTAB, Sigma), 3 mL of 5 mL of 0.5 mM HAuCl4 (Sigma), and 300 µL of 0.01 M NaBH4 (Sigma) in an ultrasonic bath, which was let aged for 2h. To grow into a rod shape, 12 uL of seed were mixed with 5 mL of 0.2 M CTAB, 5 mL of 1 mM HAuCl4, 250 µL of 4 mM AgNO3, and 70 µL of 78.84 mM ascorbic acid. The GNRs were centrifuged to obtain the pellet and resuspended in ultrapure water. After dissolving chitosan powder into a 1 M acetic acid solution, we uniformly resuspend GNRs inside. We evaluated the ink optical properties performing a UV-vis analysis.

B. Micropattern printing and characterization

Printing was carried out using a drop-on-demand (DOD) piezoelectric printer (Dimatix Materials Printer 2800 - DMP 2800m,Fujifilm, Santa Clara, CA), equipped with a 16 nozzle and 10 pL cartridge (DMCLCP-11610). The grid pattern, designed using the printer software, was printed on the MEA active area, and the photosensitive substrate obtained was characterized to evaluate its plasmonic properties. A fiber-optic laser (785 nm, 450 mW, B&W Tek, USA) was used to stimulate the patterned MEA, and the laser beam created an illumination area 5 mm in diameter on the MEA chip. An infrared thermographic camera (TG165-X, FLIR, USA) was used to measure the temperature change during near-infrared (NIR) irradiation (3 minutes at a time), and the samples were cooled to room temperature (RT) before the next measurement.

C. *Immunostaining*

On the top of the patterned device we seeded neuronal cells obtained differentiating human-derived induced pluripotent stem cells (h-iPSCs). After labelling the neuronal dendrites with Microtubule Associated Protein 2 (MAP-2) and the nuclei with 4′,6-diamidino-2-phenylindole (DAPI), we acquired the image using a fluorescent microscope.

D. *Neural activity recording, stimulation and analysis*

The neural activity was recorded at 35 days *in vitro* (DIV) using a standard MEA1060 system (MEA 1060-Inv-Standard amplifier, Multichannel Systems, Germany). Collected data inkjetwere processed using MATLAB (Mathworks) and the Spycode toolset [51]. A fiber-optic laser (785 nm, 450 mW, B&W Tek) was used as the light source for the photothermal stimulation, and the laser beam from the bottom generated an illumination area on the MEA chip that was 5 mm in diameter. The stimulation protocol consists of 20 cycles, with each cycle having the laser on for 10 seconds before switching off for 20 seconds. Recording channels whose mean firing rate (MFR) was higher than 0.1 spikes/sec were selected as active channels and used for neural activity analysis. We define MFR(ON) as the average firing rate when the laser is on, while MFR(OFF) corresponds to the average firing rate calculated 10 seconds before the laser stimulation. The following formula was used to calculate the inhibition percentage (IP):

$$IP\ [\%] = [1 - MFR(ON) / MFR(OFF)] * 100 \qquad (1)$$

III. Results

Figure 1a shows the spectrum of the photosensitive ink, where the two peaks characteristic of gold nanorods can be seen, concluding that the nanoparticles are uniformly dispersed and not aggregated. The synthesized ink was printed with grid geometry on an MEA, as shown in Figure 1b. The thickness of the lines is about 50 um, which is comparable to the size of microelectrodes, resulting in excellent control over the geometry concerning the resolution possible for activity recording.

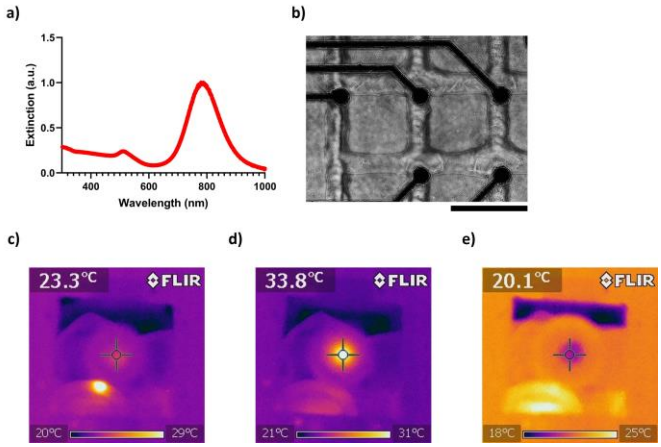

Figure 1: Photosensitive ink synthesis and characterization. a) Spectrum of the photosensitive ink. b) Contrast phase image of the grid pattern printed on the MEA substrate (scalebar: 200 µm). c) Thermal image of the patterned substrate realized using the control ink acquired during a laser stimulation with 450 mW. d) Thermal image of the patterned substrate realized using the test ink acquired during a laser stimulation with 450 mW. e) Thermal image of the patterned substrate realized using the test ink acquired during a laser stimulation with 0 mW.

To evaluate the photothermal properties of the patterned substrate, we stimulated it with a NIR infrared light and measured the temperature change on the surface of 1 mL of medium using a thermal imaging camera. In fact, thanks to the plasmonic properties conferred by GNRs, the ink can convert NIR light into heat, through which neuronal activity can be modulated [12,13,15]. Figure 1c shows the temperature change measured in a control sample (ink without GNRs) stimulated for 3 minutes with a power of 450 mW, while Figure 1d shows the test sample (ink with GNRs) stimulated under the same conditions. In the test sample, it can be seen that NIR stimulation leads to a temperature increase of about 10 degrees compared to the control sample (figure 1c), which remains close to the sample not stimulated (figure 1e). An increase in temperature close to 10 degrees is thought to be sufficient to inhibit the activity of an in vitro neural network [12,15]. After demonstrating the properties of the patterned substrate, we seeded neurons obtained by differentiating human stem cells on top of it. Figure 2a shows how the neuronal culture grows following the geometry indicated by the patterned substrate. In addition, Figure 2b shows the average waveform recorded by a microelectrode, demonstrating that the activity recording is not precluded by the pattern printed on the microelectrode array.

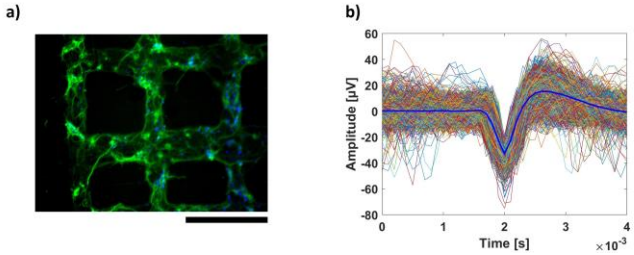

Figure 2: Neural network structure and activity recording. a) fluorescence image of a neuronal network growing onto a grid micropattern (green: MAP2, blue: DAPI, scalebar: 200 µm). b) set of waveforms with the average one (blue) recorded in an MEA's microelectrode.

Finally, we have shown that we can modulate the activity of a neuronal network by photothermal effect. Figure 3a shows the raw data where the stimulation protocol was performed with 0 mW power, from which we can conclude that the activity does not change its frequency when the sample is stimulated with zero power. In contrast, the activity is inhibited with a power of 450 mW. However, as shown in the figure, the inhibition is perfect within the 10 seconds of the stimulation, providing high temporal control over the activity modulation. Currently, the spatial resolution of stimulation is potentially that of the drop (diameter of 50 µm). In addition, the intensity of the inhibitory phenomenon can be controlled by changing the power of the laser used to stimulate the sample (figure 3c).

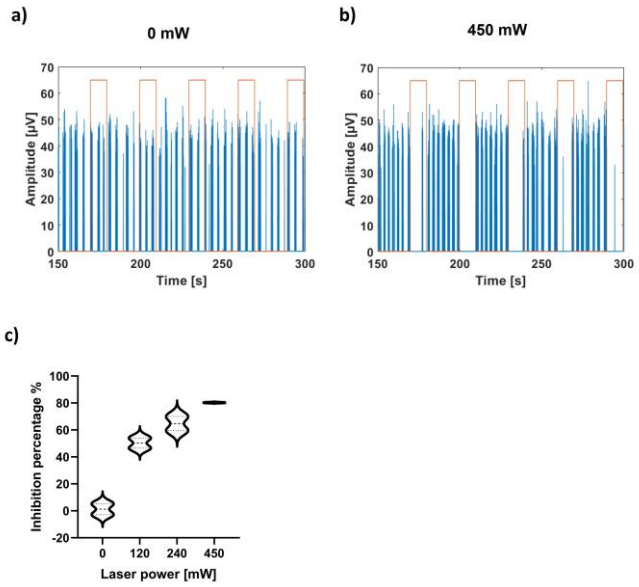

Figure 3: Photothermal modulation of the micropatterned neural network activity. a) raw neural network data grew on a photosensitive micropattern during laser stimulation with 0 mW (laser stimulation time: 10 s on and 20 s off, orange plot). b) raw neural network data grew on a photosensitive micropattern during laser stimulation with 450 mW (laser stimulation time: 10 s on and 20 s off, orange plot). c) inhibition percentage average at different laser power.

IV. DISCUSSION

The ink can be printed with a resolution comparable to the size of a microelectrode of MEA to obtain specific patterns and has both bioadhesive properties given by chitosan, which are necessary for cell anchoring and guided development of the neuronal network in the desired geometry, both those plasmonic given by GNRs, for the modulation of neuronal activity. Furthermore, it is also possible to independently stimulate different areas of the network, depositing the ink with GNRs in some areas and the ink without GNRs in others, which can be stimulated electrically using the MEA electrodes. This technology, therefore, provides a simplified system for studying a complex topic, such as the study of the recurrent relationship between the structure and function of a neuronal network. However, although a two-dimensional cell culture provides a simplified environment for studying such a complex subject, this is also a limitation of the system, which can hardly imitate the environment in vivo. For this reason, the next step would be to develop this system in three-dimensional cell cultures.

V. CONCLUSION

In this work, we have synthesized a photosensitive ink useful to realize patterns with a resolution comparable to an MEA's microelectrode. Due to its bioactive and plasmonic properties, it is possible to control a neuronal network's geometry and activity. By printing the pattern on the active area of a microelectrode array, it is possible to obtain a completed device that can control the geometry of a neuronal network, record its activity, and modulate it by thermoplasmonic effect. The photosensitive, patterned substrate MEA is helpful for the in vitro study of the recurrent relationship between structure and function of a neuronal network, providing a tool for studying neural communication and associated disorders.

***Abstract*—The present work aims to assess the exposure of young people due to two 5G wearable devices. The two antennas are posed on the trunk of the male and female teenager virtual models, in order to simulate typical scenarios in which the wearable devices are used. For the exposure assessment, the extracted parameters have been the Specific Absorption Rate averaged over 10 grams of tissue and the Absorbed Power Density averaged over a square of 4-cm^2 over the skin, depending on the frequency of the EMF emitted by the antenna, with an input power of 100 mW. The results showed no overcome of limit values set by international regulation in any of the cases when the input power is set as realistic values. Moreover, evident differences between the male and female model were observed in both studied cases.**

***Keywords*— RF human exposure assessment, wearable antennas, 5G, young people.**

I. Introduction

In recent years, we are witnessing the spread of new radiofrequency technologies, not only in terms of the common smartphone, but also involving new devices: the wearable devices. Examples of wearable devices commonly adopted are the smartwatches, the cameras mounted on the head and so on. The diffusion of the wearable technologies is evidentially growing and the age category purchasing and using more of them is the young people, for instance, in Germany in 2022 the 46% of the teenagers (12-19 years) has at least one wearable device at home [1].

It's important to discern "mobile" devices from "wearable" devices; the substantial difference is the fact that the mobile devices are designed for having many functionalities and not for being comfortable; conversely, in the word "wearable" there are many characteristics, such as the comfort, the integration in the garment and the continuous monitoring of the user's activities [2].

Furthermore, the characteristic that led to such a widespread diffusion of this technology is the versatility; indeed, the wearable device finds application in many fields: wireless communication, military environment, and medical monitoring [3, 4].

From the purely technologic point of view, a wearable device is the primary block of a larger network called Body-Area-Network (BAN), in which there are many sensors, each one able to detect a specific parameter (e.g., heart rate, respiration rate) and to transmit these data to the principal node of the network that has the aim to exchange information with an external device (e.g., smartphone) [5]. The IEEE 802.15.6 standard [6] gives a detailed characterization of the Wireless-BAN, a subgroup of the BANs, where the communication protocol is precisely defined. The typical bandwidth used so far for the wearable communication is called Industrial-Scientific-Medical (ISM) band where the central frequency is 2.45 GHz [7]. Nowadays, the requested functionalities for these devices are more and more and the amount of data requested to exchange is growing. In this perspective, the 5G technology is the option that may answer to this issue, therefore there are many studies regarding the design of 5G wearable antennas, involving their first two bands: the sub-6GHz band and the mm-wave band (>24GHz) [8].

Since by definition each wearable device must be worn by the user, the distance between the human tissues and the electromagnetic field (EMF) source is minimal. Therefore, the question about the quantitative assessment of the power absorption due to the wearable devices by biological tissues becomes crucial [9].

Thus, this work aims to address the question about the exposure assessment due to wearable devices, in particular wearable antennas working the 5G emerging frequencies considering the diffusion of the Internet-of-Things. More in detail, the simulated exposure regarded the use of two different antennas, each one tuned in a 5G typical band. Moreover, the assessment has been performed considering virtual models of young human, to assess the EMF exposure in a scenario as realistic as possible, also according to the statistics.

II. Materials and Methods

In order to study the exposure in realistic situations, two main scenarios have been simulated: in both of them the patch antennas have been posed on the trunk of the human model, at the height of the center of the model's heart, 2 mm apart from the trunk' skin. More in detail, for the study the young female and male models of the Virtual Population [10] have been deployed, Billie (age = 11 yo., height = 1.49 m, weight = 34 kg, BMI = 15.3 kg/m^2) and Louis (age = 14 yo., height = 1.68 m, weight = 49.7 kg, BMI = 17.6 kg/m^2) respectively.

From the point of view of the source, the antennas have been designed as simplified as possible in order to simulate an overall situation. They are wearable patch antennas, designed for off-body communication. More in detail, they are single-patch structure with a three-layered body: the patch layer and the ground plane are made of copper ($\sigma = 5.813\text{x}10^7$ S/m, $\varepsilon_r = 1$) and the substrate layer is made of polyester ($\sigma = 4.6785\text{x}10^{-8}$ S/m, $\varepsilon_r = 2.2$), a common material used for this application.

The first antenna is tuned in the lowest 5G band, the sub-6GHz band, with a central frequency of 3.5 GHz. The geometrical characteristics and the radiation performances are

reported in Fig.1.

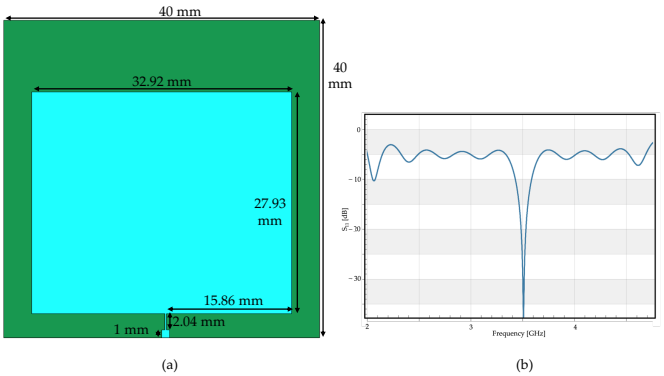

Fig. 1: First wearable patch antenna simulated, tuned to f = 3.5 GHz: (a) geometry of the antenna, front view; (b) performances of the antenna in terms of the reflection coefficient (S11).

In the second wearable antenna (Fig.2) the materials and the widths of each layer are the same for the first antenna; the main difference is the size of the patch, whose dimensions change the radiation pattern and the central frequency of the tuning. Indeed, the second antenna is tuned in the >24GHz-band, at frequency set as 26.5 GHz.

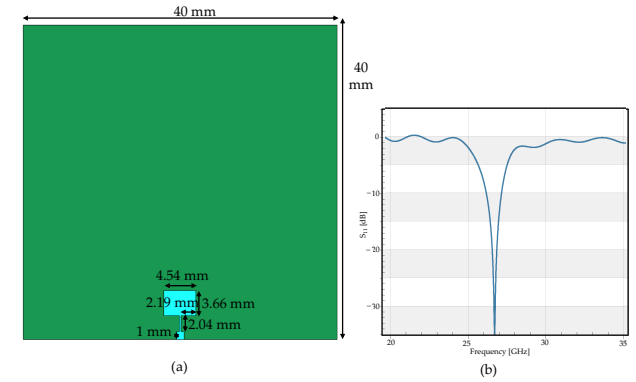

Fig. 2: Second wearable patch antenna simulated, tuned to f = 26.5 GHz: (a) geometry of the antenna, front view; (b) performances of the antenna in terms of the reflection coefficient (S11).

The computational exposure assessment has been carried out solving the Maxwell's equations by the Finite-Difference Time-Domain (FDTD) method implemented in the commercial simulation software Sim4Life v.6.2 (ZMT Zurich Med Tech AG, Zurich, Switzerland, www.zurichmedtech.com, accessed on 15 January 2023). More in detail, the boundary conditions have been set as Perfect Matched Layer (PML) and the mesh size ranges from 0.005 mm up to 1 mm. Finally, the dielectric properties of each human tissue have been chosen according to the literature [11-13] and the frequency of the antenna.

Finally, the parameters of interest extracted for the assessment have been the Specific Absorption Rate averaged over 10 grams of tissue (SAR_{10g}) and the Absorbed Power Density (S_{ab}) averaged over a square 4 cm^2 surface over the skin. According to the International ICNIRP Guidelines [14], the SAR_{10g} is the parameter to assess the exposure for the antenna tuned in 3.5 GHz because it is below the threshold of 6 GHz, whereas the S_{ab} is the parameter devoted to the exposure assessment due to frequencies greater than 6 GHz up to 300 GHz. Moreover, all the values have been extracted from a box with size of 250 x 250 x 250 mm; the study focused on the peak values of the parameters and the percentages of the values that are greater than the 70% of the peak value in order to better know the distributions of the data around the peak. Finally, the peak values have been compared with the ICNIRP Guidelines limits for the general public; the values here reported have been obtained with an input power to the antenna of 100 mW, a realistic power for the common use of the wearable devices.

III. Results and Discussion

In this section the results obtained in the study will be presented and discussed. More in detail, Table I shows the peak values of the SAR_{10g} obtained in the first simulated scenarios i.e., where the antenna emitting at 3.5 GHz is posed on the chest of Louis and Billie.

TABLE I: Peak SAR10g and percentages of S_{AB} values greater than 70% of the peak SAR10g for each configuration

Human Model	*Peak SAR_{10g} [W/m^2]*	*Values greater than 70% of the peak SAR_{10g} [%]*
Louis	0.12	0.78
Billie	0.16	0.72

The comparison between the obtained results and the general public limit in the ICNIRP Guidelines i.e., 2 W/kg, did not show the overcome of it and the values of the reported percentages mean that most of the data are not concentrated around the peak SAR_{10g} so most of the data are lower than the showed peaks, in both scenarios.

Furthermore, emphasizing the anatomical gender comparison, it is clear that the variation between the male and female model implies noticeable differences, considering that the peak SAR_{10g} in Louis is 76.4% of the Billie's peak SAR_{10g}.

Then, Table II shows the extracted results of S_{ab} in scenarios with the wearable antenna tuned to 26.5 GHz.

TABLE II: Peak S_{AB} and percentages of S_{AB} values greater than 70% of the peak S_{AB} for each configuration

Human Model	*Peak S_{ab} [W/m^2]*	*Values greater than 70% of the peak S_{ab} [%]*
Louis	6.67	0.27
Billie	3.35	0.18

Comparing the obtained peak values of S_{ab} with the respective ICNIRP Guidelines limit i.e., 20 W/m^2, it is noteworthy that both results do not exceed the international limit. Moreover, it must be considered that the values here reported have been obtained with a realistic input power, so these results correspond to an actual use of the wearable device.

Additionally, in these second scenarios, the difference depending on the anatomical gender is more evident than the first scenarios; indeed, here the peak S_{ab} of Billie is 50.2% of the peak S_{ab} in Louis. A possible explanation is the fact that the male model has a thinner layer of the skin instead of the female model and the S_{ab}, by definition, is averaged over the skin.

IV. Conclusions

The presented study is an attempt to assess the exposure due to 5G wearable antennas that are now spreading in the everyday life, also in the teenagers. Here, two different teenager human models have been simulated with two different antennas placed on the same position with respect to the model. Comparing the obtained results by gender, the most evident difference is in the case with the antenna tuned to 26.5 GHz; nevertheless, it is important to state that in the scenarios with the antenna at the lowest frequency the SAR_{10g} detected in the female male is higher than the one from the male model.

Overall, all the obtained values have been compared with the ICNIRP Guidelines and, when the peakx values are calculated according to a realistic value of input power, there is no overcome in any of the cases studied.

***Abstract*—The development of reliable *in vitro* models is particularly important to understand the basic physiology of the neuronal system, to study the insurgence of diseases and to test potential therapies. One of the main challenges is to develop a model that allows extracting realistic and easy-to-interpret information without forsaking some key aspects (e.g., modularity, heterogeneity, three-dimensionality, mechanical properties) of the complex organization of *in vivo* tissues. In the present work, we present the results we obtained by progressively integrating these essential features into *in vitro* models. We studied how information propagates in different neuronal types with particular topologies. Then, we investigated how modularity and heterogeneity interact in a cortico-hippocampal model, finding that micro-circuits emerge in this condition. This level of complexity of *in vitro* models already carries a different sensitivity to drugs with respect to the standard testbeds, as we demonstrated with bicuculline (BIC). Moving yet another step forward, we introduced the third dimension, finding a redistribution of the spiking and bursting activity. Then, we studied how to integrate the mechanical properties of the extracellular matrix by creating neurospheroids. Overall, these results demonstrate the improvements that could be achieved with modern *in vitro* models and aim at partly filling the ever-lasting need new more affordable, efficient, and cross-disciplinary *in vitro* models, therefore moving towards more ethical research.**

***Keywords*— *in vitro* brain models, micro-electrode arrays, modularity, heterogeneity, three-dimensionality.**

I. Introduction

THE human brain is composed of about 86 billion neurons which originate rich and intricate networks. Moreover, neurons are organized in well-defined spatial locations that define clusters of neurons or modules. From a morphological and physiological point of view, each module is composed of specific neurons that differ in shape and function. Examples of large-scale modules are the cortical or hippocampal regions. Each cognitive and motor function is possible thanks to the correct interaction between the different modules. The disruption, loss, or alteration of these connections can produce pathological conditions. To understand how the information is transmitted and computed, we need to investigate the communication among the different modules. Another essential feature to comprehend how the electrophysiological signals are transmitted is the three-dimensional (3D) spatial organization of such modules [1]. The 3D microenvironment is fundamental for the correct expression of the neuronal cell phenotypes and for the modulation of the electrophysiological activity patterns [2]. There are different approaches to investigating the transmission of the information: many studies use an *in vivo* approach but, in this case, it is very difficult to study a specific circuit. If the focus is understanding the effect of a specific module (e.g., of the hippocampal one on the activity of the cortical one), we are unable to isolate this specific system *in vivo* as we cannot severe the connections of the cortex with other brain districts. Thus, the cortical activity we observe is always influenced by all its inputs. In this perspective, *in vitro* engineered models could be a powerful tool. They reduce the complexity of the system, but at the same time they keep the key features of the *in vivo* environment of the brain, thus ensuring consistent results.

In the present work, we exploited polymeric masks coupled to Micro-Electrode Arrays (MEAs) to investigate the role of the key features of the human brain (modularity, heterogeneity and three-dimensionality) in the electrophysiological activity of *in vitro* neuronal networks. Studying the cortical-hippocampal circuit, we observed a more scattered signal propagation when the hippocampal population was present. We explained such behaviour by investigating the functional connectivity: in the cortical-hippocampal configuration, a higher segregation was observed. Moreover, the inhibitory hippocampal connections strongly modulated the cortical activity. The differences observed in the heterogenous networks arose a new question: how does the complexity of the *in vitro* models influence the effects of drugs? We investigated the effects induced by bicuculline (BIC) and our results suggested that oversimplified *in vitro* models could lead to under- or overestimate its effects. Finally, we introduced the third feature, three-dimensionality, recreating a wider pattern of activity with respect bidimensional networks. In perspective, we moved one more step towards recreating the mechanical properties of the extracellular matrix by building cortical and hippocampal spheroids, which are able to better reproduce the intrinsic characteristics of the native tissues, and which can be combined to create different interacting neuronal modules (building blocks). This new model can be exploited as platform for precision medicine.

II. Materials and Methods

A. Cell preparation and PDMS mask

We used two polymeric devices to recreate modular heterogeneous cultures [3], [4]. The dimensions of the device are reported in Table I. To recreate a biocompatible scaffold where neuronal networks can grow in a 3D fashion, we used pre-sterilized and pre-coated glass microbeads (Ø = 40 µm). About 4-6 layers were stacked, reaching a height of about 220 µm. The entire procedure is reported in [4].

TABLE I: Polymeric masks

	2-compartment mask	*3-compartment mask*
Compartments dimensions	4 mm x 2 mm	6.5 mm x 4.3 mm 3.4 mm x 3.4 mm
Microchannels dimensions (w x l x h)	10 µm x 250 µm x 5 µm	
Microchannels spacing	50 µm	

B. Electrophysiological characterization

We investigated both the homogenous (only cortical or hippocampal neurons were plated in each compartment) and heterogenous (cortical-hippocampal) cultures at 18 days *in vitro* (DIV). We detected the occurrence of spike events employing the Precision Spike Detection (PTSD) algorithm [5]. From the spike train, the burst identification was performed by applying the string method devised in [6]. The identification of the choral activity (network burst) was performed by means of the self-adaptive algorithm devised in [7]. Spiking and bursting activity were evaluated in terms of Mean Firing Rate (MFR) and Mean Bursting Rate (MBR). To derive the neuronal recruitment mechanisms of the network, we computed the average Spike Time Histogram (STH), and we extracted the slope of the rising and decaying phases [8], [9]. To investigate the signal propagation among the compartments, we delivered electrical biphasic stimuli (positive phase first) with a duration of 400 µs, 50% duty cycle, 0.2 Hz and an amplitude of 1.5 V peak-to-peak. We extracted information about the stimulus-evoked activity by computing the Post-Stimulus Time Histogram (PSTH) and investigating the early and late responses [10]. To discern the excitatory and inhibitory functional connectivity, we adopted the Total Spiking Probability Edges (TSPE) algorithm [11]. Then, we discarded the noisy connections applying a hard threshold [3] and a spatial-temporal filter that guarantees a physiological propagation speed [12].We evaluated the effects of increasing concentration of bicuculline (BIC) on the spontaneous activity in terms of IC_{50} value. It was computed for each condition by fitting normalized MFR values (with respect the basal value) with the Hill Function [13].

III. Results

A. Spontaneous and evoked activity of modular homogeneous cultures

Firstly, we evaluated the spontaneous electrophysiological activity of modular networks made up of two different neuronal populations, namely a cortical and a hippocampal one, to characterize their intrinsic parameters and highlight their differences. The homogeneous cortical (Cx) and hippocampal (Hp) modular cultures were created by means of the polymeric mask described in Sect. II.A. Qualitatively, both cortical and hippocampal dynamics displayed both a random spiking activity and highly packed bursts (Fig. 1A, *first row*). Generally, the cortical populations displayed higher spiking activity with respect to the one of hippocampal networks, which on the other hand had very little variability. Moving on to the characterization of the bursting dynamics of the two populations, we observed that the increase in the firing did not induce a difference in the bursting rate. However, the different cell types of the two networks brought a change in the shape of the bursts, as they were significantly longer in the Cx case.

Then, we investigated the low-frequency response (0.2 Hz stimulation) of these two populations to investigate how the signal propagates within modular cortical and hippocampal populations. We compared the stimuli-evoked response of the cortical and hippocampal populations as a function of the location of the stimulation sites (i.e., stimulated assembly) by means of the PSTH (Fig. 1A, *second row*). This analysis was carried out by considering the different synaptic responses of the network, namely, the early phase-mediated AMPA receptors, lasting no more than 35 ms; and the late NMDA mediated, lasting hundreds of milliseconds. The two considered neuronal types display a very different response. The cortical assemblies are generally more reactive than the hippocampal ones to the delivery of low-frequency stimulation protocols, as we can qualitatively deduce from the PSTH areas (Fig. 1A, *second row*). Moreover, although both the cortical and hippocampal cultures exhibited a fast (< 35 ms) response, this did not propagate uniformly in the hippocampal networks. In addition, only cortical assemblies displayed a significant late (35–500 ms) response (second peak in the PSTH).

B. Spontaneous activity of modular heterogeneous cultures

The difference in the signal propagation in cortical and hippocampal cultures suggests a different organization of the two networks, which facilitates synaptic integration in the case of cortical ensembles. However, these intrinsically different populations are densely connected and therefore constantly in communication in the brain. Therefore, we investigated how the two different circuitries influence each other. This was achieved by creating a heterogeneous configuration (CxHp) by means of the same polymeric mask, which allowed the separation of the cell bodies but the communication between the two neuronal types by means of bundles of neurites. The simultaneous presence of two different neuronal modules shaped the functional connections (excitation vs. inhibition), orchestrating the emerging patterns of electrophysiological activity. Our main findings demonstrated that hippocampal neurons project strong inhibitory connections toward the cortical counterpart from both a functional and a structural point of view (Fig. 1B). The strong inhibitory afferences modulated the typical “population event” signature of dissociated neuronal cultures, i.e., the network bursts, by acting on their temporal scale. In contrast, cortical neurons established a larger amount of intrapopulation connections, suggesting the emergence of micro-circuits. Moreover, we

(**B**) Percentage of incoming inhibitory functional connections in modular homogeneous and modular heterogenous networks both in the cortical and hippocampal case. Representative stained glutamatergic (VGlut1, green) and GABAergic (VGAT, red) synaptic receptors used to quantify the morphological connections. (**C**) Drug administration protocol and relative IC_{50} value in modular homogeneous, modular heterogenous, and non-modular homogeneous networks both in the cortical and hippocampal case. (**D**) Modulation of the population events in 2D heterogeneous, 3D homogeneous and 3D heterogeneous networks evaluated by means of the Spike Time Histogram (STH) and decaying exponent, * refers to $0.01 < p < 0.05$ and ** to $0.001 < p < 0.01$, Kruskal-Wallis, non-parametric test.

proved topological properties such as small-worldness, degree distribution, and modularity of neuronal assemblies were favoured by the physical environment of this configuration [3].

C. Chemical modulation of the activity of modular heterogeneous cultures

We investigated whether the introduction of modularity and heterogeneity would determine different results (with respect to the conventional homogeneous models) when applying a chemical stimulation. In particular, we evaluated the effects of bicuculline (BIC), a competitive antagonist of $GABA_A$ receptors, on the firing activity of modular heterogeneous, modular homogeneous, and non-modular homogeneous networks. We computed a dose-response curve for each configuration, and then we extracted their IC_{50}value (Fig. 1C). IC_{50} values of the heterogeneous configuration were statistically lower than the ones of homogenous modular networks, both in the case of cortical and hippocampal assemblies. A statistical difference in terms of cortical IC_{50} emerged also among homogeneous non-modular and heterogeneous cortical configurations (which had the lowest values, indicating an anticipation of the effect). Instead, in the hippocampal case, another difference was highlighted by the addition of the modularity: modular IC_{50} resulted to be significantly higher than non-modular controls. These results showed clear differences between modular, homogeneous and heterogeneous cultures, suggesting that ignoring modularity and heterogeneity could lead to underestimate or overestimate the effect of a drug and therefore they should always be included in *in vitro* neuronal model adopted to perform pharmacological studies.

D. Increasing the realism of the in vitro model: 3D modular heterogeneous cultures

However more accurate a model that includes modularity and heterogeneity may be (cf., Sect. III.A and III.B), a key aspect of the *in vivo* microenvironment is still missing: three-dimensionality. By exploiting the same polymeric mask used in the previous sections, we created a simple 3D heterogeneous culture with glass microbeads as scaffold where neurons can organize their connectivity in 3D. Despite the differences in mechanical properties (porosity, Young' modulus, etc.) of this type of scaffold with respect to the *in vivo* extracellular matrix, the recreated 3D connectivity is nonetheless able to modulate the duration and the organization of the bursting activity of the entire network. The mere presence of three-dimensionality defined a redistribution of the spiking activity, less packed, and modulated the duration and the organization of the bursting activity, as suggested by the exemplary STH in Fig. 1D . On the other hand, the hippocampal inputs modulated the duration of the network bursts independently of the spatial organization of the cultures. When combined, these two features mainly act on the network bursting features: the activity rate is higher than the solely 3D control, but lower with respect to the 2D heterogeneous one, the coexistence of three-dimensionality and heterogeneity seems to drive the dynamics to an intermediate state.

E. 3D modular and heterogeneous cultures with realistic biomechanical properties

The previous 3D model, however, has a great limitation as it does not recreate the *in vivo*-like biomechanical properties of the extracellular matrix. To overcome this limit, we developed neurospheroids, i.e., neuronal 3D cultures obtained from primary cortical (Cx) and hippocampal (Hp) cells without any scaffold. Spheroids were realized by plating neurons in an ultra-low attachment 96-microwells (Life Technologies). The shape and the low adhesion properties of the wells induced the creation of a single neuronal spheroid per well of about 8'000 cells each (Fig. 2A). We evaluated the morphology of the Cx and Hp spheroids as a function of their maturation degree. During the development, Hp spheroids presented a faster volume growth than the Cx ones (Fig 2B). Indeed, Cx and Hp spheroids displayed a different growth curve from the DIV 1 (Fig. 2B), indicating a slower cellular aggregation in the cortical case. These results suggest a greater proliferation of hippocampal cells possibly supported by their phase, as they could still be in their mitotic state. Indeed, neurogenesis of hippocampal tissue is delayed during the development of neuronal system [14]. Overall, this 3D model is very powerful, and it could also be exploited to integrate modularity and heterogeneity by coupling spheroids of different neuronal types defining complex neuronal assembloids.

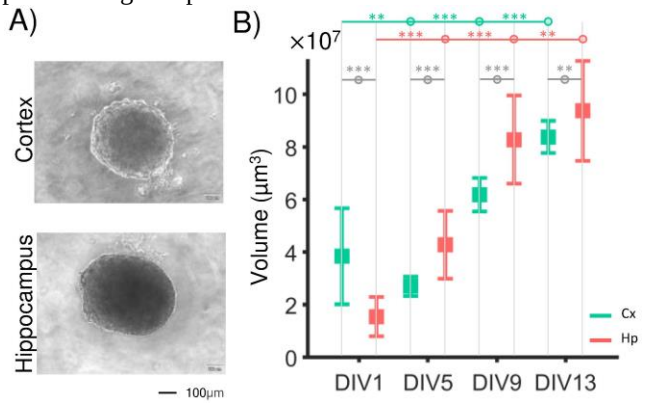

Fig. 2: Neurospheroids. (**A**) DIC microscopy image of a representative cortical and hippocampal spheroid. (**B**) Volume development of the cortical and hippocampal spheroids.

IV. Conclusion

In the present work, we showed that the engineering of *in vitro* neuronal networks allows the modulation of the spontaneous (Sect. III.A, B, and D) as well as the evoked electrophysiological activity (Sect. III.A, C). In particular, we proved the role of the three ingredients (modularity, three-dimensionality and heterogeneity) considering the case-study of cortical-hippocampal ensembles. Our results pointed out the relevance of the simultaneous presence of these features to achieve more realistic *in vivo*-like models of the brain. Considering these findings and exploiting the recent advances in the field of neuroengineering, in light of transferring stimulation protocols to *in vivo* applications, it becomes fundamental to design more and more realistic *in vitro* brain-on-a-chip models to investigate the dynamical properties of complex neuronal circuits. Neurospheroids are a step forward, as they combine many *in vivo* properties such as a realistic 3D connectivity and could be combined in a heterogeneous structure. As for future applications, they may be useful for therapeutics and diagnosis [15], to test and understand the different effects of nanoparticles and nanomedicines on the cells. The combination of these technologies will allow not only to perform a variety of tasks, such as drug delivery in a prolonged or targeted way, but also to identify the cells at the origin of a particular disease (such as cancer) to modulate their activity.

***Abstract*— In the present study a comparison of radiofrequency (RF) exposure levels on a pedestrian in the nearby of the vehicle specifically generated by two different vehicle-to-everything (V2X) communication technologies, i.e., the well-validated ITS-5.9 GHz and the more innovative 5G-V2X was performed. EMF exposure was calculated using a numerical dosimetry approach. Two different kinds of vehicular connectivity antennas have been considered, i.e., two quarter-wave monopoles (for ITS-5.9 GHz) and two 4x2 patch array antennas (for 5G-V2X) that were mounted on a 3D CAD model of a city car. Numerical dosimetry simulations have been performed using the software Sim4Life exploiting the FDTD method. The human model was positioned near the vehicle in different configurations and orientations. The comparison of exposure assessment generated by the two different technologies was performed by comparing the Specific Absorption Rate (SAR) values over 10 g of human tissues. The results show generally higher exposure levels when the ITS-5.9 GHz technology is applied, rather than the 5G-V2X.**

***Keywords*— RF human exposure assessment, C-V2X, 5G, ITS-5.9 GHz.**

I. Introduction

The automotive field is nowadays increasingly pushing toward the development of new wireless technologies and remote sensing in vehicular connectivity to prevent the safety of people on road. This leads to the new concept called "Intelligent Transport System" (ITS) [1][2]. In particular, the ITS is a multifaced concept that embedded many services, among which there is the possibility to connect vehicles with other entities, generating the so-called vehicle-to-everything communication (V2X), such as (i) other vehicles (vehicle-to-vehicle communication, V2V), (ii) pedestrians (vehicle-to-pedestrian communication, V2P), (iii) infrastructures (vehicle-to-infrastructure communication, V2I), and (iv) networks (vehicle-to-network communication, V2N) [3][4]. The V2X communication technology mainly relies on two wireless technologies: (i) the WiFi mobility based on the well-consolidated IEEE 802.11p protocol (or ITS-G5 in the European version) that works at the ITS-5.9 GHz band [5] and the recent technology of the Cellular-V2X (C-V2X) based on the 3G/4G and LTE band [6][7][8]. The C-V2X is also widening to the 5G New-radio (NR) wireless communication, in which the vehicular communication technologies will be open on the 5G world, generating the 5G-V2X technologies. The 5G-V2X technology will enable a very reliable and efficient low-latency communication and high data rate transmission, thanks to the use of two additional larger RF frequency ranges, namely frequency range 1 (FR1), from 410 kHz to 7.125 GHz, and frequency range 2 (FR2), from 24.25 to 52.6 GHz, in the millimeter waves spectrum [9][10].

Many of these vehicular innovations will be widespread in the next years and will strongly change the radio frequency electromagnetic fields (RF-EMF) exposure of people in a car and in the vicinity of a car, causing possible concerns among the road-users [11]. To the best of our knowledge, few articles exist on the investigation of the dose absorbed by the human body generated by these vehicular technologies [12]. To that purpose, Tognola et al. [13] investigated the in-vehicle dose absorbed by a passenger generated by V2V communication operating at 5.9 GHz and Benini et al., [14] and Bonato et al., [15] investigated the exposure of a pedestrian nearby a vehicle equipped with V2V communication at ITS-5.9 GHz and 5G-V2X operating at 3.5 GHz, respectively. All the dose absorbed values obtained [13][14][15] were well below the limits imposed by the basic restriction of the ICNIRP [16] and IEEE guidelines [17]. However, it would be interesting to investigate the differences in the exposure levels of a pedestrian nearby the vehicle generated specifically by the well-known ITS-5.9 GHz and the innovative 5G-V2X technologies. Thus, the aim of this paper is to compare the exposure levels of a pedestrian generated by the consolidated ITS-5.9 GHz and the new 5G-V2X. In the next section the exposure scenario investigated will be presented.

II. Materials and Methods

The exposure levels were assessed by exploiting the simulator software Sim4Life (ZMT Zurich Med Tech AG, Zurich, Switzerland, www.zurichmedtech.com) though the use of the FDTD method. To provide the V2V communication based on the IEEE 802.11p protocol from literature two quarter-wave monopoles are used, operating at the 5.9 GHz [13][18], while the one based on the 5G-V2X communication are 4x2 patch elements array antennas operating at the 3.5 GHz, in the FR1 frequency range [19]. All the elements of the array had a phase shift of 0° to obtain a central frontal beamforming perpendicular to the plane of the array antenna. Figure 1 illustrates the two antennas used for performing the two different vehicular technologies which their respective geometrical dimensions; below each antenna are reported also the corresponding radiation patterns. For each technology investigated the corresponding antennas were positioned on a 3D CAD model of a city car, one in the front of the car, i.e., on the 36° tilted windscreen, and the other one on the back roof of the car to replicate the real montage setting [20]. Figure 2 showed the montage positions of the antennas highlighted by the red dot points.

An adult female phantom (Ella, 26-yo girl) was positioned in 5 configurations near the vehicle in two different orientations, i.e., frontal and orthogonal, for a total of 10 different simulations for each V2V technologies investigated. Figure 2

shows the human model in the 5 different configurations near the car: one configuration in the front of the car (CONF 1), one in the back of the car (CONF 5), and three on the lateral side of the car (CONF 2, CONF 3, CONF 4), in the frontal (Fig. 2A) and lateral orientation (Fig. 2B). The dielectric properties of the human model were chosen according to the literature [21][22][23]. The maximum step of the mesh in the simulations was made to correctly discretized all the human model tissues. For the absorbing boundary conditions was set the Perfectly matched layer (PML).

For assessing the exposure levels, as indicated by the ICNIRP guidelines [16], the peak of the Specific Absorption Rate (SAR [W/kg]) over 10 g of tissue ($pSAR_{10g}$) has been investigated, specifically for the skin of the whole body and the eyes tissues (composed of the vitreous humor, sclera, lens, and cornea) which are the most superficial tissue and organs, respectively.

The peak SAR values were calculated considering an input power of 1 W for each antenna.

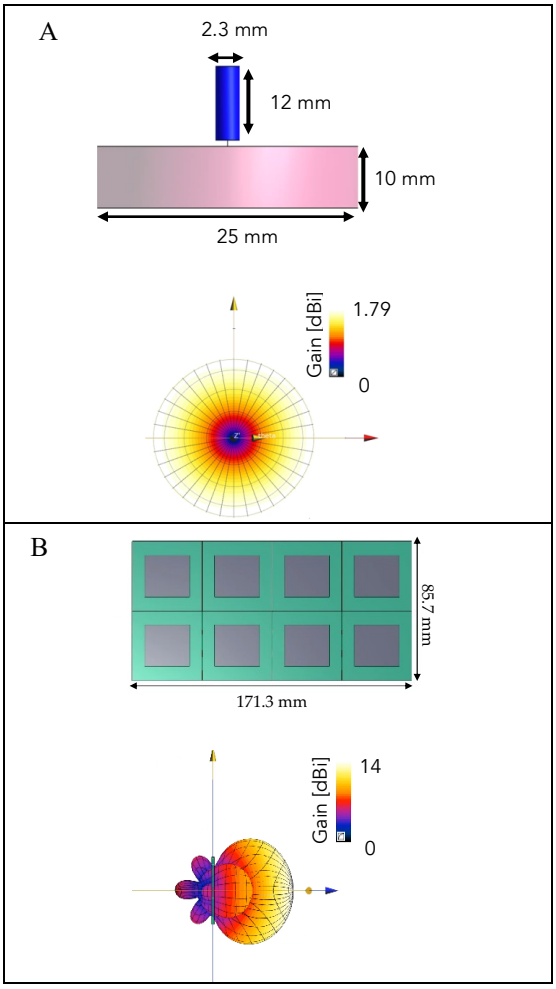

Fig. 1: The two different antennas used to operate the two V2V technologies: (A) the quarter-wave monopole used in the ITS-5.9 GHz and (B) the 4x2 patch elements array antenna operating at 3.5 GHz used for the 5G-V2X. Below each antenna are illustrated the corresponding radiation patterns.

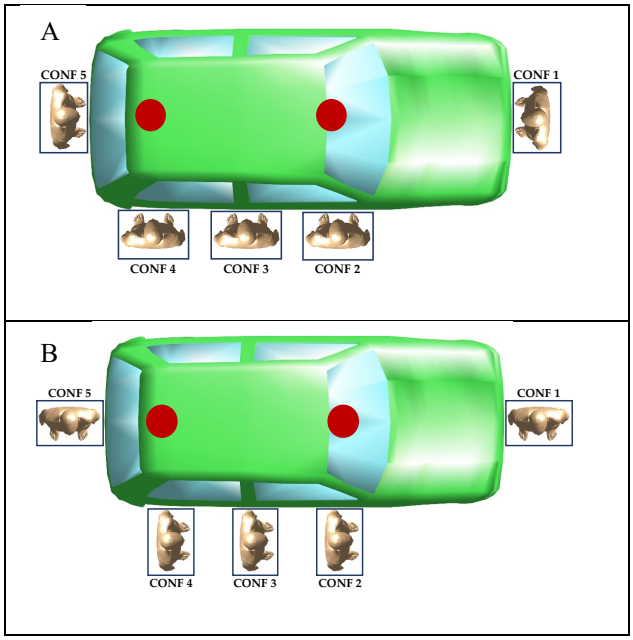

Fig. 2: Frontal view of the 5 different configurations (CONF 1, CONF 2, CONF 3, CONF 4, CONF 5) of the human model near the vehicle in the two different orientations: (A) frontal and (B) orthogonal orientation. The red dots represent the position of the two antennas.

III. Results

In this section we reported some results obtained from the comparison of the exposure levels on a pedestrian nearby the vehicle generated specifically by the ITS-5.9 GHz and 5G-V2X at 3.5 GHz. Figure 3 reported the $pSAR_{10g}$ values of the whole-body skin and eyes tissues as a function of the 5 configurations near the vehicle for each of the two technologies investigated, i.e., ITS-5.9 GHz and 5G-V2X, in the frontal (fig. 3A) and orthogonal (fig. 3B) orientation. Generally, from figure 3, for each technology, the $pSAR_{10g}$ values obtained in the frontal orientation (Fig. 3A) were always higher than that obtained in the orthogonal one (Fig. 3B). Furthermore, comparing the two technologies, for each tissue region investigated, the $pSAR_{10g}$ values generated by the ITS-5.9 GHz were always higher than that obtained with the 5G-V2X at 3.5 GHz except for the CONF 1 in the orthogonal orientation (Fig. 3B) in which the maximum $pSAR_{10g}$ values is when the 5G-V2X is applied. In both two technologies, the maximum $pSAR_{10g}$ was always located in the skin, more precisely in the upper body region, rather than in the eye's tissues. In particular, the maximum peak with the ITS-5.9 GHz, i.e., 34.67 mW/kg, was when the human model was located in the back of the car (CONF 5) in the frontal orientation (Fig. 3A), while with the 5G-V2X the maximum $pSAR_{10g}$, i.e, 6.8 mW/kg was presented when the human model was located in the front of the car (CONF 1) in the orthogonal orientation (Fig. 3B). These relevant differences lie on the different kind of antennas used during the simulations, i.e., the quarter-wave monopole antenna for the ITS-5.9 GHz and the array antenna for the 5G-V2X (previously mentioned in the *Materials and methods* section), which generated different radiation patterns which differently affected the human body region near the vehicle. The former is an omnidirectional antenna that spreads radiation equally on the azimuth plane; the latter is a directional antenna with 0° phase

shift that generates a beamforming perpendicular to the plane of the array antenna (as shown in figure 1).

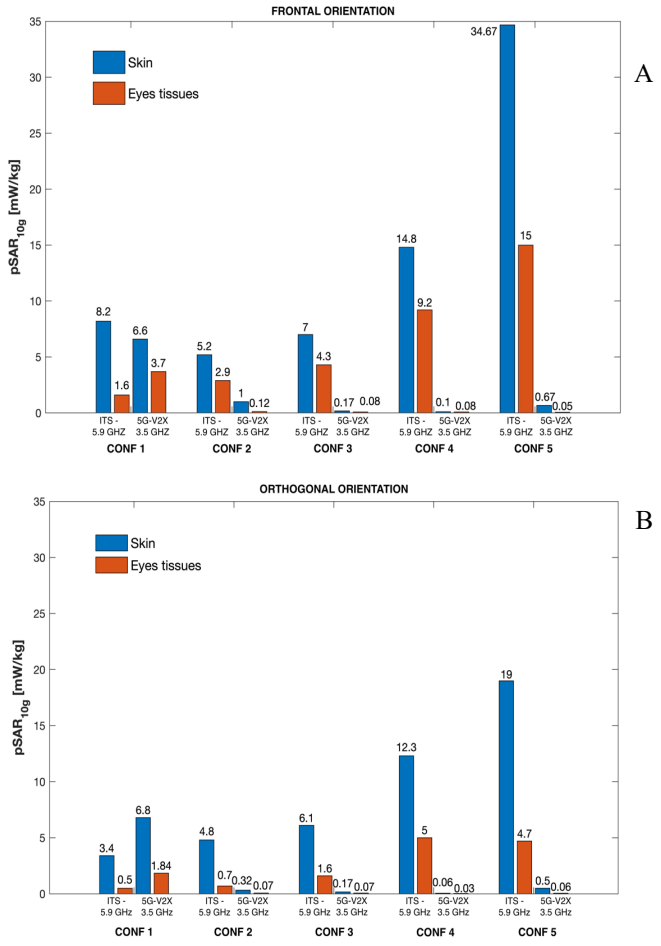

Fig. 3: $pSAR_{10g}$ values in the skin (blue bar) and eyes tissues (red bar) of the human phantom as a function of the five different configurations near the car in the frontal (A) and orthogonal (B) orientation generated by the ITS-5.9 GHz (data collected from [14]) and 5G-V2X at 3.5 GHz (data collected from [15]) technologies

IV. Conclusion

This is a preliminary study aimed to compare the exposure levels of a pedestrian nearby a vehicle equipped with the consolidated ITS-5.9 GHz and the innovative 5G-V2X vehicular technologies which will be widespread in the forthcoming years.

The main differences in the exposure levels generated by the two vehicular technologies are due to the different radiation patterns of the different antennas used to operate the two vehicular technologies. As a general remark, the human model was more exposed to the radiation in the ITS-5.9 GHz condition that the 5G-V2X condition. However, the exposure levels in both vehicular technologies were well below the safety limits imposed by the ICNRP [16] and IEEE guidelines [17]. Further investigations on different tissues (e.g., the head skin and in the skin of the genitals area) will complete the investigation of the comparison of the exposure assessment generated by the two technologies.

***Abstract*—In this work, we computed sleep-wake cycle (SWC) stage-specific cross-frequency couplings in order to identify patterns of neural synchronization with neurobiological relevance. This may be used for the control of neuroengineering systems capable of delivering personalized therapeutic electrical stimulation according to relevant sleep events.**

***Keywords*—Cross frequency coupling, neural plasticity, neuromodulation, sleep stages.**

I. Introduction

THE sleep-wake cycle (SWC) is a circadian neurobiological rhythm of major importance across several animal species, humans included [1]. It is characterized by a recurrent alternation of brain states (or stages) with distinct behavioural and electrophysiological features [2]. In a simplified fashion, states can be classified in three: 1) wakefulness (WK) with desynchronized low-amplitude local field potentials (LFP) and active movement; 2) slow wave sleep (SWS) with synchronized high-amplitude LFP in lower frequencies (delta range) and absence of movement, and; 3) rapid eye movement sleep (REM) with low-amplitude LFP or synchronization in the theta range with deeply reduced muscular tonus and absence of behaviour.

Differently from the lay notion of a brain "shut down", SWC is in fact a result of complex interactions of neurobiological phenomena serving multiples purposes indispensable for homeostasis and life in general [3]. These molecular and cellular processes result in the production of stereotypical electrophysiological oscillations, the synchronization of which is highly descriptive of the effectiveness of the interaction between areas. Among others, these interactions underlie cognitive processing during both wakefulness and sleep. Particularly, a triple coordination between oscillations of different frequencies (synchronization between cortical slow waves, corticothalamic spindles, and hippocampal ripples) during SWS is a key biomarker for the consolidation of memory traces and the migration of information from hippocampal to cortical areas [4], [5], [6].

Considering the importance of sleep in the support of core neural functions (such as those related to brain plasticity), taking SWC into account may be beneficial to the development of personalized solutions in neuroengineering. In this sense, algorithms for event detection (spindles and ripples), SWC staging and, particularly, measurements of synchronization are of great value. Among these, cross-frequency couplings described above, obtained by measurements of phase-amplitude coupling (PAC) such as comodulograms and modulation index and [7], seems well fit for the purpose. In line with this rationale, we hypothesize that, if PAC is in fact important for information transfer across areas of the brain – and thus memory consolidation – and also if such is carried out during SWC, then brain stages can be described on the basis of such synchronization pattern.

In this first work, we benefited from well-established SWC staging algorithms, as well as spindle detection tools, in order to assess the distinct PAC profiles of each major stage (WK, SWS, and REM) and during these specific events. The findings will be used for future developments of algorithms for real time assessment of sleep electrophysiology, including detection of signature waves (e.g. spindles and/or ripples), measurement of synchronization levels, novel PAC-dependent strategies of stage detection, and others.

II. Methods

A. Electrophysiological recordings

LFP recordings used for the SWC staging, creation of hypnograms, and PAC calculation were obtained from an open source database resulting from the study of Barger and colleagues [8] and can be found online at https://osf.io/py5eb/. They were recorded from C57BL/6 mice (N = 10) using surgical screws positioned in the parietal cortex and comprehended five daily sessions of at least 4 hours duration (bandpass filtered 1-500 Hz; sampling rate of 512 Hz).

B. Sleep-wake cycle staging

For the detection of SWC stages and construction of hypnograms (sequence of stages across time), we adopted two approaches. We first used AccuSleep [8]. This software package uses a machine learning approach to classify images composed by the z-scores of both mice LFP and their electromyography. For training the network, the model uses the dataset composed of all animals in the first day of recording which has been previously labelled (staged) by an experienced investigator. Sequentially, the network is applied to automatically label the other four days (five in total) of data. Results presented here correspond to non-labelled days.

The second staging algorithm is taken from the work of Gervasoni and colleagues [9]. Termed here 'State Space', the algorithm consists of describing the SWC as a dynamical system in which the trajectory is computed from LFP spectral content – particularly ratios of power in specific frequency ranges (ratio 1: 0.5–20/0.5–55 Hz; ratio 2: 0.5– 4.5/0.5–9 Hz) – further processed by dimensionality reduction (Principal Component Analysis) and smoothing. Such neurodynamical representation results in clear cluster of points which can be automatically (or manually) detected and which were empirically demonstrated to correspond to each one of the

major sleep stages. Differently from AccuSleep, it does not depend on EMG (although the signal can be used), nor does it need the input from manual labelling.

The purpose of applying both approaches and comparing them is twofold. First, although the State Space algorithm has been used in different studies (e.g. [10], [11]), it has never been compared with other approaches for additional validation. Second, the algorithm can run online [9], paving the way for hardware implementations.

C. *Spindle detection*

We used two filtering algorithms from [12] and [13] for the detection of spindles. They both consist essentially in filtering the LFP recording in the spindle range (e.g. 7 – 15 Hz) and later detecting the envelope of the filtered tracing for the detection of the "waxing and waning" format which characterizes the wave. Both detections are constrained in amplitude and time features for improved performance: minimum duration of spindles, minimum separation between events, minimum amplitude (detection threshold), and maximum amplitude to exclude artefacts. The goal of using more than one tool is similar to that of the SWC staging: comparison and further validation.

D. *Phase-amplitude coupling*

Cross-frequency coupling was measured here as the driving force between the phase of a low-frequency oscillation and the amplitude of a high-frequency oscillation, a type of synchronization called Phase-Amplitude Coupling or PAC, as mentioned before. To do this, we computed the coupling for several pairs of frequencies (phase frequencies: 1 – 30 Hz; amplitude frequencies: 10 – 210 Hz) using a well-established metric termed modulation index or MI [7]. Briefly, the LFP is first filtered in the frequency bands of interest (for which one wants to compute the coupling). In the filtering process, the phase of the slow oscillation is obtained. Then, the envelope of the high-frequency oscillation is computed using the Hilbert Transform to obtain its amplitude. After the Amplitude–Phase (0 to 720°) histogram is obtained, the presence and magnitude of peaks in this distribution (evidence of coupling) is computed by the Kulbach-Leibler distance, which yields the MI. By their turn, comodulograms are obtained when the MI values of a set of frequency pairs varying in a certain range are depicted as color-coded 3D plots (such as those in Figure 1). Comodulograms were obtained from 30 s excerpts of the LFP extracted from the middle of the periods in each of the stages.

E. *Profiling the coupling pattern*

After the comodulograms were built, we picked specific points (pairs of frequency) for statistical comparison. They were chosen for both their neurobiological relevance and also for the qualitative differences that could be observed by the visual inspection of the plots. Table I summarizes pairs of frequency (centre values) assessed in this study.

TABLE I: PAIRS OF FREQUENCIES ASSESSED BY PAC

Identifies	*Frequency used for phase (low)*	*Frequency used for amplitude (high)*
A	Theta (7.5 Hz)	High gamma (140 Hz) / ripples
B	Theta (7.5 Hz)	Low gamma (70 Hz)
C	Slow wave (1 Hz)	Theta (11 Hz) / spindles
D	Slow wave (1 Hz)	High gamma (150 Hz) / ripples
E	Theta (11 Hz) / spindles	Low gamma (70 Hz)
F	Delta (2.5 Hz)	Theta (11 Hz) / spindles
G	Slow wave (1 Hz)	Higher gamma (200 Hz) / ripples

III. RESULTS AND DISCUSSION

A. *SWC stages modulate couplings*

The algorithms for SWC staging and spindle detection displayed strong agreement between results (data not shown), specially after fine adjustment of filtering parameters in the second case. Hypnograms showed a healthy polyphasic alternation of WK, SWS, and REM, with REM always following SWS. Moreover, spindles were detected almost exclusively during SWS and virtually never (< 1% of times) during WK, as expected.

Stage-specific (obtained from AccuSleep) comodulograms of a representative animal (left: WK; center: SWS; right: REM) are displayed on Figure 1, which shows some regions that are strongly modulated across sleep, such as coupling between theta and gamma (low and high).

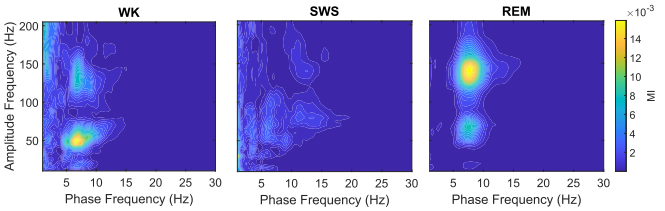

Fig. 1: Comodulogram plots of Mouse 1 during WK (left), SWS (center), and REM stages (right) show strong stage-specific modulation of PAC. Colour scale in the right represents MI values.

Group measures of specific frequency pairs can be found in the curves of Figure 2 (comparisons between WK and SWS), Figure 3 (WK and REM), and Figure 4 (SWS and REM). Each panel (A to G) corresponds to a specific frequency pair (as described in Table I) and shows all animals (light gray lines) and the mean with SEM (bold red lines). As it can be seen, the average MI for several frequency pairs displayed differences with statistical significance when comparing distinct stages (***p < 0.001; **p < 0.01; *p < 0.05; paired t-test).

From start, it is clearly apparent that the PAC between the phase of theta range and the amplitude of the gamma range (both high and low; Figures 3 and 4, panels A and B, respectively) are strongly increased during REM sleep in comparison to both WK and SWS. These same couplings also show to be slightly increased in WK when compared to SWS (Figure 2, panels A and B).

Interpretation of such results is straightforward and can be related to the acquisition of memory traces by active exploration during WK and posterior consolidation during sleep, both processes in which theta and gamma oscillations play important roles [14]. Particularly, theta is a very

stereotypical electrophysiological signature of REM and can be clearly noticed in raw tracings. Such observation is in line with other studies on theta-gamma coupling dynamics [15] and is reviewed in [16] on the context of High Frequency Oscillations. Although theta is a rhythm generated within hippocampal circuitry, its influence in cortical areas (such as the prefrontal region) can be captured by cortical electrodes such as those used in the acquisition of the recordings.

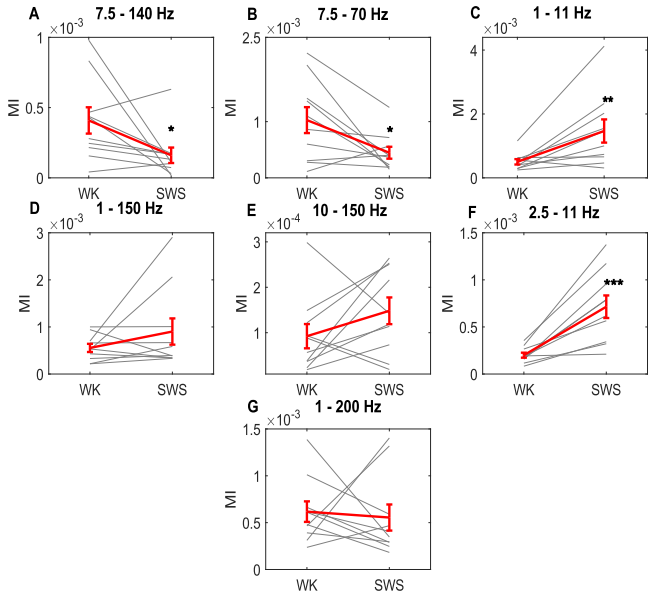

Fig. 2: Group measure of PAC for all different pairs of frequencies considered, comparing WK to SWS (***p < 0.001; **p < 0.01; *p < 0.05; paired t-test). Grey lines: individual animals; red lines: average and SEM.

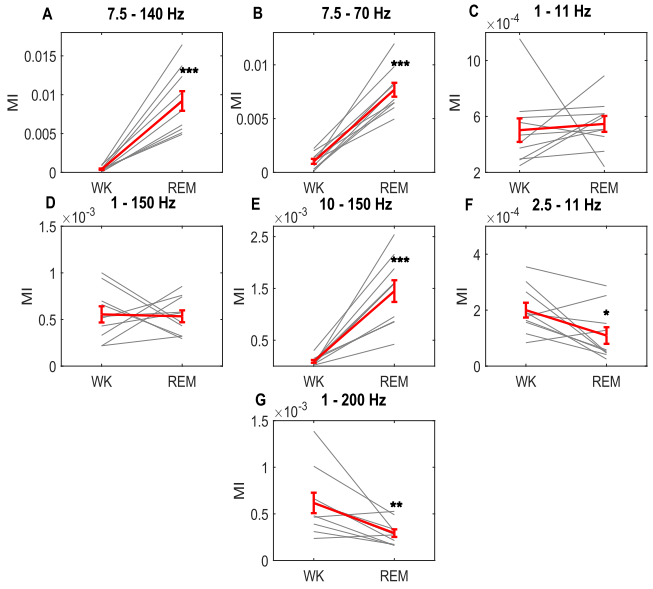

Fig. 3: Group measure of PAC for all different pairs of frequencies considered, comparing WK to REM (***p < 0.001; **p < 0.01; *p < 0.05; paired t-test). Grey lines: individual animals; red lines: average and SEM.

Additionally, PAC values between slow oscillations and theta or between delta and theta are clearly increased during SWS when compared to both WK (Figure 2, panels C and F) and REM (Figure 4, panels C and F). In fact, slow oscillations and delta waves are the predominant rhythms observed during this stage. On the other hand, theta rhythm during SWS is usually suppressed in comparison to the other stages, impairing a straightforward interpretation of this particular coupling result. One possible, even plausible, explanation relies on the known strong coupling between slow oscillations and spindles, which partially occupy the theta band.

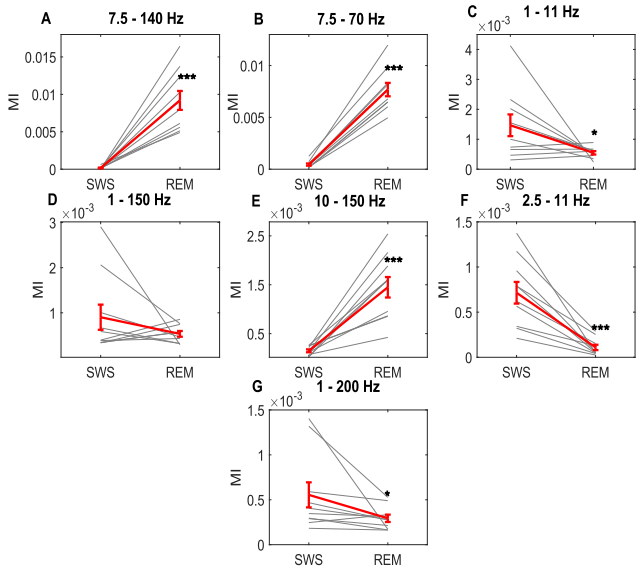

Fig. 4: Group measure of PAC for all different pairs of frequencies considered, comparing SWS to REM (***p < 0.001; **p < 0.01; *p < 0.05; paired t-test). Grey lines: individual animals; red lines: average and SEM.

B. Coupling strength during spindle events is uncertain

In line with this reasoning, it is intriguing that there is no increase in PAC values between theta and gamma during SWS (Figures 2 and 4, panels B and E), which could represent spindle-ripple coupling known to occur during this stage. For this purpose, we also assessed MI values in 30 s excerpts of LFP centered in every occurrence of detected spindles (see sections II.B and II.C). Figure 5 shows a representative animal to illustrate the results of this analysis. Here, hypnograms are depicted as a temporal sequence of color-coded SWC stages (WK: green; SWS: red; REM: blue) and spindles are indicated as dots in the uppermost portion of the hypnogram. In the bottom of hypnograms, black tracings depict the MI values computed across time each 30 s. Top hypnogram is superimposed with slow-oscillation and spindle PAC and bottom hypnogram with spindle and ripple PAC. It is important to register that, in this case, we did no use single comodulogram points, but actually computed the MI onto frequency ranges to better represent the oscillations of interest: 0 – 2 Hz for slow oscillations, 7 – 15 Hz for spindles, and 140 – 200 Hz for ripples.

Some clear features are immediately distinguishable from these plots. First, as mentioned before, hypnograms show clear stereotypical polyphasic alternation of stages with REM always preceded by SWS and spindles occurring mostly during SWS (spindles in WK are probably detection artifacts). Furthermore, REM seems to exert a strong stage-modulation between the frequency ranges of both slow oscillations to

spindle coupling (decreasing) and the spindle to ripple modulation (increasing). Notice, from the bottom hypnogram, that the MI curve peaks during REM periods in blues and flattes during SWS (red). On the other hand, when MI is computed only during occurrence of spindles (30 s windows), no statistically significant statistics can be found.

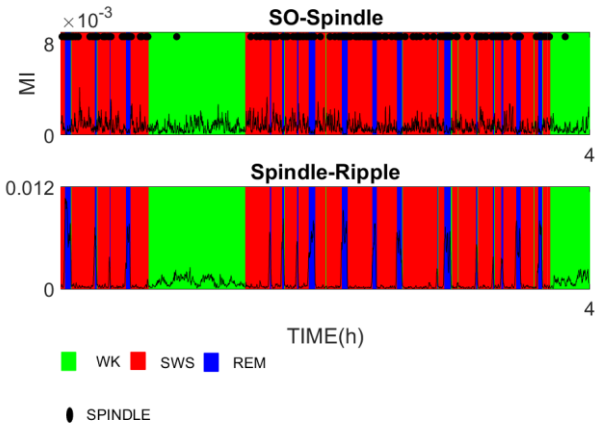

Fig. 5: Hypnograms superimposed with spindle events (dots) and MI values for slow oscillation-spindles (top) and spindle-ripples (bottom) pairs illustrate the fact that REM stage strongly modulate the latter (peaks on blue and flats on red periods of bottom panel), while the former (top panel) does not seem to be affected by states.

Although current results are not enough to explain the reason behind this, we hypothesize that the lack of difference may be due to the fact that spindles, and even more so ripples, are too short events to contribute enough to MI values computed over reasonably long-time windows of 30 s. Although this effect has not been directly measured here, we understand that this is one simple explanation that is in harmony with all results found here. In time, such long window has been adopted given the known errors induced on the measure if smaller windows are used [7].

IV. Conclusion

Although PAC (and measurements such as MI) may not be suitable for objectively quantifying the important coordination between slow oscillations, spindles, and ripples, its modulation across the SWC may be instrumental for stage detection methods based on neurobiological-plausible rationale such as cross-frequency synchronization. Table II summarizes the pattern of modulation found in this study, which may serve as basis for future staging algorithms. Here, arrows indicate significant increases or decreases during SWS or REM in comparison to WK.

TABLE II: SIGNIFICANT PAC ALTERATIONS REFERENCED TO WK

Pair	*SWS*	*REM*
A	↓	↑
B	↓	↑
C	↑	-
D	-	-
E	-	↑
F	↑	↓
G	-	↓

In any case, the possibility of being able to assess the SWC and detect its stages by solely the CFC pattern is of major neurobiological importance, particularly considering, as previously mentioned, the relationship of such synchronization mechanism with the function of sleep.

***Abstract*— Brain-Computer Interfaces based on Motor Imagery (MI-BCI) have been validated as promising systems to support rehabilitative protocols for the post-stroke motor recovery of the upper limb. To date, the long-term effects of MI-BCI training in post-stroke patients need to be clarified. In order to fill this gap, we analysed electroencephalographic (EEG) data collected during the neurophysiological assessment sessions (longitudinal study) in a context of a two-arm Randomized Controlled Trial. Seventeen subacute stroke patients were enrolled and randomly assigned to the interventions: MI training supported by BCI (BCI group) and MI training without feedback (CTRL group). The aim of this work is to investigate for each intervention group the long-term effects of the MI training on the EEG sensorimotor responsiveness. Therefore, for each group we analysed the alpha and beta frequency band activity for the motor imagery task of grasping and finger extension, performed both with the affected and the healthy side separately collected, before and after the rehabilitation treatment and 1, 3 and 6 months later. Results obtained in this preliminary study show that in the BCI group the activity in alpha and beta band are located over the sensorimotor areas and that such pattern is maintained over time while the amplitude decreases. In the CTRL group the alpha activity is evident on the sensorimotor channels, the amplitude decreases with time till T4 when the pattern turns to be again widespread over the scalp and in the beta band no temporal modifications are reported. Our findings suggest that the MI-BCI induces a sensorimotor EEG reactivity rebalance in hemispheres.**

***Keywords*— Stroke, upper limb rehabilitation, Brain-Computer Interfaces, Motor Imagery.**

I. Introduction

Stroke survivors in 75% of cases face permanent disability mostly of the upper limb [1], [2]. This adversely impacts their quality of life and their integration into society. Hence the need to proposing and validating new rehabilitation treatments that can promote the recovery of the motor function.

Over the last decade Brain-Computer interfaces (BCIs) based on Motor Imagery (MI) have been validated as effective tool for supporting post-stroke motor rehabilitation [3], [4]. In the rehabilitation setting BCI paradigms are predominantly based on the electroencephalographic (EEG) technique to detect the modulation of neuroelectric signals like, in most cases, the sensorimotor rhythms (SMRs), EEG oscillations that occur in the alpha (8-13 Hz) and beta (13-30 Hz) bands over the sensorimotor areas. The amplitude of SMRs decreases during movement or movement imagination, indeed the MI elicits the same activation patterns as motor execution [5]. Hence the MI-BCI system based on SMRs tracks their amplitude changes and translates them in control signals for external devices that provide feedback to the patient about the specific processes occurring in his brain.

At IRCCS Fondazione Santa Lucia (Rome, Italy) the multidisciplinary team (neuroscientists, bioengineers, and clinical rehabilitation experts) of the Neuroelectrical Imaging and BCI Lab conceptualized and developed a BCI prototype to support hand MI training in stroke patients. The device, called Promotœr [6], is currently employed as add-on to standard therapy in one of the rehabilitation wards.

Briefly, during rehabilitation sessions with the Promotœr, patients perform affected hand MI tasks while their EEG activity is recorded and translated into movements of a virtual hand (feedback) shown on a screen placed in front of the patient.

To the best of our knowledge, however, the long-term effects of the MI-BCI training are still unclear and debated [7].

To address this question, we analysed in a longitudinal study the EEG activity recorded from a sample of subacute post-stroke patients that follow a rehabilitation MI training supported by the BCI system (BCI group) and from a sample of patients that perform the MI training without BCI feedback (control group). EEG data were recorded during 5 assessment sessions: before and after the rehabilitation treatment and at 1, 3 and 6 months apart.

The purpose of this study is to investigate the long-term effects of the MI-BCI training and the MI training without closed-loop feedback in the EEG bands related with MI tasks, i.e., alpha and beta bands.

II. Methods and Materials

A. Data Collection

The EEG dataset analyzed in the present study was collected in the context of the Randomized Controlled Trial described in [6]. The dataset includes 17 subacute stroke patients (48 ± 15 years mean ± standard deviation, 10 M / 7 F), who underwent a 12 – session rehabilitation treatments. Clinical and neurophysiological assessments were performed at different time points: before (T0) and after (T1) the rehabilitation intervention and 1 (T2), 3 (T3) and 6 (T4) months after the intervention. In every assessment EEG data were recorded from 61 channels, with a cap mounted according to an extension of the International 10/20 System. Simultaneously the electromyographic (EMG) activity of the Extensor Digitorum and Flexor Digitorum muscles were collected from both upper limbs. EEG and EMG data were sampled at 256 Hz. At each time point, participants were instructed to perform

the MI of grasping and finger extension tasks with both the healthy and affected hand, separately. For each experimental condition, 20±1 task trials and 20±1 rest trials were acquired, and the total trial duration was of 7 s; the first 3 s were of rest and the next 4 s of performance of the task (MI)/rest. The Fugl-Meyer Assessment (FMA) outcome measure was collected.
Patients were divided into two groups that receive a different rehabilitation treatment: the BCI group (N=8) performed the MI training in a close-loop condition receiving a feedback that was ecological and congruent with the MI task, i.e. a virtual representation of the affected hand that moves according to the modulation of SMRs, and the CTRL group (N = 9) performed the MI training in the same setting of the BCI group but in an open-loop condition, i.e. they did not see any movement of the virtual representation of the affected hand. The two groups were balanced in terms of age (45 ± 14 / 51 ± 16 years, BCI / CTRL mean ± standard deviation) and gender (4M/4F BCI, 6M/3F CTRL). All participants received the intervention as add-on to the standard therapy.

B. Data pre-processing

Both EEG and EMG of the assessment's recordings data were pre-processed in the Brain Products Analyzer (BrainVision Analyzer, Version 1.05.0005, Brain Products GmbH, Gilching, Germany) environment and following analysis were performed on MATLAB (R2020b; MathWorks, Natick, MA).
The continuous EEG data were 1-45 Hz bandpass filtered (Butterworth Zero Phase Filter, slope 48 dB/oct) and the Independent Component Analysis (ICA) was performed to remove ocular artifacts. Data were segmented in 4 s - trials considering the last 4 s of the total trial duration. Trials were further segmented into 1 s - windows, and an amplitude threshold (±100 μV) was applied on each window to detect artifacts; if the number of channels detected in each 1 s-segment was less than or equal to 5, the artefactual channels were replaced by spherical interpolation of neighboring channels, otherwise the entire segment was eliminated. EEG data were re-referenced to the Common Average Reference.
To verify the compliance with the motor imagery tasks, EMG data were pre-processed and visually inspected to identify any attempted movement. EMG data were high pass filtered at 10Hz (Butterworth Zero Phase Filter, slope 48 dB/oct), segmented in 7 s trials, considering all trial duration, and visually inspected. Trials in which EMG activity coherent with the experimental task (finger extension or grasping) was detected on the target muscle, i.e. flexor digitorum muscle for grasping and extensor digitorum muscle for the finger extension, were eliminated from the analysis.

C. Spectral Analysis and Focal Index

The power spectral density (PSD) was computed for each EEG channel on concatenated windows pooling the motor imagery tasks performed with the same side, due to the similarity between the spatial and frequency patterns elicited by finger extension and grasping MI task [3]. Welch's method was used to compute the PSD with 1-s Hamming window plus zero-padding to obtain 0.3 Hz resolution.
In patients with left-sided lesions, PSDs were flipped based on channel scalp positions along the midsagittal plane [8], [9] so that eventually all patients share the right hemisphere as the affected.
PSDs were averaged separately across the band ranges alpha (8-13 Hz) and beta (13-30 Hz) to extract a representative value for each band. PSD values, calculated for task and rest trials (PSD Task, PSD Rest), were used to obtain the statistical maps (see *D. Statistical Analysis*).
We introduced a biomarker accounting for desynchronization distributions on scalp maps, in particular, we considered a Focal Index, that quantifies the activity spread on scalp maps based on Event-Related Desynchronization (ERD). For each participant, we calculated the ERD according to G. Pfurtscheller [10] for each channel separately as PSD Task minus PSD Rest, divided by PSD Rest. From the ERD scalp distribution, we computed the Focal Index as an esteem of the variance over the scalp as in Eq. (1):

$$Focal\ Index_b = Var(ERD)_b \qquad (1)$$

where *b* stands for the frequency band.
This index was computed for the experimental task performed with the affected side, at each timepoint, separately in alpha and beta bands and compared between BCI and CTRL groups.

D. Statistical Analysis

Statistical PSD maps were generated for each group, i.e. BCI and CTRL, timepoint, i.e. T0, T1, T2, T3, T4, and task, i.e. MI of the affected hand and healthy hand as follows.
Having tested and verified the distributions normality, with the Kolmogorov-Smirnov test, the 2 tailed paired t-test was performed between MI and rest PSD values (patients were considered as observations of the t-test) and computed for each EEG channel and frequency band. The tests returned negative t values in the case that desynchronization occurred (i.e., a decrease in power) and a positive t value in the case of synchronization (an increase in power).
The Focal Index was compared (2 tailed independent t-test) between the BCI group and the CTRL group at each timepoint and for both bands, i.e. alpha and beta bands.
The FMA values collected at T0 on BCI and CTRL participants, were tested (2-tailed Wilcoxon rank sum test) in order to check the impairment level homogeneity between the two groups.
For all tests we set the significance level to 0.05.

III. RESULTS

At T0 no significant differences were found between the BCI and CTRL group in term of level of motor impairment ($p = 0.44$): FMA(T0) = 14.8±5.9 / 19.4±4.7 (average ± standard error) BCI / CTRL. The FMA measures at T1 reveal that both groups improved after the treatment (FMA(T1) = 27.4 ± 6.9 / 32.5 ± 7.8 BCI / CTRL, mean ± standard error) and at T4 participants reached an averaged (± standard error) FMA value of 48.3 ± 5.8 in the BCI group and 39.6 ± 8.9 in the CTRL group.
In Figure 1 are shown the topographical distributions of t values obtained from the comparisons between task and rest trials performed at all timepoints (T0, T1, T2, T3, T4). In the panels (a)-(b) the results obtained for the BCI group for the MI task executed with the affected hand, panel (a), and with the healthy hand, panel(b), are reported, both for alpha and beta bands on the first and second raw, respectively, of each panel. The t-value distributions obtained from the task/rest

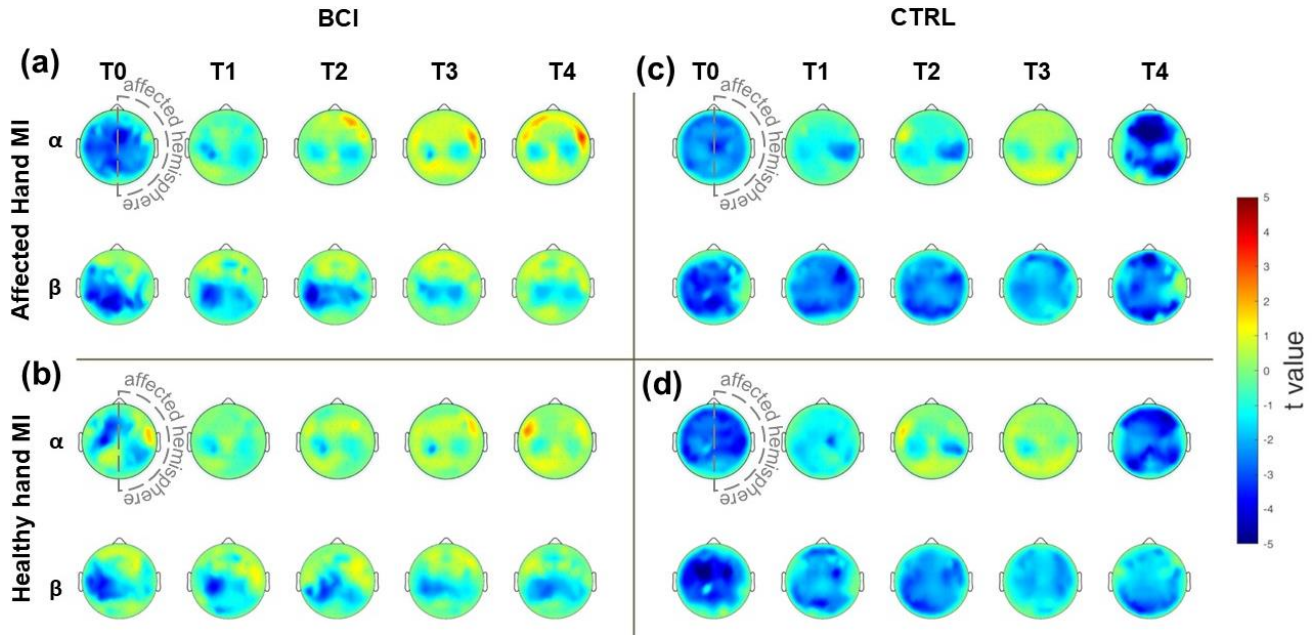

Figure 1. Scalp topographic distribution of the t-value obtained from the power spectral density (PSD) comparison (paired t-test, alpha=0.05) between task (MI) and rest conditions at timepoints T0 (baseline), T1 (after MI training), T2 (one month after training), T3 (three months after training), T4 (six months after training) for the BCI group, in the panel (a) for the task performed with the affected hand and panel (b) for the task performed with healthy hand, and for the CTRL group in the panels (c) and (d) respectively. The affected hemisphere is the right one for all participants; the task performed with the left hand refers to the affected side and vice versa. In each panel are reported the t values obtained from the comparisons both in the alpha band (first raw) and for the beta band (second raw).

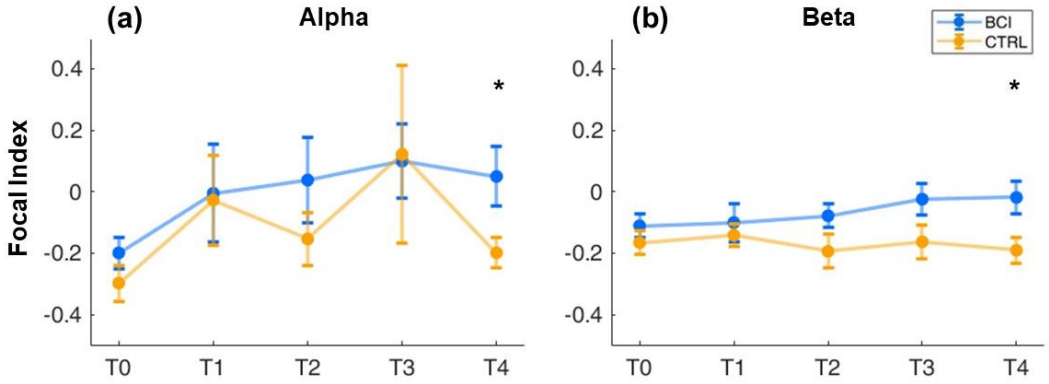

Figure 2. Focal index, computed as variance of event-related desynchronization across the EEG electrodes, presented as average ± standard error across 8 and 9 stroke patients for the BCI (blue) and CTRL (yellow) group at timepoints T0, T1, T2, T3, T4. The ERD variance is reported for the task performed with the affected hand, in alpha (panel (a)) and beta (panel(b)) bands. Significant differences (independent t-test) between the BCI and CTRL group are marked (*) for each timepoint.

comparisons in the CTRL group are shown in the panels (c)-(d), organized similarly to the BCI group panels. The results obtained for the task performed with the affected side in the BCI group in panel (a) show a desynchronization over the sensorimotor areas of both hemispheres, in the two bands, after MI-BCI-based rehabilitation training. This pattern is maintained up to 6 months after treatment while the t value amplitude decreases over time. When the MI task is performed with the healthy hand in the BCI group in panel (b), there is, likewise on the affected side, the activity in both bands is mainly over the sensorimotor areas contralateral to the involved hand in the task and it is maintained over time. The t-value maps obtained for the CTRL group, for both the affected, panel (c), and healthy hand, panel (d), show that the beta band activity is spread over the scalp and this pattern does not change over time. Results obtained in the CTRL group for the task performed with both the affected and healthy side, reveal a desynchronization in the alpha band over the sensorimotor areas of both hemispheres at time T1. This pattern is maintained for the next 3 months and then the amplitude decreases at T3 and returns to a widespread activation after 6 months (T4).

The results obtained from the comparison of the Focal Index between the two groups for the MI task performed with the affected hand are shown in Figure 2 at all timepoints for alpha and beta bands in panels (a)-(b). In both bands, the variance value of ERD turns out to be mainly lower in the CTRL group than in the BCI group. This difference is significant in both bands when the task is performed with the affected side at T4 ($p = 0.032$ in alpha, $p = 0.023$ in beta). Despite the graphical evidence, at 3 months from the treatment the difference of

ERD variance between the two groups in beta band, isn't significant ($p = 0.083$).

IV. Discussion

In this study, EEG data from two experimental groups were analysed, one that underwent MI-BCI-based training and the second that practiced only MI. As demonstrated by the clinical results both groups of patients improved their upper limb motor functions following treatment as expected since the patients were going through the subacute phase of the disease and also received the standard rehabilitation.

In the BCI group in alpha and beta bands, there is a bilateral desynchronization over sensorimotor areas for the task performed with the affected hand. This result is in line with the study [3] in which F. Pichiorri et al. investigated the effects of MI-BCI training but in the present work we observed a greater involvement of the healthy hemisphere after the training. Scalp maps of alpha-beta desynchronizations obtained for the healthy hand task in the BCI group after the treatment reflects a more contralateral activation. In the present work we discovered that such rebalance of activity in the two hemispheres, in the bands of interest, is maintained in the subsequent time instants up to 6 months from treatment highlighting the Motor Imagery activity learning via the closed-loop training and suggesting brain plasticity effects of such treatment.

Following the treatment, in the control group desynchronizations occurred over the sensorimotor regions only in the alpha band for the task performed with the affected and healthy hands, but after 6 months the responsiveness of SMRs seems to return to the initial condition. In beta band no temporal changes are evident in the CTRL group. Together the CTRL group findings suggest that there is an initial reorganization due to the Motor Imagery training, but it is not preserved over time.

Testing the significance of comparisons, between task and rest conditions, is part of the future purposes of this study, currently not yet implemented, which could be carried out using a cluster-based analysis approach.

The Focal Index confirms the results evidenced by the spectral maps, suggesting that the activations in the CTRL group are similar i.e. no differences resulted among EEG channels and therefore the ERD Variance is lower in the CTRL group rather than in the BCI group and such difference is significative at T4 in alpha and beta frequency bands. Further investigations including a larger sample of stroke patients will deepen effects on brain plasticity of the BCI-assisted MI training.

V. Conclusion

This preliminary study reveals long-term effects of MI-BCI, respect to the MI training opened-loop, on sensorimotor EEG reactivity. The Focal Index computed in alpha and beta frequency bands seems to be a good candidate to describe changes over time of the EEG patterns.

A multimodal wearable system for Human Activity Recognition during daily activities

P. Benvenuti[1], E. Rovini[1], L. Fiorini[1,2], and F. Cavallo[1,2]
[1] *Department of Industrial Engineering, University of Florence, Via Santa Marta 3, Firenze, 50139, Italy*
[2] *The BioRobotics Institute, Scuola Superiore Sant'Anna, Viale Rinaldo Piaggio 34, Pontedera (Pisa), 56025, Italy*

***Abstract*—This study proposes a wearable system consisting of inertial and electromyography (EMG) sensors for the recognition of activities of daily living in the context of neurodegenerative diseases. The value of Human Activity Recognition (HAR) rests in its ability to test motor cognitive abilities objectively and precisely at home and to keep track of activities performed, for instance when it's necessary to follow the impact of pharmacological therapy. Current technologies for HAR primarily rely on two types of systems: camera-based systems and wearable sensor systems. In this study, a wearable multimodal system based on the fusion of EMG and inertial sensors was designed and developed. Data have been collected from 21 young subjects performing 5 gestures and, after a data pre-processing, a multi-modal dataset has been created. Then, classification has been performed using two machine learning techniques, i.e. a multiclass Support Vector Machine (SVM) and a Random Forest (RF). The best combination of sensors is analyzed, considering both classifiers' accuracy and wearability. Following the proposed approach, levels of accuracy of 79% are reached using EMG and the inertial sensor on the dominant index finger and wrist, whereas, using EMGs and only the hand's wrist sensor achieves an accuracy of 78%, showing that an excellent yet non-invasive activity recognition system can be obtained with just a few sensors. Finally, this system can be a reliable solution to be used both in clinics and home care.**

***Keywords*—Multimodal Wearable Sensor, Gesture Recognition, EMG sensors, inertial sensors, Neurodegenerative Disease.**

I. Introduction

ITALY in 2015 had the greatest portion of older people in the labour force in the European Union. By 2050, this statistic is expected to nearly double, prompting concems about caring, according to Eurostat predictions [10]. Human Activity Recognition (HAR) is one of this scenario's most promising assistive technologies. Indeed, recognition of activities of daily living can be of paramount importance in a monitoring context: people with dementia have difficulties performing daily activities and caring for themselves and are almost dependent on caregivers.

Smartphones, smartwatches, smart clothing, and other specialized devices are currently the most common wearable technology utilized in HAR [1,2,3]. In general, HAR can work better and be more robust by adding different types of sensors in different parts of the body [4,5].

In this context, this study aimed at designing and developing a multimodal wearable system composed of inertial devices and electromyography (EMG) sensors for upper limbs, for the recognition of activities of daily living (ADL) that can be useful for the non-invasive monitoring of frail people at home. Signals acquired by the sensors during a well-defined experimental protocol were processed to extract features characterizing the performed activities. Then, two machine learning classifiers (i.e., Support Vector Machine, Random Forest) were applied to identify the performed activities and their performance was evaluated. Finally, the authors figured out the best combination of sensors in terms of accuracy in activity recognition and wearability.

II. Materials and Methods

A. System Architecture

A multimodal wearable system was designed and developed including both inertial and electromyographic sensor devices (Fig. *1*). Then, a user interface was developed to collect data from both devices.

Fig. 1: The full wearable system with Myo & SensHand

- *Electromyographic sensor device: Myo Armband*

The Myo Armband (Thalmic Labs) consists of 8 EMG electrodes with a bipolar configuration that acquires muscle activity, and a low-energy Bluetooth (BLE) transmission module for transferring the acquired data to a docking station for post-processing data analysis. The sampling rate of this device is 200 Hz.

- *Inertial sensor device: SensHand*

The SensHand is a wearable device developed by the Assistive BioRobotics Joint Lab (Scuola Superiore Sant'Anna and University of Florence, Italy) composed of four inertial modules positioned in correspondence to the wrist and the first three fingers (thumb, index, middle finger). Each module is composed of a complete 9-axis inertial sensor (6-axis geomagnetic module LSM303DLHC and 3-axis digital gyroscope L3G4200D, STMicroelectronics, Italy) and includes a microcontroller (ARM®-based 32-bit STM32F10RE MCU, STMicroelectronics, Italy) which can acquire, filter and store data at a frequency of 100 Hz [6]. It collects and transmits data towards a generic control station through a wireless communication based on the SPBT2632C1A V3.0 (STMicroelectronics, Italy) Bluetooth serial device. The placement of the sensors has been

determined according to the state of the art, examining the gestures that need to be recognized [7].

- *The Wearable System Interface*

A user interface was developed using Python to integrate the two sensor devices (i.e., SensHand and Myo armband). The implementation of the interface guarantees the simultaneous gathering of data from all the sensors. Two Python executables have been developed: one to initiate data transfer and acquisition and the other one to connect SensHand and Myo to the Personal Computer (PC). As for SensHand, the transmission of data is based on Python's pySerial library, which reads directly from a serial port, whereas a Python module, "Pygatt", was used to connect Myo to the PC, to read and write to GATT descriptors on the BLE device. Then, a web interface, based on HTML code, has been developed for this work to manage the connection and data stream of the system's sensors. It is a navigable user interface that takes the form of a Web page and can be accessed with a common web browser.

B. Experimental Setup

Twenty-one people participated in the trial, including 13 males and 8 females, right-handed, who were asked to wear the SensHand and the Myo on their dominant arm. These people were then asked to perform 5 different activities (Fig. 2):

- Eat with the Fork (EF): take the fork from the table and simulate bringing food to the mouth ten times and then resting the fork.
- Grasp to Drink (GD): take a water bottle from the table and simulate drinking for 3 seconds and then resting the glass.
- Brushing Teeth (BT): take the toothbrush, simulate the brush teeth ten times, and put it back.
- Using Laptop (UL): type on the keyboard with both hands.
- Talking on the Phone (TP): to take the phone, talk on for 3 seconds, and put it back.

Fig. 2: Set of activities performed by the participants

These activities were chosen by comparing two of the most widely used public datasets in the field of HAR, i.e., the Comel Activity Dataset [8] and the MSR Daily Activity Dataset [9]. People performed the activities while seated, and 3 seconds before and after the execution of each gesture were also recorded, with people in a position of complete rest to have a baseline for each trial. While performing the movements, participants are always seated.

C. Data Analysis

Acquired signals from both devices were processed and analyzed to extract features able to characterize and differentiate the performed activities. Then, after the feature reduction, two supervised machine learning classifiers were applied to evaluate which configuration of sensors resulted in the best accuracy for recognizing the performed activities.

- *EMG Preprocessing*

A "full wave rectification" was done for the EMG signals and then they were filtered with a 4th-order Butterworth low pass filter with a cutoff frequency of 10 Hz. After that, signals have been normalized and segmented. Each signal was normalized according to the subject's baseline, calculated in the first two seconds of rest. Windows of 1 s length (two hundred samples), with 0.5 s overlap (i.e., 50%), were used to segment the signal. For the region of muscle activity to be detected automatically, the waveform length (WL) feature was used as in Eq.1.

$$WL = \sum_{n=1}^{N} |x_{n+1} - x_n| \qquad (1)$$

Where x_n is the EMG data and N is the number of samples in each time window. The maximum value in the waveform length values in the first 2 seconds of the resting signal was calculated. Then, the threshold value was determined by multiplying this value by $\sqrt{5}$. A second threshold was fixed $\sqrt{3}$ times the first threshold to determine the end of the gesture [11]. After extracting each channel's start and end index, we took the minimum and maximum of the previously found indexes as the start and end indexes. Thus, we established common indices to have the same samples on all channels. The method was evaluated one by one on all EMG signals in the dataset, and the correct region was detected.

- *Inertial Preprocessing*

A Fourier analysis of the signal was carried out. The signal's primary frequencies are between 0 and 3, hence a 4^{th}-order digital low-pass Butterworth filter was utilized with a 5 Hz cutoff frequency. Once the muscle activation window on EMG signals was found, we identified the precise instant the user began the action in the EMG signals, and then we looked for the correlated inertial sample closest to that EMG sample based on the system's time stamps. The same procedure was applied for the end movement detection. The signal has then been divided into segments by moving windows with a 3-second size and 50% overlap according to the typical length of each gesture.

- *Feature Extraction*

Twenty-seven parameters were extracted for each window. In particular, the following 17 features were from the EMG signals:

1. Root Mean Square
2. Mean Value
3. Mean Absolute Value
4. Standard Deviation
5. Variance
6. Waveform Length
7. Number of Peaks
8. Mean Peak Value
9. Mean Firing Velocity
10. Slope Sign Changes
11. Difference Absolute Mean Value
12. Willison Amplitude
13. Mean Absolute Value Slope
14. Integrated Absolute Value

15. Hjorth Mobility Parameter
16. Difference Absolute Standard Deviation Value
17. Maximum Fractal Length.

Moreover, 10 features were extracted from the inertial signals as follows:

1. Root Mean Square
2. Mean Value
3. Mean Absolute Value
4. Standard Deviation
5. Variance
6. Skewness
7. Kurtosis
8. Integrated Absolute Value
9. Root Mean Square Jerk
10. Mean Jerk.

Each instance was then assigned to the corresponding performed activity (Table I).

TABLE I: PERCENTAGES OF ACTIVITIES AND THE DISTRIBUTION OF THE NUMBER OF INSTANCES WITHIN THE DATASET

Label	*Activity*	*Percentage %*
0	Eat with the Fork (EF)	30
1	Grasp to Drink (GD)	18
2	Brush Teeth (BT)	19
3	Use Laptop (UL)	13
4	Talk on the Phone (TP)	20

- *Feature Reduction and Classification*

Seven different configurations of sensors were analyzed, including stand-alone systems (e.g., inertial data from wrist unit only) and different combinations of the sensors. Then, a Principal Component Analysis (PCA) was done to reduce the number of features in the dataset for each configuration. Once the new datasets were obtained, they were used to train and test two supervised classifiers: a Support Vector Machine (SVM) with a Radial Basis Function (RBF) kernel, and a Random Forest (RF). The datasets were split with percentages of 70% for training and 30% for testing, and a k-fold cross-validation with k=5 was performed. To evaluate classification performance, the following metrics were used: accuracy (2), precision (3), recall (4), and F-score (5):

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (2)$$

$$Precision = \frac{TP}{TP+FP} \quad (3)$$

$$Recall = \frac{TP}{TP+FN} \quad (4)$$

$$Fscore = 2 \cdot \frac{Precision \cdot Recall}{Precision+Recall} \quad (5)$$

Where:

- TP: True Positive
- TN: True Negative
- FP: False Positive
- FN: False Negative

III. RESULTS

Overall, by evaluating the seven sensor combinations, SVM performed better than RF. The best combinations are given by the wrist inertial data combined with Myo data (W+M) and by the index and wrist inertial data jointed with Myo signals (I+W+M) (Fig. *3*), reaching an overall accuracy among all the activities for SVM equal to 0.78 and 0.79, respectively.

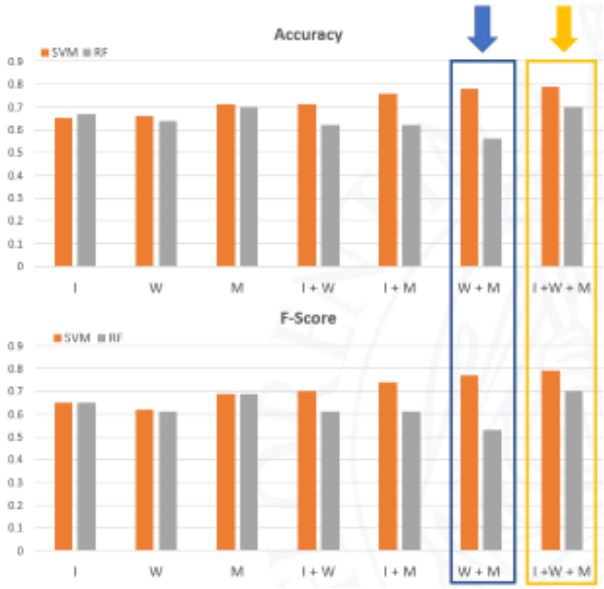

Fig. 3: Accuracy and F-score of the seven sensor combinations for RF and SVM. I = inertial data from the index finger unit; W = inertial data from the wrist unit; M = EMG data from Myo

The two best-performing configurations (i.e., W+M, and I+W+M), have similar classification performance (Fig. *4*):

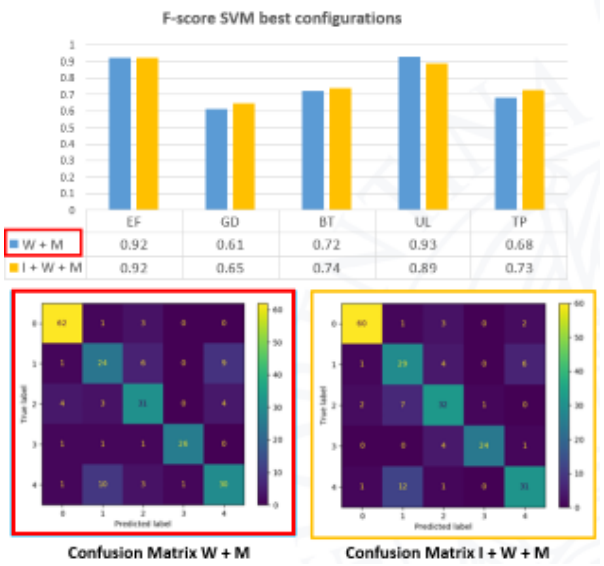

Fig. 4: F-score and Confusion Matrices for the two best configurations using the SVM classifier

However, there are some differences among the following activities:

- "Eat with the Fork" (EF) and the "Use the Laptop" (UL) activities, are those best predicted in the two configurations.
- "Grasp to Drink" (GD) and "Talk on the Phone" (TP)

activities are generally the most confusing among them.
- "Grasp to Drink" (GD) is the worst predicted activity.

In contrast, between the two best configurations there are also differences, indeed, adding the index inertial sensor:

- Increase discrimination between "Grasp to Drink" (GD) and "Talk on the Phone" (TP).
- Decrease "Using the Laptop" (UL) performances.
- "Eating with the Fork" (EF) and "Brushing Teeth" (BT) have similar performances in the two configurations.

IV. Discussion and Conclusion

A multimodal wearable sensor system, composed of EMG and inertial sensors, was designed and developed to support HAR during activities of daily living. With our system, we were able to obtain reliable gesture recognition for such activities. The wrist is the ideal site for wearables due to its low intrusiveness, and due to its capacity to capture hand orientations and hand movements [12], however, the results showed that this sensor alone is insufficient to distinguish between some gestures with finger movements. In our study, EMG sensors placed on the forearm improved the recognition of hand shapes and finger movements confirming the results from Wu, Sun and Jafari [12]. Finally, the combination of multiple sensors gives better results than standalone solutions. In particular, as for choosing the best configuration of the sensor system among the seven studied configurations, a trade-off between performance and wearability was applied. Best results were obtained by using wrist inertial sensor data combined with the EMG data and by using both wrist and index inertial sensor data combined with the EMG data. Given the similar performance, we can choose the one with the least number of sensors as the best configuration to maximize wearability without decreasing accuracy. Choosing the fewest number of devices could be a suitable solution that would allow the usage of such a system also in a home setting, where frail people can be monitored during the performance of their ADL. Therefore, in this study, the best combination of sensors in terms of a trade-off between accuracy and wearability encompasses the Myo wristband combined with the wrist inertial sensor, which achieves an overall accuracy of 78% among the five performed activities, exceeding 90% for eating activity. However, a modular solution that allows easy including or excluding some sensor units could be the best option to provide a multimodal system that can be adapted to different activities. Indeed, in this study, only the wrist and index finger from SensHand were included, but also information from the thumb unit could be important for activities encompassing the grasp or require a fine assessment of finger motion.

The main limitation of this study is the sample size. Indeed, a small sample of users was involved in the experimental tests and the dataset resulted unbalanced among the different activities. Moreover, the use of armband EMG sensors limits electrode placement and increases the likelihood of electrodes being placed in different positions from subject to subject due to natural muscle differences. In future works, the authors are planning to enlarge both the number of gestures and participants enrolled, including older people and people with motor-cognitive disabilities. Also, the authors are interested in introducing new types of sensors (e.g., other types of physiological signals) to investigate not only the motion and muscle activity during the ADL but also the physiological response of the users while performing such activities.

Concluding, this system is a promising solution for realizing an evaluation of physiological and kinetic parameters during the performance of specific activities. Finally, the system could be applied to people who may have physical disabilities, such as people with neurodegenerative diseases. In this context, a trial has already been started at the "Don Primo Mazzolari" hospital in Bozzolo (MN). Seventeen people with Parkinson's disease are participating in this trial, where the system designed and developed in this study is used to assess the patient's motor performance during the execution of standard motor exercise within the neurological examination to evaluate the effect of the assigned rehabilitation program.

***Abstract*— The aim of this study was to quantify the effectiveness of a tele-rehabilitation program for post-Covid-19 patients who reported disabling motor and respiratory symptoms after the infection. Nine post-covid patients were assessed in three session: at hospital admittance time (T0), at discharge time (T1) and at the end of the tele-rehabilitation program (T2) via instrumental (i.e. instrumented six-minute walking test and handgrip) and clinical (i.e. spirometry) tests. So far, just the data coming from the instrumented tests of three patients who completed the program were considered, showing an increasing trend in terms of both motor and strength parameters between the considered time points. The preliminary results suggested that the proposed tele-rehabilitation approach could have positive effects on motor function in post-covid patients.**

***Keywords*— Covid-19, tele-rehabilitation, 6-min walking test, handgrip.**

I. INTRODUCTION

THE Covid-19 pandemic significantly affected our daily life and brought new challenges to the global healthcare systems. Worldwide, even months beyond the discharge from acute care, many Covid-19 survivors reported incomplete healing [1]–[4], negatively impacting on daily activities and on the quality of life [5].

In fact, patients recovering from severe COVID-19 infection often report motor (e.g. muscle and joint pain, decreased exercise capacity) and respiratory symptoms (e.g. dyspnoea, impairment of pulmonary function) together with a wide range of other issues, such as chest pain, cognitive impairment, anxiety and sleep alterations [6]–[11].

In order to manage the disabling motor and respiratory post-Covid-19 symptoms and effects, an adequate rehabilitation is required in all stages of the disease, from the acute to the post-acute phase.

However, the suspension of the majority of outpatient services on the national territory and travel restrictions made the access to rehabilitation services more and more challenging, especially in those areas, such as the cross-borders, which were already poorly served by health facilities.

In this context, tele-rehabilitation represents a new solution to support health-care structures in the management of the rehabilitation demand for Covid-19 survivors.

Tele-rehabilitation programs mainly apply to physiotherapy and neural rehabilitation [12]–[14] and, according to the literature, they allow for the treatment of various phases of diseases by substituting the traditional face-to-face approach in the patient-rehabilitator interaction [15], [16] thus representing a solution to reconcile the quality of life and the sustainability of the health services. Additionally, such applications are useful to cover situations in which it is complicated for the patients to reach the traditional rehabilitation infrastructures [16].

The aim of this study is to evaluate the effectiveness of a home-based motor and respiratory rehabilitation program for post-Covid hospitalized patients.

II. METHODS

A. Participants

The study was approved by the Ethics Research Committees of Istituto Auxologico Italiano (Ospedale San Giuseppe, Piancavallo, VB) and Clinica Hildebrand – Centro riabilitazione Brissago (Brissago, CH).

A group of post-covid inpatients was recruited. The principal selection criteria were the follows:

1) Adults of both sexes, aged between 35 and 75 years, admitted to the functional recovery units due to disabling motor and/or respiratory SARS-CoV2 outcomes.
2) Subjects living in cross-border regions with low density of rehabilitation facilities.

Conversely, the exclusion criteria were:

1) Presence of psychiatric pathologies or cognitive deficits that did not allow for a correct use of the devices for the tele-rehabilitation

Considering these criteria, 9 post-covid individuals were enrolled (age: 54.5 ± 7.23 years, M: 2, F: 7) so far.

The recruited subjects were evaluated at the beginning of their hospital-based rehabilitation program (T0), at discharge time (T1) and the end of their three-week home-based rehabilitation program (T2) via instrumental (e.g. 6-minute walking tests) and clinical tests (e.g. spirometry).

B. Experimental set-up

Following their discharge from the hospital, the post-Covid patients continued their rehabilitation process at home, using a proper easy-to-use equipment. The technology provided to each patient consisted on a respiratory muscle training device

(SpiroTiger, MVM Italia, Lainate, MI) and a motor rehabilitation device (Euleria Home, Euleria, Rovereto, TN) respectively.

With regards to respiratory rehabilitation, the SpiroTiger system is a device designed for the specific training of the respiratory muscles without overloading the cardiovascular and the musculoskeletal system as it allows for the execution of deep and fast breathing acts were performed without incurring the consequences of hyperventilation (e.g. hypocapnia).

The device **(Fig. 1)** consists on a portable grip equipped with a bag for air recycling and a valve that controls the isocapnia state and provides via its software the information on how to perform the correct breathing in terms of depth and frequency.

Fig. 1: Visual representation of the device used for respiratory rehabilitation (SpiroTiger, MVM Italia, Lainate, MI)

With respect to motor rehabilitation, Euleria Home is a CE class 1/m medical device that allows clinicians to remotely configure and monitor exercise-therapy paths for their patients. The device **(Fig. 2)** consists on a wearable inertial sensor and a dedicated application, installed on a tablet, which guides the patient through a personalized rehabilitation program directly from home. Such technology, in addition to the guidance provided in the correct execution of the exercises, uses the biofeedback technology (i.e. audio and visual feedback) and integration with the sensor to simplify the execution of the exercises and the completion of the session, motivating the patient with an effective gamification mechanism based on scores, badges and prizes.

Fig. 2: Visual representation of the device used for motor rehabilitation (Euleria Home, Euleria Health, Rovereto, TN)

Using a cloud-based web-management system, the clinicians updated and personalised the exercise-therapy programmes to the patients, remotely monitoring their results, progress and compliance with the rehabilitation program on a weekly basis.

The exercise protocol for home-based rehabilitation was sorted by clinicians according to patients' health status and performance during their hospital stay. Regarding respiratory rehabilitation, each patient performed a set of breathing exercises personalized in terms of depth and frequency up to five times per week. With respect to motor rehabilitation, it was decided to keep the protocol as simple as possible, including only easy free body exercises up to five times per week. After a short warm-up, the patients performed a set of exercises for trunk (e.g. lateral bending and anterior flexion), upper and lower limbs (e.g. shoulder abduction and knee flexion). At the end of each training session, a report containing information about articular angles, repetitions and score was generated and checked out by the clinicians, in order to monitor patient's performance and eventually tune the program.

C. Instrumental and Clinical Tests

All the patients underwent instrumental and clinical test at the three time points in order to evaluate the effectiveness of their rehabilitation process. In particular, the performed instrumental evaluations were the maximum handgrip isometric force, assessed with a dynamometer, and the instrumented Six-Minutes Walking Test (i6MWT) [17]–[21].

The i6MWT was recorded via a miniaturized (70 mm x 40 mm x 18 mm) inertial sensor (G-Sensor®, BTSBioengineering, Milan, Italy), integrating different triaxial sensors (i.e. accelerometer, gyroscope and magnetometer), and performed indoor, along a 30-m hospital corridor with marked turnaround points, instructing the patients to walk as fast as they could [17], [22].

A report for each i6MWT trial was automatically generated via BTS G-Studio and the following parameters were considered for further analysis:

- Walked distance (m).
- Walking speed (m/s).
- Stride length (m).

Concerning the clinical evaluations, a complete spirometry with DLCO (Diffusing capacity of the Lungs for Carbon Monoxide), MIP (Maximal Inspiratory Pressure) and MEP (Maximal Expiratory Pressure) was performed. Additionally, oxygen saturation and dyspnoea perception after the i6MWT were tracked.

III. RESULTS

Out of the current sample of 9 subjects, 3 women have completed the tele-rehabilitation program so far. Due to the small sample for the data analysis, it was chosen not to perform a full statistical analysis and to report the results in term of percentage change to highlight changes between the considered time points. According to the preliminary data coming from the instrumental tests, an improvement of patient's performance could be noted between the considered

time points.

Concerning the i6MWT, the results shows an improving trend in terms of walked distance (T1-T0: + 16.4 %, T2-T0: 29.7 %) **(Fig. 3)**, walking speed (T1-T0: 15.3 %, T2-T0: 30.1 %) and stride length (T1-T0: +8.3 %, T2-T0: 19.5 %).

The same improving trend can be seen also for the maximum handgrip isometric force for the dominant limb between the baseline and the end of the tele-rehabilitation program (T2-T0: +13.8 %).

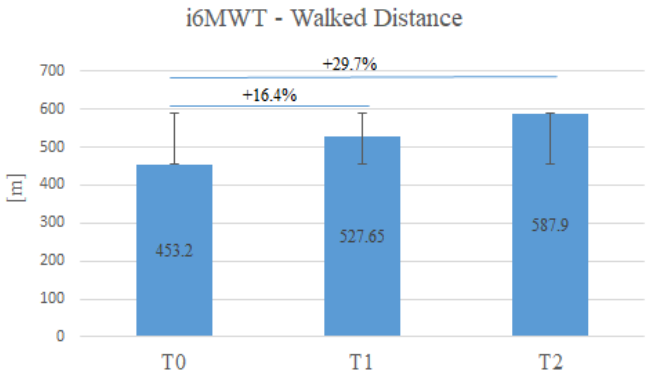

Fig. 3: Mean and standard deviation of walked distance during the i6MWT for the patients who have completed the program so far. Difference between T1-T0 and T2-T0 is reported in terms of percentage change.

IV. DISCUSSION

The purpose of this study was to evaluate and quantify the effectiveness of a motor and respiratory home-based tele-rehabilitation program for post-Covid patients. The preliminary results concerning the instrumental tests performed by the patients who complete the program showed encouraging data about the effectiveness of the proposed telerehabilitation approach. In fact, with respect to i6MWT, the considered parameters allow for the observation of a trend towards an increase that could be due to a general improvement of health conditions.

The same considerations could be done for the handgrip, with the difference that the increasing trend was noticeable between T0 and T2, probably because it normally takes more time to see visible changes in strength while following a targeted training [23].

So far, just the preliminary outcome of the instrumented tests was explored and the small number of participants who completed the program limited the actual strength of the statistical findings. The complete data analysis, including also the clinical tests and the respiratory aspects, will be performed on the full sample of participants to the tele-rehabilitation program.

ACKNOWLEDGEMENT

The research was conducted in the field of TRIALS Project “La teleriabilitazione nel paziente post-covid: l’esperienza Italia-Svizzera”, project co-funded by the European Union (FESR), Italy, Swiss Confederation and Swiss Cantons – Interreg V-A Italy-Switzerland".

The authors would like to acknowledge Eng. Federica Camuncoli, Eng. Serena Mandaresu and Eng. Cristina Ferrario for their valuable contribution to the project.

***Abstract*—We designed a robot capable of challenging an opponent on a board game for rehabilitation purposes, with the aim to keep the patient busy during rehabilitation hours while allowing them to learn or improve mobility and strategic skills using a recreational game. To maximize the effectiveness of the therapy, the user experience must be as close as possible to a real game (e.g., chess or draughts) with a physical opponent. For this reason, the robot has to move real pieces on a real board, mimicking the other player's role. In this preliminary study, the concept and design of the robot were performed in a simulated environment. The simulated robot is of the parallel type, having the end effector directly connected to the base through rigid structures that work in coordination. Robot Operating System (ROS) was used to develop and design the robot controller. We describe the assembly of the designed structure of the robot and the controllers for movement along the Cartesian axes. Finally, game intelligence was introduced to enable the robot to play a chess game against the user autonomously. As a result, the implemented simulated robot can conduct a game of chess: recognizing and moving the pieces within the board perimeter, while the user can interact using a graphical interface. In conclusion, we have implemented the simulated version of an autonomous robotic board game that could be translated into a physical system able to engage the user for rehabilitation purposes.**

***Keywords*—Robotics, Rehabilitation, Chess, Gazebo**

I. Introduction

After a traumatic or acute event, such as a stroke, the human brain suffers from a shock that may result in motor, cognitive, or language deficits. Regarding motor functions, in an attempt to regain lost abilities, patients undergo motor rehabilitation. Robotic devices deal with robotic technology that provides physically disabled people with tools to assist the rehabilitative exercise and to improve their quality of life. Key elements of an effective rehabilitation approach include high repetitions and patient involvement [1]. In this view, it is possible to design serious games or to take advantage of traditional games to assist in physical rehabilitation. In developing such an approach, particular attention must be paid to users' requirements, as they are part of the process. Possible target patients for this work are those who can move their upper limbs and are in Grade 1 of the NIH Stroke Scale [2]. Patients who have suffered from a stroke, spinal cord injury, or muscular dystrophy are ideal targets for the project [3], [4].

The rehabilitation therapy should include both sensorimotor and cognitive aspects, all fundamental during the execution of complex tasks and activities of daily life. Robot-assisted rehabilitation has proved to be similar and at least non-inferior to standard sessions with a physical therapist. It has also been proved that active participation from the patient is needed to maximize the therapeutic effects in people who suffered from stroke [5]. In this view, playing board games, particularly chess or draughts, might be an important asset since i) it foresees multiple repetitions of precise pinch movements in the space, ii) it foresees the full cognitive involvement of the subject, iii) it can be played anytime, even outside the standard therapy hours. While commercial solutions enable patients with impaired upper-limb functions to play board games such as chess or draughts, most of these solutions foresee only a virtual board displayed on a screen, making the game entertaining for the patient but without a rehabilitation outcome. Other solutions foresee the automatic movement of physical pieces on the board, moved using magnetic actuators hidden under the board plane, making the experience better but still far from an actual match between two human players. It was reported that people who played against a physically embodied agent had higher enjoyment experiences than those who had played with a virtual agent [6]. For these reasons, we designed and virtually prototyped a physical robot able to play a board game, like chess, in the most human-like way (i.e., reaching for physical pieces on the virtual board, picking and moving them around according to the strategies defined by its game intelligence system). In this way, the robotic chessboard can be used for rehabilitation purposes, keeping the patient engaged and entertained while he/she is recovering motor functions. The goal is to allow patients suffering from motor impairments to perform tasks that can be muscularly feasible and within their reach, such as lifting and moving a simple object. The robot is not designed to assist the user or help them in the movement; rather, it is proposed as an opponent to be able to lead a game of chess.

II. Materials and methods

The choice of the robot fell on a parallel robot for ease of use and simulation, as a device that can move on a Cartesian plane and lift the pieces in order to lead the game is sufficient. Parallel robots are also preferable on this occasion because, despite their rigidity, they are reliable and precise when working on limited areas, such as the edge of a chessboard. They are also simple to adapt to physical devices such as a 3D printer, with easy-to-find hardware and inexpensive additional parts.

In order to simulate the structure of the robot and the movements, ROS (Robot Operating System) Melodic and Gazebo were used [7]. ROS is an open-source system for robot programming. It provides the services expected from an operating system, like hardware abstraction, device control, implementation of functionality, message-passing among processes, and package management. It has therefore proved to be the ideal solution to simulate a robot that, although simple, must be able to move in space and needs specific libraries to meet our objectives. In addition, we used Gazebo, an open-source 3D robotics simulator, to simulate the physical world and to visualize the robot. It offers a robust physics engine, high-quality graphics, and a convenient programmatic that includes an advanced graphical interface. It also offers useful functionalities for knowing the behavior of the robot and what is around it.

A. *The robotic chessboard*

A parallel robot is a structure composed of mechanical arms that converge in a platform or end effector. In this case, the robot is composed of a base that supports the whole object, four rigid poles on which there are links for movement along the z axis, and an upper structure on which there are spools and a platform for movement in y and x axes (Fig. 1). The pieces on the board are taken by the robot end-effector from above.

The robot can either play against a human player by moving only its pieces or the pieces of black and white, as happens in the simulation. The former is the rehabilitation scenario, where the human player is the patient performing the rehabilitation session. In principle, the opponent can either be the robot itself, controlled by its game intelligence, or remotely controlled by another human opponent via an internet connection. From a control point of view, in this work, we have implemented a simple game intelligence so that the rehabilitation session can happen without any external intervention.

The 32 pieces are the soul of the game and each one moves distinctly. Pieces can be generally distinguished from others by their shape, but this difference represents a problem for the robot, as it lacks a sophisticated grasping end-effector. For this reason, simplified geometries were used. They had to be defined as static robots to enable a proper interaction between the pieces and the robot. The main robot is described by its Unified Robot Description Format (URDF) and it is composed of dynamic parts that interact with each other and move, while the pieces are other static robots defined with simple URDFs. Therefore, every piece has its own name, allowing the robot to correctly identify each piece and its position throughout the game. There are also other important parameters that must be set to make sure that each piece remains in its initial position and does not move: the initial position (within the limits of the board range, from -0.6125 to 0.6125 m), a visual tag (each piece is a square base box with a side of 0.15 m and a height of 0.3 m), and inertia (0.00833 $kg \cdot m^2$).

All the pieces are thus arranged in their initial positions and ready to be moved by the robot. We have added a Graphical User Interface (GUI) to show the top view positions of the pieces and to let the human player select their move with a drag-and-drop movement via mouse or trackpad (Fig. 2).

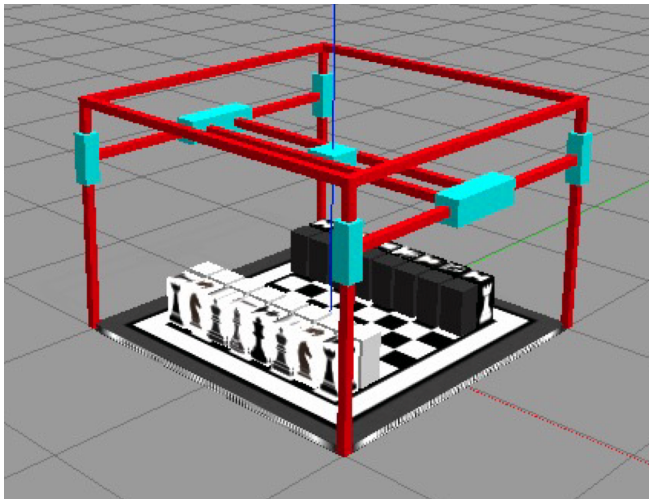

Fig. 1: The full structure of the robot (links in red and moving joints in light blue) and the chessboard on which it operates. 16 pieces per team, black and white, are instantiated on the board and initially positioned on their starting squares.

B. *Robot controller*

We have designed the controller for the robot arm to move the pieces on the board. Each square on the board is mapped to x and y axes coordinates, and the vertical position (z) has only two states: low, 0.3 m above the board level, therefore touching the underlying piece, and up, 0.9 m. Controllers receive the position and modulate the velocity of the joints to move the robot. The *ROS control* package takes as input the joint state data from the robot actuators' encoders and a target set point [8]. It uses a generic control loop feedback mechanism, which is a simple proportional controller (P = 2 s^{-1}), to set the linear velocity of the actuators, moving the end-effector horizontally and vertically and the side fuses that allow the lowering. Each

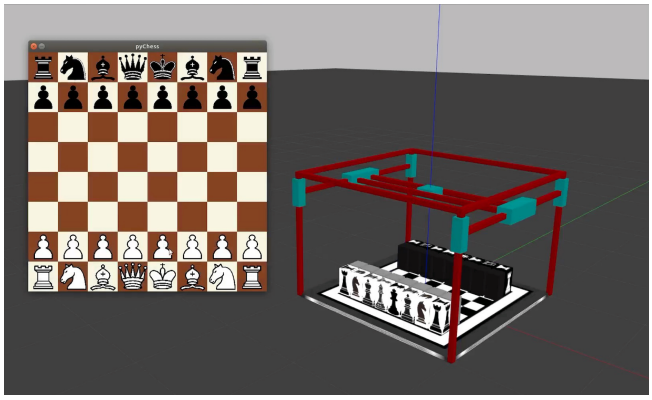

Fig. 2: The game setup with the integration of the GUI shows the top view of the chessboard and the current position of the pieces. The GUI is used by the human player to select the next move.

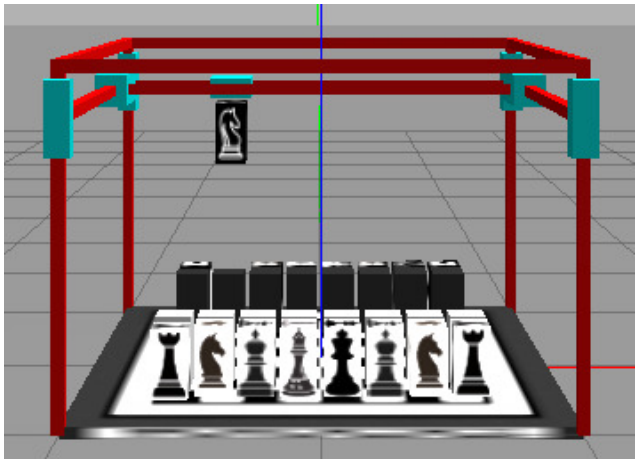

Fig. 3: Frontal view (from the human player side, playing with whites) of the board while the robot is moving one of its knights. In particular, this is the situation at the end of step 3).

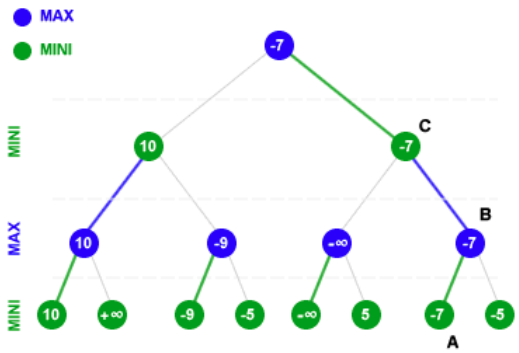

Fig. 4: Simple example of the decision tree generated by the *Minimax* algorithm. Lowest level: at the terminal nodes, it is the turn of the MINI player. It finds the minimum values at the terminal nodes and assigns them to the parent node. Middle level: here, it is MAX player's turn. It chooses the nodes with the highest values and assigns them to the parent node. Upper level: again, it is MINI player's turn; between the nodes 10 and -7 it chooses the latter one, and it reports it at the root node of the tree (current position). Once the tree is reconstructed, the *Minimax* algorithm chooses the sequence with the best strategic choices for the MINI player from its current position, which is the path C→B→A.

move is composed of at least six steps: 1) move the end-effector to the desired x, y position, where the piece to be moved is located; 2) lower the end-effector and attach the piece; 3) raise up the end-effector (e.g., as depicted in Fig. 3); 4) move the end-effector to the final x, y position, where the piece needs to be moved; 5) lower the end effector and detach the piece; 6) raise up the end-effector. In case of special moves, e.g., *castling*, promotion of a pawn, or capturing an opponent piece, the 6-step sequence has to be repeated two times. For instance, if a piece is captured, it has to be moved outside of the board perimeter first, and then the capturing piece is moved to the position previously occupied by the removed one.

C. Game intelligence

We used a decision system (i.e., game intelligence) to let the robot decide the moves of its pieces. We adopted a machine learning system based on convolutional neural networks, leveraging the *MiniMax* algorithm, which is often used in 2-players games [9], [10]. The game intelligence system is connected to the GUI to both read the status of the game and to show the user the situation of the board in a comfortable way. It is also connected to the robot controllers in order to execute the planned moves.

The *MiniMax* algorithm is a recursive algorithm for finding the best move in a zero-sum game (as chess) that takes place between two players. It is a decision rule that minimizes the maximum possible loss of a worst-case scenario for the player. The *MiniMax* algorithm is able to minimize potential loss by using positional evaluations to predict the opponent's next move. Algorithms of this type have to find ways of reducing computational cost in games where it would otherwise be impossible to find a good move with a certain depth of search, as the computational load increases considerably going down the branches. Since the tree of combinations can become very large, it is requested some kind of mechanism to cut down the number of built sub-trees, ideally eliminating (pruning) moves that do not look promising and concentrating on those which are likely to lead to a positive outcome. For this purpose, it is introduced the idea of a cost function that assigns a number to a game position representing how likely that position is to lead to a win. This score can be calculated for each playable position. The *MiniMax* algorithm allows to identify the best choices of the two players (one called MINI and one MAX) during the game, analyzing backward the game tree starting from the terminal nodes, i.e., from possible situations in which the game can end and progressively ascending to the current position of the players. For example, in the game tree reported in Fig. 4, a sequential game between two players is represented. The first player (MAX) must maximize the value of the game, while the second player (MINI) must minimize the output. In addition, a pruning mechanism called the *Alpha-Beta* algorithm had been added to reduce the number of branches and nodes in the research tree to analyze [11]. We have adapted the code that can be found at https://github.com/luweizhang/chess-ai.

III. Results and Discussion

A. Physical simulation and control

The physical simulation is simple and intuitive for the user: it is enough to open the command GUI and execute the selected move, waiting for the artificial intelligence response. The robot's decision is not instantaneous but takes a few seconds to execute. This improves the game's realism and, at the same time, allows the human player some time to think about future moves. Furthermore, one can expect that the robot can perform similar moves in the opening and deviate from them only at a certain point in the game. This is due to the intrinsic architecture of intelligence, which selects the

best move from a set of choices. Initially, when the choices are limited and the pieces are in the same position, the robot responds in a similar way. As the game progresses, the intelligence deviates from the main path. In the simulation, the control of the pieces takes place directly on the GUI. Here the player can make their move by dragging the piece to the desired position.

As shown previously, it is possible to play a match against the robot. For convenience, white has been chosen as the color for the human player and the robot will use black. The game intelligence chosen is not particularly strong, but it is still able to establish a certain advantage if the opponent makes unusual moves. In case of capture of other pieces, they are moved outside the game perimeter. This is very similar to what would happen in a real chess game, and it is more realistic than virtual games, where the captured pieces just disappear from the screen.

B. Potential rehabilitation use

Although the result of this work is only a virtual prototype, we can foresee the potential rehabilitation effectiveness for patients suffering from upper limb disabilities. In the case of patients who have suffered from spinal cord injury, the device can be useful for people with a non-disabling degree of disease. If the injury is too severe or at a too advanced stage, e.g., for neurodegenerative diseases, it is impossible for the patient to move the pieces on the board. Even in the case of particularly disabling strokes in which there is a low level of consciousness (important to play a game with a significant cognitive load), or the motor skills are so limited that they prevent movement against gravity, a patient's ability to engage in this game is out of the question. In the case of muscular dystrophy, on the other hand, there is an impoverishment of motor skills over time. A limitation can be represented by age: Duchenne Muscular Dystrophy affects patients who are generally very young and may find it difficult and little fun to try a complex game such as chess. In the case of Becker Muscular Dystrophy, loss of ambulation generally appears later. It is, therefore, more natural for these patients to become interested in a board game.

The robotic chess game itself has two types of advantages as regards the rehabilitation aspect: i) it allows patients to grasp and move their pieces, exercising different muscles and motor strategies; ii) it requires intellectual effort and, for this reason, can be stimulating and can entice the patient to play multiple games in a single session.

C. Future implementations

We foresee implementing a real physical model based on the simulations presented to fulfill the rehabilitation purposes. The robot can be adapted to a system that reproduces the geometry and structure of a parallel robot, such as a 3D printer. In this case, the nozzle (which will become the grasper) can move on the Cartesian space similarly to the virtual prototype. With a physical system, the patient could move the piece by themselves. However, it may happen that they suffer from a degree of impairment that prevents them from moving the piece without support or help. In this case, it is possible to use a motion adapter (e.g., a joystick). Other robot structures can be used (e.g., an anthropomorphic robot arm, potentially a solution that integrates a vision system already), with the advantage of having a robotic opponent more closely resembling a human player, with the potential of using the same robot for different tasks and not only for playing. The higher versatility yields an increased cost for the platform. Regardless of the choice of the robot, solutions for active and passive safety need to be included to avoid possible harm in human-robot interactions. Finally, the game intelligence can be modulated according to the skill of the human player, and sophisticated controllers can be employed to generate a more realistic game experience, especially for advanced players.

IV. Conclusion

The implemented simulated robot is able to conduct a game of chess: recognizing and moving the pieces. While the use of robotic games is not still present in clinical practice, one can expect that patients can benefit from this type of technology. The main limitation of the project is that the robot was developed in a virtual environment. In case of future implementations, we expect that patients will be interested in playing with a physical system. It is also important to highlight the greatest value of the robotic approach in rehabilitation: while physical therapists can devote a limited time to each patient, the robotic system can engage the user for several sessions, prolonging the therapy and its effectiveness.

***Abstract* — Severe spinal cord injuries or detrusor muscle degeneration due to aging can cause the loss of contractility of the urinary bladder. To date, long-term clinical solutions to restore contraction control include neurostimulators with unpleasant long-term side effects. Thus, implantable artificial detrusors turn out to be an urgent promising solution in this field.**

In this paper, an origami-based fluidic system is proposed as a robotic prosthesis for human bladder voiding. Both on-the-bench and *ex vivo* tests highlighted promising results with a bladder voiding efficiency range of 75-90%.

***Keywords* — spinal cord injury, bladder, soft robotics, implantable prostheses**

I. Introduction

Millions of people in the world are affected by the inability to contract the detrusor muscle, which is essential for the voiding of the urinary bladder. Underactive or inactive bladder is usually the consequence of severe spinal cord injuries below the thoracic segment (T12 vertebra), which are approximately 30% of the total cases [1], [2]. In Europe, severe spinal cord injuries have an estimated incidence of 10,000 new cases per year [3]. Impairments in the control of bladder voiding are also associated with body aging due to detrusor muscle degeneration and spinal neural tissue alterations [4].

In this field, medical treatments are often based on intermittent or indwelling catheterization, which turn out uncomfortable and induce several complications [5]. Sacral neural stimulators are the only available permanent option but feature severe long-term side effects [6]. Therefore, a different kind of permanent solution is extremely urgent.

To date, no commercial implantable artificial detrusor is available. Researchers have recently proposed prototypes based on thermo-responsive hydrogels [7], or on shape memory alloy (SMA) elements [8] embracing the bladder. Nevertheless, these devices have been designed for small animal bladders, and several challenges have to be faced in order to upscale these designs to achieve effective solutions for humans.

In this paper, we propose a new kind of implantable artificial detrusor based on a fluidic actuation strategy, with the aim of exploring an intrinsically safe approach for controlled bladder voiding. Indeed, fluidic systems have already been demonstrated to be a successful solution in many different applications, such as direct cardiac compression (*i.e.*, artificial myocardium) [9] or valve systems in the widespread commercial artificial sphincter AMS 800™ [10].

The proposed solution is composed of two identical, hull-shaped actuators embracing the natural bladder. Each one consists of a water-filled chamber made of soft silicone skin enclosing a flexible acetate origami skeleton with a '*waterbomb*' pattern [11]. This kind of origami has proven a volumetric contraction of up to 90% at a depression of –60 kPa in a shape-morphing actuator [11]. It has been exploited for self-expanding stents [12] but not yet for implantable artificial prostheses.

In our device, the significant shape change of the waterbomb origami guides that of the whole artificial detrusor. From a domed shape at rest, the two actuators become almost flat when they are depressurized, subtracting space from the inside bladder and thus assisting its voiding.

For operating the system, a liquid was selected instead of gas for safety reasons. Indeed, an implantable gas reservoir would require storing the gas at moderate to high pressures for all of the device life, with a high risk of bursts [13]. On the contrary, a liquid medium can be stored at the same abdominal pressure, thanks to a higher force-to-volume ratio [14]. Water was used in the current design, but it might be easily replaced by an isotonic saline solution.

Two different sizes of the *waterbomb* origami were compared in terms of produced bladder voiding efficiency. The design, manufacturing, and used experimental setup are presented in Section II. The results of the voiding performances are reported in Section III. Finally, in Section IV, the added value of the proposed work in the field of implantable urinary prostheses is discussed.

II. Materials and Methods

A. Design overview

The proposed artificial detrusor muscle relies on two identical fluidic actuators, which are bound together by a surgical thread and can totally embrace the human bladder (Fig. 1a). The two-module design allows for a convenient surgical procedure for the prosthesis implant, in which no temporary resection of the urinary ducts (ureters and urethra) is needed.

Each actuator is featured by a semi-rigid sheet shaped as a *waterbomb* origami and enclosed between two ellipsoidal, soft but inextensible skins (Fig. 2c). These two skins delimitate the actuation chamber, which is filled with the service fluid by means of a rigid tube, connected to a miniaturized fluidic circuit. When the fluid is drawn out of the chamber, the generated depression promotes a shape switch of the origami skeleton from a domed configuration to a contracted and flat one. Indeed, the soft chamber pulls the adjacent sheet crests of the origami one towards the other during depressurization, since the skins cannot extend. The shape transition of the actuators produces a uniform contraction force over the natural bladder, promoting its voiding.

To evaluate the effect of different origami cell square sizes (SQ in Fig. 1b) on the contraction capabilities of the bladder, two different detrusor models are proposed.

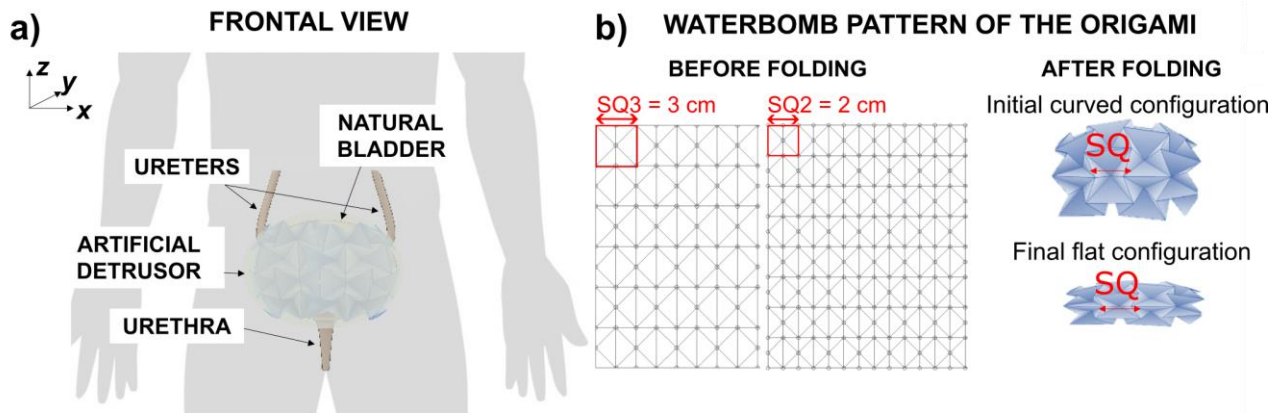

Fig. 1: (a) Drawing of the fluidic artificial detrusor in situ, installed around the urinary bladder (one of the two actuators is visible). (b) Structure and operating principle of the *waterbomb* origami. SQ = squared cell size.

The 'SQ3' model origami skeleton consists of 6 x 4 square cells with a side of 3 cm and 1 mm-thick silicone skin; while the 'SQ2' model origami skeleton consists of 8 x 6½ cells with a side of 2 cm and 0.5 mm-thick skin.

B. Fabrication method

The artificial detrusor was fabricated following four phases (Fig. 2). Firstly, two origami skeletons (one for each actuator) were realized by engraving through a laser cutting machine the *waterbomb* pattern on a semirigid sheet, composed by the stacking of 0.16 mm-thick acetate (EVA), 0.07 mm-thick polyethylene (LDPE), and thin double-sided tape (in between) (Fig. 2a). The pattern was folded manually.

Secondly, the two skins composing the fluidic chamber of each actuator were fabricated by molding a soft silicone (Ecoflex™ 00-30, Smooth-On, Inc., USA) in which a medical gauze was embedded prior to curing (Fig. 2b). The gauze gives the skin inextensible yet flexible properties. The used mold was designed in the SolidWorks CAD software, and 3D-printed.

Subsequently, the single actuator was assembled by sewing with a thin thread the origami skeleton to one of the skins, which in turn was sewed to the second one (Fig. 2c). Then, the chamber was hermetically closed by pouring some fresh silicone all over the seams and a polyurethane tube was fastened to the outer wall with silicone glue (Sil-Poxy™, Smooth-On, Inc.).

Finally, the hydraulic artificial detrusor is obtained by tightly sewing the two actuators around the natural bladder upon implantation (Fig. 2d).

C. Characterization of the detrusor voiding performances

For the evaluation of the effectiveness of the proposed solution, the prosthesis was tested on *ex vivo* adult swine bladders, whose sizes are similar to the human bladder.

The electro-hydraulic circuit drawn in Fig. 3 was exploited for this purpose. It included two operative lines:

- *Line 1*, connecting a syringe pump (NE-1000, New Era Pump Systems, Inc., USA) to the two actuators around the bladder and to a reservoir. A differential pressure sensor (MPX5100DP, Freescale Semiconductor, Inc., USA, interfaced to an Arduino™ Mega 2560 connected to MATLAB™ R2021b) was placed just upstream of the detrusor actuators to monitor the inlet pressure.
- *Line 2*, connecting the *ex vivo* bladder to a collection reservoir placed onto an electronic scale (WLC 2/A2, Radwag, Poland). This allowed recording the ejected simulated urine weight for deriving the ejected volume over time, $V_{out}(t)$. In addition, a second MPX5100DP sensor was placed just downstream of the bladder to monitor the intravesical pressure. The micturition was allowed via a two-way manual valve emulating the natural sphincter.

A micturition test was conducted by: (*i*) filling the actuators with water by exploiting Line 1; (*ii*) filling the bladder with water by a manual syringe, at a volume (V_u) corresponding to an intravesical pressure of 3.0 kPa – this value was chosen from the literature, being below the average threshold of self-urination reflex triggering (*i.e.*, 4.3 kPa) [15]; (*iii*) opening the artificial sphincter contemporarily to the actuation start by triggering the syringe pump.

During the assisted micturition, time and ejected volume on the scale (V_{out}) were recorded. All tests were conducted with the bladder oriented horizontally to simulate the worst condition for voiding (*i.e.*, bed-ridden patient). The micturition was allowed until the V_{out} increment was lower than 0.03 g in the last 50 samples, corresponding to ~8 s with the used laptop.

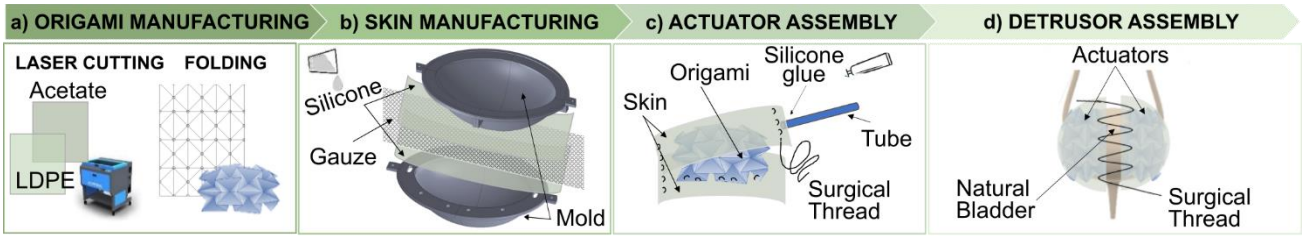

Fig. 2: Manufacturing procedure of the fluidic artificial detrusor.

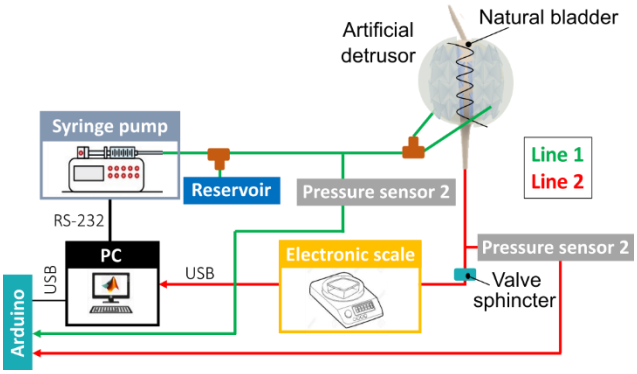

Fig. 3: Experimental setup for the ex vivo characterization of the fluidic artificial detrusor. Line 1 connects the syringe pump to the detrusor, Line 2 connects the natural bladder to a collection pool on an electronic scale.

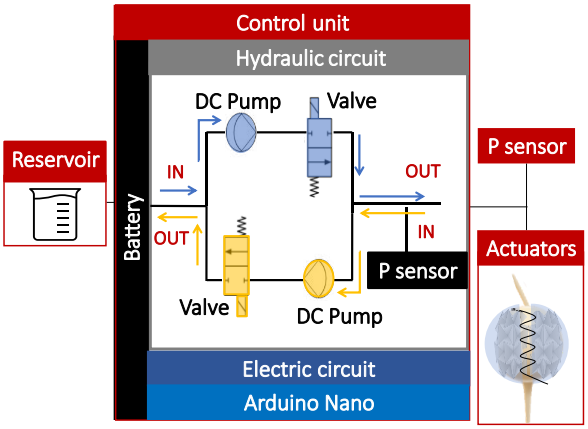

Fig. 4: Schematic representation of the compact micropumps-based control unit for the prosthesis actuation.

For each detrusor model (SQ2 and SQ3), two parameters of the micturition were considered as performance indicators of the prosthesis: (*i*) the Voiding Efficiency (VE [%]), *i.e.* the ratio of V_{out} and V_u (target VE value 90%); and (*ii*) the Post-Voiding Residual volume (PVR [mL]), *i.e.*, the urine in the bladder when the micturition was ended (target PVR value below 50 ml [16]). Each parameter was tested on bladders surrounded by the artificial detrusor, oriented horizontally, in the 'active' and 'passive' states (namely, with detrusor units activated and not activated), and for both the SQ3 and SQ2 designs. Moreover, each configuration was tested 4 times on 3 different *ex vivo* bladders, to include also the role of biological variability.

D. Driving circuit design

A first prototype of a compact electro-hydraulic circuit was developed to manage the activation of the artificial detrusor. As shown in Fig. 4, the circuit comprises two opposite hydraulic lines to drive water from the actuators to a reservoir during the contraction phase (actuator ON, in yellow), and from the reservoir to the actuators for restoring the initial state (actuator OFF, in blue).

A micropump for liquids (SP 270 EC-L, Schwarzer Precision, Germany) and an electromagnetic 2-way valve (Series 3, Parker Hannifin, USA) are integrated into each line. The output of an MPX5100DP differential pressure sensor is used to stop the water flow and close the electro-valves at the pre-defined *P* pressure thresholds for each state. The logic of the system is managed by an Arduino™ Nano 3 microcontroller connected to MATLAB R2021b on a Windows PC.

A powering circuit provides 5 V to the pumps and to the Arduino, while 12 V to the electro-valves. The source is a 7.4 V battery.

The designed control unit was tested with the artificial detrusor positioned on an *ex vivo* swine bladder, placed inside a human manikin (Fig. 5). Surrounding organs were simulated by placing other swine *ex vivo* tissues around the prosthesis. Only the SQ3 model, featuring higher performances on bench, was tested also in the simulated environment.

III. Results

A. Voiding performances in ex vivo setup

The results of VE and PVR obtained from the *ex vivo* tests are reported in Fig. 6.

The tests performed with active micturition yield significantly better results compared to the passive one, especially for the SQ3 model (VE increases by ~ 1.5 times and PVR decreases by ~ 4 times). Indeed, a VE of 91% and an average PVR < 10 mL is reached with the actuation of the SQ3 model, while VE of 75% and PVR < 30 mL are obtained with the SQ2 model.

The performances of the SQ3 model are particularly good compared to the SQ2, since the origami with a lower fold density (SQ3) is found to contract more at the same depression grade. Considering the results obtained for assisted urination, the use of the actuation system allows for a more effective urination.

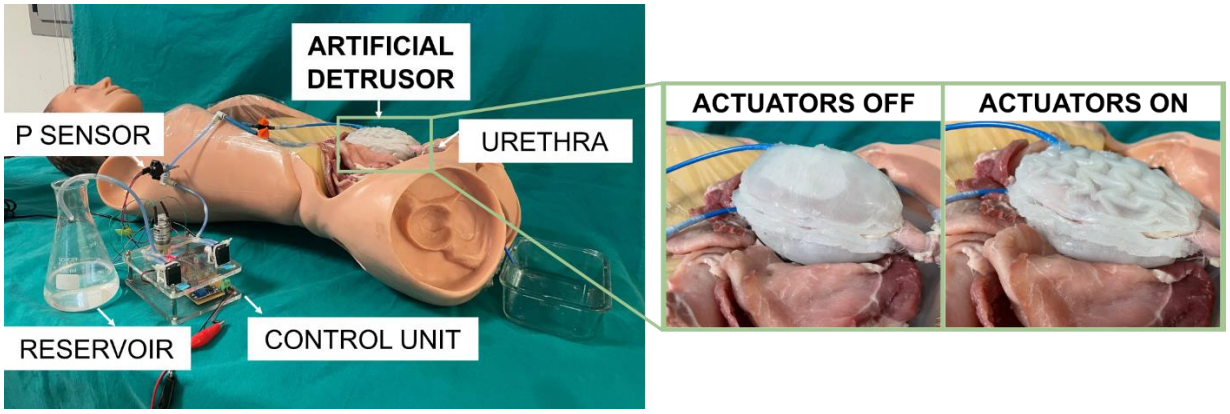

Fig. 5: Photo of the fluidic artificial detrusor in a simulated anatomical environment, connected to the first prototype of the control unit. *Ex vivo* tissues placed above the prostheses during the tests are here removed for visualization purposes. The prototype is mounted around an *ex vivo* swine bladder.

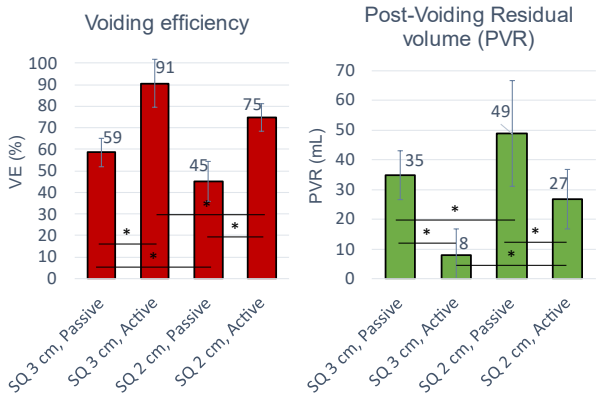

Fig. 6: Experimental results of the micturition quality evaluated by: voiding efficiency (VE [%]) and post-voiding residual volume (PVR [mL]). * denotes *p-value* < 0.05 in two-population *t*-test with the specified groups (*a* = active, *p* = passive urination).

B. Voiding performances in the anatomical simulated environment

When located among the simulated surrounding organs (Fig. 5), the fluidic soft robotic detrusor demonstrated an active VE of 84.8% ± 7.4%, which is similar to the results observed during bench tests.

IV. Discussion and Conclusion

In this work, we proved the feasibility of using a hydraulic, origami-based soft actuator as an artificial detrusor for controlled micturition. It is the first time that such strategy is applied to urinary system – while fluidic devices for direct cardiac compression are present in the literature [9], [17].

The advantage of using the *waterbomb* origami as a core element for the actuation is the large contraction stroke achieved on the bladder. The shape of the proposed artificial detrusor was found essential to produce acceptable voiding degrees on a thin and hollow organ such as the bladder. Indeed, we were able to obtain VE around 90% and PVR below the clinical warning threshold of 50 mL, both on the bench and in a simulated environment.

Some research-stage prototypes of implantable artificial detrusors have been proposed in the last five years (*e.g.*, based on thermo-responsive hydrogels [7], shape-memory alloy wires [8], and magnetic solutions [18]). All these devices share with our fluidic detrusor the easiness of implantation, and comparable voiding performances (respectively of ~75% in [8] and 90-100% in [18]). However, the proposed artificial detrusor is featured by an inherent safety (no heating of elements in direct contact with organs, nor high current/ voltages needed), the uniformity of the compressive action on the bladder, and the use of low-cost electro-mechanic components.

Compared to the temperature-based and magnetic coupling-based approaches, our prosthesis suffers from higher encumbrance and weight, due to the presence of the service fluid. Based on the above considerations, future developments on fluid-based detrusors will include a redesign of the origami-based actuators to reduce the hull thickness and the actuating water volume. Furthermore, to allow full system implantability, the stand-alone control circuit – here successfully tested – will be miniaturized, powered by a single rechargeable battery, and endowed with autonomous firmware for wireless operation.

In conclusion, this work represents a valuable contribution to the field of implantable and totally artificial biorobotic organs, specifically for coping with the challenge of assisted voiding of the inactive bladder.

***Abstract*— In recent years, the integration of virtual reality (VR) technology is seeing a significant increase and has the potential to greatly impact the future of healthcare. The use of VR systems in conjunction with electroencephalography (EEG) offers new possibilities in rehabilitation scenarios. This study focuses on comparing the feasibility of using a head-mounted display (HMD) while acquiring EEG data in both semi-immersive and fully immersive environments. The impact of an Oculus Quest 2 on the frequency domain of 64-channel EEG measurements recorded on healthy subjects was investigated by performing six different tasks, including a 3D video game.**

Results showed statistically significant differences in beta and gamma frequency bands with and without the use of the HMD. Also, significant differences were found in the occipital brain region while playing the 3D video game with the HMD vs desktop mode due to the introduction of the immersive visual feedback.

Based on our preliminary findings, future studies will test the feasibility of combining HMDs and EEG headsets before running EEG brain-computer interface studies.

***Keywords*—virtual reality (VR), electroencephalogram (EEG), rehabilitation, human-computer interaction (HCI).**

I. Introduction

VIRTUAL reality (VR) is a next-generation technology and VR applications have the potential to revolutionize healthcare and rehabilitation treatments [1]. VR technologies emulate a virtual environment that immerses the user to experience the concept of "being there", such as a realistic representation of themselves in the VR setting.

There are three types of VR: i) non-immersive virtual experience; ii) semi-immersive VR; iii) immersive VR. Non-immersive VR uses a computer or a video game console with an embedded computer-generated environment and keyboard or other controllers, allowing the user to keep control of their physical environment. Semi-immersive VR provides users with a partially virtual environment, including 3D graphics game applications to improve a more immersive feeling, high-resolution displays, and computers. Lastly, fully immersive VR gives users the most realistic simulation experience. In this case, the user needs VR glasses, or head-mounted displays (HMDs) and 3D game applications installed on the HMD or on a laptop connected to the HMD [2].

The use of VR is rapidly increasing in healthcare and research applications, and it is often combined with other wearable sensors and technology. Virtual environments offered via VR technology make it possible for individuals with disabilities who undergo rehabilitation therapies (e.g., individuals with cerebral palsy, amyotrophic lateral sclerosis, ALS, multiple sclerosis, etc. [3-4] to perform physical tasks in a fun way in more naturalistic settings like those encountered in real life, instead of, for example, watching a video of someone showing the exercises [5]. There is an increasing need to investigate how VR can be used in combination with other wearable devices, especially in research protocols that include hardware and electrodes positioned close to the HMD systems. Existing VR simulators rely on joysticks or hand trackers, which are unusable for individuals with severe upper limb (UL) motor impairments. Eye-tracking and voice recognition may be alternative solutions, but they are not always suitable for people with visual, speech, and motor impairments. In this context, brain-computer interfaces (BCIs) would constitute an innovative control interface for most individuals with UL motor impairments [6]. Related to this context, in recent years, there has been an increase in studies that employed both VR and electroencephalography (EEG) headsets focused on cognitive and neuromotor rehabilitation. For instance, BCIs have already been integrated into VR systems for neurorehabilitation and game entertainment [7]. A few studies tried to control a virtual wheelchair via BCI achieving high performance using motor imagery EEG-BCI [8], EEG event-related desynchronization BCI, and tactile P300 BCI [9].

A few studies compared brain activity in virtual and non-virtual environments [10-13]. Also, there is an urgent need for frameworks and guidelines to combine VR and EEG headsets and headcaps. In fact, current HMDs may affect the EEG signal quality due to the sensor positions. Differences in the frontal midline theta rhythm may be due to the effect of being in a virtual setting, as shown in cognitive visuospatial tasks by comparing HMDs and computer displays [10] during VR-EEG data collections. However, it has been proved that HMDs may introduce artifacts in frequencies beyond 50Hz during eyes-open and eyes-closed tasks [12]. Considering the recent advances in EEG and VR technologies [14-15], we should carefully consider previous findings due to the differences in the hardware and sensor montages of the systems available in the market and deeper research should be conducted. Previous studies [11-13] conducted data collection via Oculus Rift (Facebook Technologies LLC, 2018) or HTC Vive Pro devices (HTC Corporation, 2018), and a 64-channel wet-gel electrode EEG cap (WaveGuard ANT Neuro) [12], or an 8-channel wet-gel electrode cap (g.LADYBIRD, Guger Technologies) [11], or Oculus Quest 2 (Facebook Technologies LLC, 2021) combined with the NextMind (NextMind, 2021), a commercially available sensor for entertainment with 8 dry electrodes, placed on the back of the head [13].

In this study, we aimed to compare for the first time, EEG

data collected using a 64-channel wet-gel electrode EEG cap eego™sport (ANT Neuro, Hengelo, Netherlands) with and without the VR HMD Oculus Quest 2 through 6 different tasks, including one using a three-dimensional (3D) game developed to simulate wheelchair driving tasks, by using semi-immersive and fully-immersive VR. Through this feasibility study, we want to explore the possibility of controlling a 3D game application for HMD through an EEG-BCI, exploring the possibility of combining EEG and VR technologies.

II. Material and Method

A. Experimental setup and procedure

To compare the EEG signal quality during standard EEG data collection (i.e., no-VR condition) and VR-EEG one (i.e., VR condition), we prepared a protocol to be repeated once wearing only the EEG cap and once while participants also wore the HMD. Participants were then asked to perform six tasks during the two conditions, as follows:

1. Eyes-closed task: keeping head still and eyes closed.
2. Eyes-open task: keeping head still and eyes open.
3. Teeth grinding task: forcefully clenching and unclenching the jaw while maintaining a still head position.
4. Head rotation task: rotating the head repeatedly to the right and left.
5. Head elevation task: repeatedly head up and down tilting.
6. 3D game task: playing a video game to move forward a wheelchair on a basketball court following a specific path.

Participants executed the tasks first without and then with the HMD. For each condition, the first 5 tasks lasted 30 seconds each. All tasks were repeated five times consecutively. During the no-VR condition, participants were asked to look in front of them and listen to the researcher's instructions. During the VR condition, participants were instructed to navigate in the HMD menu environment during 1-5 tasks and listen to the researcher's instructions. As such, participants were placed in a 3D menu environment without being asked to perform any additional VR tasks that required cognitive efforts. These tasks aimed to evaluate how the coupling of the HMD with the EEG headset affected the reliability of the signals, while task 6 was used to investigate the effect of fully immersive VR on the quality of the EEG signals. Participants were asked to play a 3D game where they had to control a wheelchair avatar, navigating from a starting point to an endpoint. This task was conducted in two modalities, semi-immersive (Desktop mode) and then fully immersive (HMD mode). Both modes were played wearing the EEG cap as follows:

- Desktop mode: participants played the game on a computer desktop using a keyboard to control the wheelchair and a mouse to control the avatar's visual field. To avoid EEG artifacts, participants were asked to only move their fingers on the keyboard/mouse.
- HMD mode: participants played the same video game immersed in 3D VR using the HMD and two VR controllers positioned in their hands.

B. Electroencephalography acquisition

EEG signals were acquired via the eego™sports amplifier (ANT Neuro, Hengelo, Netherlands) and a 24-bit resolution and 64-channel wet-gel electrode EEG cap (WaveGuard, ANT Neuro, Hengelo, Netherlands). The 64 scalp positions were positioned according to the 10-20 system [16]. Ag/AgCl electrodes were filled with conductive gel and the superficial layers of the skin were abraded using a blunt needle. The reference electrode was placed at Cz and the signal was sampled at 512 Hz.

C. Head-mounted display (HMD)

An Oculus Quest 2 HMD (Facebook Technologies LLC, 2021) and two Oculus Touch Controllers were used in this study.

D. 3D video game

The 3D video game was developed to enhance the driving skills of individuals with neuromotor disabilities who require powered wheelchairs. The game was designed to be suitable for both laptops and HMD devices. It was developed using the Unity Game engine and C# programming language. The game includes several driving levels but for the aim of this work only the moving forward level was played. The levels of difficulty can be adjusted through the 1-5 speed levels. In our protocol, speed level was set to 3. Figure 2 (a) shows the scenario and the path (from the green square to the red one) that each participant was asked to follow. Figure 2 (b) shows the avatar wheelchair. To start the level, participants had to press the X button on the left controller, and then move the joystick on the right one to control the wheelchair avatar.

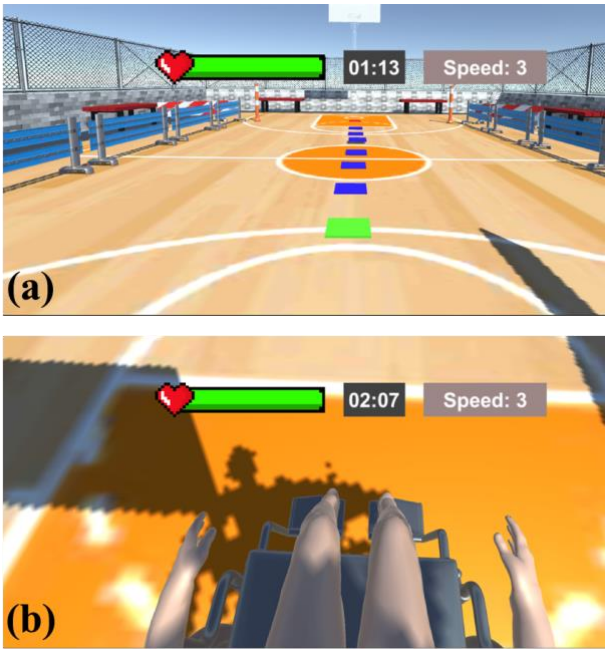

Fig. 2: 3D video game: (**a**) frontal view and (**b**) lower view.

E. Data processing

EEG signals were processed using both Python and MATLAB™ R2022a.

Figure 3 illustrates an overview of the signal processing pipeline applied to compare EEG (no-VR condition) vs VR-EEG (VR condition) scenarios.

All signals were collected during both conditions and the same pipeline was applied to all recordings.

Pre-processing consists of normalizing the signals with respect to the maximum absolute value. Signals were then filtered with a 0.1 Hz High-Pass and a 40 Hz Low-Pass Butterworth Filter (3rd order) [17], both of which were applied in a forward and backward direction using the *filtfilt* function from the SciPy library.

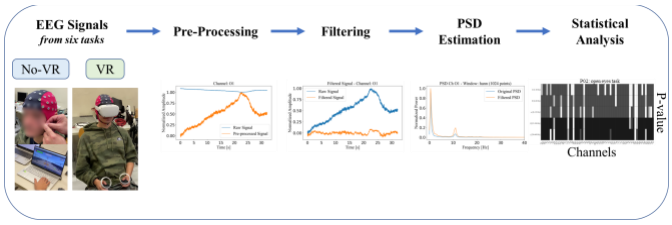

Fig. 3: System overview. EEG signals are processed through a pipeline that includes a pre-processing stage composed of LP and HP filters, in order to obtain an accurate PSD estimation for statistical analysis. Plots refer to participant P02 and channel O1 during the Eyes-open task.

Lastly, Power Spectral Density (PSD) was calculated using the Welch method [18], built into the SciPy library [19].

EEG signals were windowed using a 2-second Hanning window and spectra were represented with 1024 points.

Power spectra were then divided into frequency bands: delta, theta, alpha, beta, and gamma [12].

F. Statistical analysis

VR and no-VR conditions were compared for each task and for each participant by applying a Wilcoxon signed-rank test to the PSD frequency-band arrays through the built-in MATLAB function.

III. Results

Two able-bodied individuals no visually-impaired (P01 and P02, age range = 24–25 years, median age = 24,5 years, both males) without neurological and psychological conditions participated in this study. Both participants conducted 1 session performing the 6 tasks in both conditions. PSD arrays extracted for each frequency band were analyzed, comparing the VR and the no-VR conditions. For the first 5 tasks, p-values showed very high statistically significant differences ($p<0.001$) in beta and gamma bands among most of the channels. Lower or moderate differences ($0.01<p<0.05$) can be detected below 12 Hz. A few channels reported no significant differences but there was no consistency among the 5 tasks for both P01 and P02. As an example, Figure 4 graphically shows the p-value results for the eyes-open task from the P02's recording while the same behavior is confirmed for the other tasks as well.

PSD values extracted while the participants conducted task 6, were used to evaluate fully and semi-immersive scenarios to investigate the effect of immersive VR via HMD on EEG signals. The Wilcoxon Signed-Rank test was applied to compare the VR via HMD mode and the no-VR via Desktop mode showing high statistically significant differences ($p<0.001$) in the occipital and parietal-occipital channels among all the frequency bands and for both participants, demonstrating the impact of the VR visual stimuli on the brain activity.

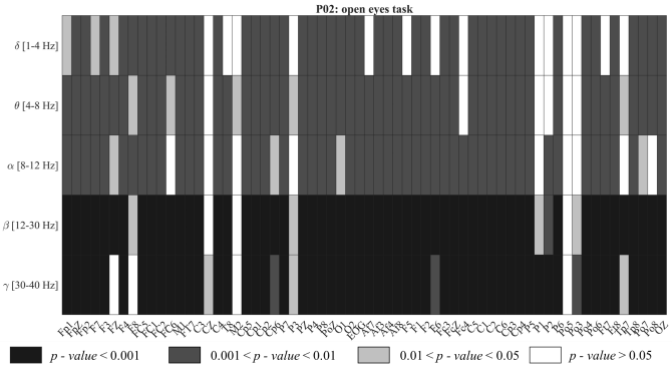

Fig. 4: Graphical representation of the p-values obtained comparing VR and no-VR conditions for participant P02 during the execution of task 2 (eyes-open task).

We compared channels P1-8, Pz, PO3-8, POz, O1, O2, and Oz, focusing on the brain activity of the occipital sulcus, as this is the region known to be involved in the early stages of processing visual stimuli [20] and the parietal area due to its correlation characteristics with the cognitive function considered in this study.

By analyzing the signals from these channels, we were able to gain insights into how immersion level and gaming activity affect the brain's response to visual inputs.

A graphical representation of the results is provided in Figure 5 which demonstrates that the statistically significant p-values were obtained for the isolated channels related to the occipital and parietal brain regions. Figure 5 helps to visually convey the significance of the results and can aid in identifying the impact of immersion level on EEG signals in each channel of the investigated brain regions for each frequency band.

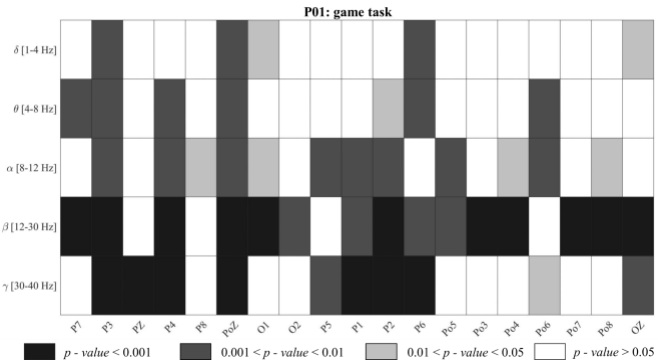

Fig. 5: Graphical representation of the p-values obtained in the occipital and parietal brain regions by comparing VR (HMD mode) and no-VR (Desktop mode) conditions of participant P01 during the execution of task 6 (3D game task).

IV. Discussion

Our preliminary results show that the use of HMDs for VR affect the brain activity measured by EEG caps with a lower impact on the lower frequency bands (<12 Hz) and a higher effect on beta and gamma bands. This is an important finding as the literature was inconclusive on whether the discomfort reported by some users of HMDs or the hardware montage could potentially impact the results. However, our results are in contrast with a previous study [12] where eyes-open and eyes-closed tasks were applied by comparing Oculus Rift and

HTC Vive Pro technologies and 64-channel EEG ANT Neuro system. In fact, Weber et al. [12] showed that HMDs consistently introduced artifacts, but they were negligible below 50 Hz. The different findings may be due to the different technologies applied in our study or to the fact that we used a different protocol pipeline.

We also observed that visual effects in semi-immersive and fully immersive scenarios appear to affect the brain activity differently, specifically in the occipital sulcus, which is responsible for processing visual stimuli.

However, while this study provides valuable insights, it will be necessary to recruit more participants and establish specific inclusion criteria, to validate these findings with a larger dataset. Additionally, while the quality of the signals obtained were deemed acceptable, multiple recordings and sessions of each task should be acquired and compared.

Our results indicate that there are statistically significant differences in beta and gamma frequency bands between fully immersive (HMD mode) and semi-immersive VR (Desktop mode), suggesting that HMDs could potentially raise concerns at these frequency ranges when compared to what is observed in the EEG signals collected while playing desktop 3D game applications. The underlying cause for this phenomenon is currently unclear and further research is needed to investigate this behaviour. One possible approach would be to design a task that gradually increases in difficulty, resulting in a higher cognitive workload. It is expected that as the task demands increase, there will be a corresponding increase in beta and gamma activity. Additionally, a longer acquisition period and an investigation of the time-frequency domain could provide valuable insights as the task progresses, as beta and gamma activity may become more pronounced toward the end of the task.

The comparison between the fully immersive and semi-immersive scenarios served as a foundation for future studies that will implement additional tasks. The main objective of this feasibility study was to establish the feasibility of obtaining valid information from EEG signals when using a BCI to control a 3D game via HMD. Based on our preliminary findings, further investigations are required, and future studies should test the feasibility of combining HMDs and EEG headsets before running EEG brain-computer interface studies.

Wearable tactile display of softness for virtual reality

G. Frediani, F. Carpi*

***Abstract*—Human-machine interfaces are currently challenged by the lack of effective, comfortable and affordable actuation technologies for wearable tactile displays of softness in virtual-reality environments. They are especially needed for applications like virtual reality-based medical training, tele-rehabilitation, tele-manipulation, tele-presence, etc. The state of the art does not offer wearable devices that can combine proper functional properties with simple structure, low weight, low size and electrically safe operation. Recently, we described a tactile display technology that uses fingertip-mounted small inflatable chambers, pneumatically driven by a compact and cost-effective portable unit. Here, we present ongoing investigations on the tactile perception of softness that can be induced by this kind of display when it is used in combination with virtual-reality environments.**

***Keywords*—Wearable, Tactile, Haptic, Softness.**

I. Introduction

MIMICKING the sensation of touching virtual objects that are soft is a major goal for the next generation of multi-sensory human-machine interfaces. Indeed, physically displaying the softness of a computer-generated item is essential to enable a diversity of virtual- or augmented-reality systems, for various possible uses. In the biomedical field, this is especially relevant for a variety of applications, including simulators for training of medical professionals in the palpation of soft tissues [1], tele-operation systems [2] and tele-presence systems for social interactions augmented by the sense of touch [3]

In order to mimic with high accuracy and realism the tactual feeling produced by the indentation of a soft object with a fingertip, so-called haptic displays are needed. They are conceived as interfaces ideally able to provide users with both tactile feedback and kinaesthetic feedback. Nevertheless, Srinivasan and LaMotte have demonstrated that, for the perception of the softness of objects having a deformable surface (and not just being compliant with a rigid surface), tactile feedback alone is sufficient, whilst kinaesthetic feedback alone is insufficient [4]. This has been interpreted as due to the fact that, for any applied force, the object's compliance determines the deformation of the fingertip's skin, and therefore it can adequately be encoded by cutaneous mechanoreceptors [4]. This is consistent with later evidences on the importance of the variation of the contact area between fingertip and object [5]-[7], such that the change in contact area has been proposed as a new proprioceptive cue [8].

As an implication, the softness of virtual objects cannot be rendered using the various existing haptic displays that provide purely kinaesthetic feedback, such as those reviewed in [9]. The simplest effective approach is to rely on purely tactile feedback, using so-called tactile displays.

Furthermore, in order to enable free motions of the hands while performing a virtual- or augmented-reality task, the tactile displays should be wearable, i.e. sufficiently small and light to be arranged on fingers [9].

Another important aspect to be considered for the design of devices capable of realistic tactile feedback is the role played by different tactile cues in the perception of softness. Although this aspect is still a matter of discussion [10], Dhong et al. have demonstrated that, besides the contact area, the indentation depth is another essential tactile stimulus and that they independently concur to the perception of softness [11]. This means that tactile displays that control only the contact area or only the indentation depth are expected to be less effective than devices that could control both of them [11]. Therefore, softness rendering cannot effectively be achieved with the variety of wearable tactile displays that apply forces to fingertips via stiff surfaces, which are however very performing in generating force feedback, especially for shape rendering [12]-[17]. Indeed, such displays just control indentations of the skin and, as discussed by Srinivasan and LaMotte, for an interface that generates a force via a rigid surface, the pressure distribution over the fingertip and the associated deformation of the skin (and so also the contact area) are independent of the interface's compliance; therefore, in this situation, compliance cannot adequately be inferred by the information gathered by the mechanoreceptors [4].

Based on these evidences, the most effective strategy to physically render the softness of a virtual object is to use tactile displays able to deliver quasi-static (non-vibratory) forces, via a soft interface (deformable surface), so as to control both the contact area and the indentation depth.

This can be achieved in different ways. An example is to use rotary motors driving flexible/stretchable structures (e.g. polymer membranes or fabrics), which however typically lead to complex, bulky and heavy mechanisms [18]-[19]. An alternative approach is to use soft materials (elastomers) in a way that allows them to be deformed without complex mechanical transmissions from an actuation source; this concept has been investigated with three technologies: dielectric elastomer actuators (DEAs), electrostatic actuators and pneumatic actuators. DEAs, consisting of electrically deformable elastomeric membranes [20], can be used for non-vibratory fingertip displays suitable for softness rendering, although their main limitation is the need for high driving voltages, which requires challenging future developments [21]. Likewise, high driving voltages are a disadvantage of purely electrostatic actuators [22]. Conversely, electrically safe, compact and lightweight

devices can be designed using pneumatic actuation, as the driving source can be displaced remotely. Recently, we described a wearable pneumatically-driven fingertip display of softness, which combined effective functionality with a simple structure, low weight and low size (not only of the wearable interface but also of its driving unit) [23].

Here, we present ongoing investigations on the tactile perception of softness that can be induced by that kind of display when it is used in combination with virtual-reality environments.

II. Materials and Methods

A. Structure and principle of operation of the softness display

Fig. 1 presents the structure of the device. It consists of a small plastic chamber, which is closed by a thin elastomeric membrane and can be pressurised with air, in order to deform the membrane.

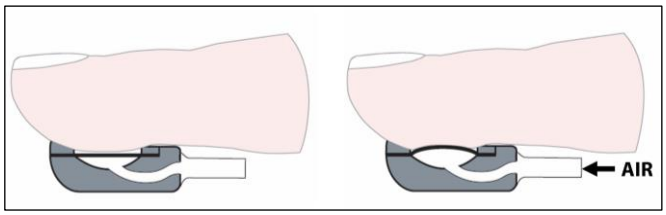

Fig. 1: Schematic drawing of the structure and principle of operation of the softness display.

An ergonomic shape of the plastic chamber allows it to comfortably conform to adult finger pulps. By securing the device to a fingertip, the actuation of the membrane can be used to indent the finger pulp and increase the contact area, as well as the applied force. As recalled in the Introduction, these features make the tactile display suited to mimic contact with soft bodies.

B. Manufacturing of prototype samples of the softness display

A prototype sample of the display is shown in Fig. 2. The internal chamber had a diameter of 12 mm, which was chosen as a (non-optimised) trade-off between the needs for maximising the contact area with the fingertip (so as to maximise the perceivable force) and minimising the device encumbrance. That size was consistent with the average width of thumb and index finger pulps among participants to a psychophysical test described in the following. The display's weight was ~3 g.

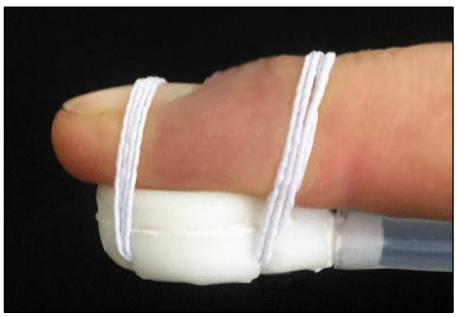

Fig. 2: Prototype sample of the softness display.

The display was manufactured using a commercial PDMS membrane (Elastosil, Wacker, Germany) having a thickness of 70 µm. The plastic parts were 3D printed. A room-temperature-vulcanising silicone was used to fix two plastic parts together (avoiding screws), so as to constrain between them the elastomeric membrane and seal the chamber.

C. Assembly of an electro-pneumatic control unit

An electro-pneumatic control unit was developed with a compact design and a low-cost architecture. It was based on a small pump, six valves and pressure sensors, as well as a microcontroller. It was USB connected to a personal computer, so as to be driven by any external software via serial communication. A custom script for the microcontroller was developed to control the pressure values of up to three fingertip displays independently. The total weight of the unit was 380 g, which made the technology easily portable, as shown in the image presented in the next section (Fig. 3).

D. Psychophysical tests

The system was investigated with psychophysical tests, consisting of an experiment of Just Noticeable Difference (JND). The experiment involved fifteen volunteers and was conceived as a comparison of the softness between two virtual objects, whose compliance was simulated and rendered on three fingertips using the tactile displays. Fig. 3 shows the experimental setup and the virtual environment used to perform the tests.

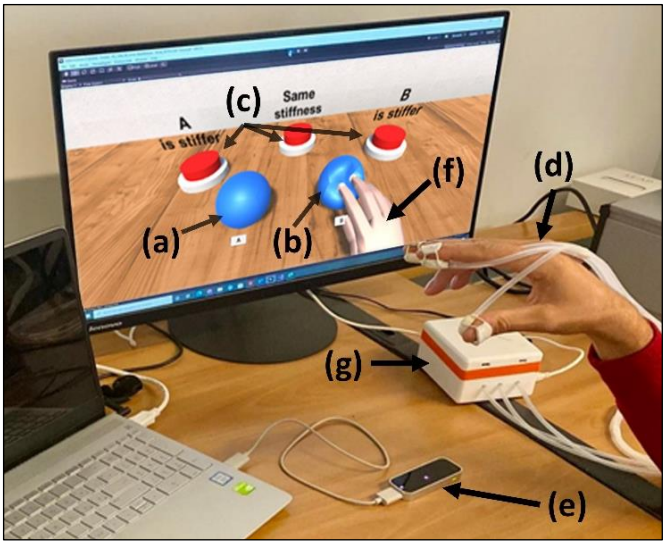

Fig. 3: Experimental setup of the psychophysical tests. The virtual environment showed a reference sphere (a) and a comparison sphere (b), both deformable, and three buttons (c) used to collect the subject's evaluation of the difference in softness between the two spheres. The movements of the real hand wearing three tactile displays (d) were tracked by a commercial optical sensor (e) and mapped within the virtual environment as movements of an avatar hand (f). A custom-made pneumatic control unit (g) supplied independent levels of pressure to the three fingertip-mounted tactile displays.

The participant was asked to wear three displays on three fingers (thumb, index and middle fingertip of their dominant hand) and to interact with a virtual environment, displayed on a computer screen, as described below.

A custom-made virtual environment was developed using the software Unity. It included an avatar hand, which mapped the movements of the real hand wearing the tactile displays. The movements of the real hand were continuously tracked by using a desktop optical sensor (LEAP Motion, USA), arranged below the hand (Fig. 3). The virtual environment showed to the participant two deformable objects (blue spheres) to be compared in terms of softness. In order to avoid a visual bias, the two spheres were identical and intentionally did not represent any specific item which could recall a 'familiar' level of softness.

The three fingers of the avatar hand could interact with each sphere, by deforming it in different ways. As a result of the indentation of the sphere by each finger (Fig. 3), a pressure was rendered on the corresponding real fingertip by the pneumatic control unit, driving the related tactile display. The three levels of pressure applied to the three fingers were independent, according to the actual extent of indentation by each finger.

The subject was asked to comparatively probe the two spheres and to evaluate which of the two was perceived as stiffer, or whether no noticeable difference could be appreciated. The subject had to express the evaluation by pressing, with the avatar hand, one of the three buttons available in the virtual scene (Fig. 3), corresponding to three possible cases: sphere A stiffer; sphere B stiffer; same stiffness.

The pressure provided to each fingertip in response to any given indentation was controlled according to a compressive stress-indentation curve associated to the sphere. Different curves were considered, so as to simulate materials with different softness. In particular, the test used the five stress-indentation curves presented in Fig. 4.

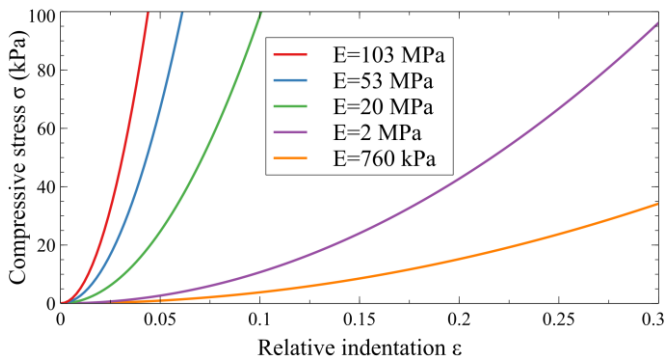

Fig. 4: Stress-indentation curves considered for the JND test, in order to simulate five materials having a different Young's modulus *E*, as indicated in the legend.

The association of any given curve to a sphere was used to create a tactile feedback that mimicked the perceptual experience of touching a real object with those mechanical properties. Indeed, as an avatar finger squeezed the sphere, the occurring variable virtual indentation was continuously monitored by the system, which reacted by driving the related tactile display with pressure levels equal to the corresponding compressive stress values given by the curve.

Each participant performed a sequence of tactile perceptual tasks. Each task was aimed at determining a JND, as the minimum noticeable difference of Young's modulus between the two virtual spheres. The test was accomplished according to the following procedure.

The algorithm initially fixed the reference sphere's Young's modulus E_R, by randomly selecting it among the pre-defined set of five values reported in Fig. 4. The comparison sphere's Young's modulus E_C was randomly selected from the remaining values of the set. The subject was asked to probe the two spheres as many times as needed, in order to evaluate the difference in softness between the two spheres, and finally express the evaluation by pressing with the virtual hand the relevant virtual button available in the scene, as described above.

Following the evaluation, the test proceeded by assigning to the two spheres a new couple of Young's moduli, where E_R was unchanged and E_C was modified according to the following criterion: if the previous comparison sphere had been perceived as stiffer/softer than the reference sphere, the new E_C was respectively decreased/increased by a half of the difference between E_C and E_R. Then, the subject was asked to probe the two spheres again and express the new evaluation. This process continued iteratively, until the subject did not appreciate any noticeable difference; at that step, the difference between E_R and E_C of the preceding iterative step was defined as the JND corresponding to E_R.

Afterwards, a new perceptual task started, with a new E_R, so as to identify the JND related to it. Therefore, at the end of the session, for each volunteer the system gathered five JND values, corresponding to the five values of Young's modulus considered.

The study was conducted according to the guidelines of the Declaration of Helsinki, and approved by the Ethics Commission of the University of Florence (n. 180, 12 October 2021).

III. Results and Discussion

Results of the psychophysical tests for the fifteen volunteers are presented in Fig. 5. It shows the average JND values corresponding to the five values of Young's modulus considered.

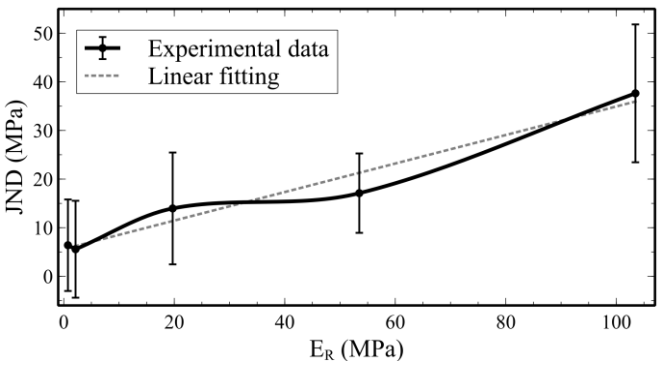

Fig. 5: JND as a function of the Young's modulus of the couple of virtual objects compared with the tactile perception task. The error bars represent the standard deviation among the fifteen volunteers.

The JND trend is consistent with the general Weber's law [24], as it grows with the stimulus intensity (represented in this case in the elastic modulus). The Weber's constant, defined as the slope of the JND curve obtained from a linearisation of the experimental data, was $k = 0.27$. This value is nearly twice the one (k=0.15) that we obtained with the same device in different experimental conditions, as reported in [23]. In that previous work, a JND investigation

was performed with three main differences: i) the test involved only one finger; ii) the experiment did not include any virtual environment; iii) the variable stimulus for the JND assessment was the pressure level, rather than an elastic modulus [23].

Ascertaining whether (and, if so, to which extent) the introduction of visual feedback might have contributed to the higher Weber's constant (e.g. possibly due to a visual distraction) requires more systematic investigations. Nevertheless, the higher Weber's constant might also be significantly caused by the fact that two levels of softness are probably more difficult to distinguish than two levels of pressure. Indeed, estimating softness requires probing the two objects with a similar indentation, so as to avoid any bias while estimating a possible difference in force. This process is even more complex in a virtual environment, owing to the inevitably lower accuracy of visual feedback in comparison to a real scenario.

IV. Conclusion and Future Developments

We described preliminary results of an ongoing study on the tactile perception of softness in a virtual environment, achievable with a custom-made wearable tactile display.

Future developments of this work include the implementation of new kinds of tests, where the virtual environment will include common-life recognisable objects (e.g. jelly), such that the user might predict their compliance prior to the tactile task. This visual bias will be exploited to comparatively assess how experience-based pre-estimates of compliance, purely based on visual cues, can influence the tactile perception. To that aim, confusion tests will also be administered, by varying the compliance in unrealistic ways, in order to evaluate the actual strength of visual bias over tactile perception.

Computational joint action: dynamical models to understand the development of joint coordination

***Abstract*—Previous joint action studies using sensorimotor games suggest that human dyads develop coordination strategies which can be interpreted as Nash equilibria. In a previous study, we argued that if players are uncertain about what their partner is doing, they develop a coordination strategy which is more robust to the actual partner actions. This suggested that humans maintain an explicit representation of what the partner will be doing – a partner model – which also accounts for their degree of confidence about it. However, the mechanisms underlying the development of a joint coordination over repeated trials remain unknown. Very much like individual sensorimotor control, dynamical models can be used to understand how joint coordination develops. Here we present a general computational model – based on game theory and Bayesian estimation – to understand the mechanisms underlying the development of a joint coordination. A joint task is modeled as a quadratic game. Each player predicts their partner's next move (partner model) by optimally combining predictions and sensory observations, and selects their actions through a stochastic optimization of its expected cost, given the partner model. We show that the model captures well the temporal evolution of performance in a previous joint action experiment, and the estimated parameters provide a comprehensive characterization of individual participants in a dyad.**

***Keywords*—Joint action, game theory, partner models**

I. INTRODUCTION

Many of our everyday activities take place in social settings and are coordinated with other persons. Even seemingly simple interactions, like a pair of workers sawing timber with back and forth movements, a couple executing complex steps in a dance floor, two children playing badminton or providing physical therapy to a patient, require that two individual minds are somehow connected and their bodies coordinated [1]. The characteristic feature of these interactions is that subjects influence each others' behavior through coupled sensorimotor exchange within continuous action spaces, continuously in time and possibly over repeated trials. Many of those interactions require active coordination, which is manifested by physical and cognitive responses related to explicit knowledge of the interacting partner. For instance, if while walking through a corridor someone is coming towards us, we could move right while the other person passes on the left or vice versa. In our everyday life, we usually tackle these decision-making situations and master it, sometimes with awkward readjustments. Peculiar types of joint action are those in which the two partners are physically coupled through a tool [2] or a pair of haptic interfaces which can be programmed to implement a variety of interaction modalities [3]. This scenario is particularly useful for quantifying various aspects of joint action performance, because it allows to experimentally manipulate all aspects of the interaction. Further, two subjects which are physically connected and have two partly incompatible goals need to negotiate a shared strategy[4]. During the last two decades, discrete-time dynamical models have been used to investigate the mechanisms underlying sensorimotor learning and adaptation [5] and neuromotor recovery through robot-assisted training [6], but have never been used to address the development of joint coordination.

Here we present a general modeling framework for the development of stable coordination strategies in joint action. We specifically focus on situations in which individuals have distinct and possibly conflicting sub-goals, and have minimal or no knowledge of the goals of their counterparts. The model can be used to simulate joint action scenarios, and to analyze joint action experiments. We demonstrate the method in the context of a task where participants are mechanically coupled, have a shared final target, and are instructed to cross a via-point (VP, different for each player) while minimizing the interaction force.

II. METHODS

A. General Computational Framework

We model a joint coordination task as a static non-cooperative infinite game [7]. We assume that players have incomplete information. In particular, each player (i) knows their own goal, but not their partner's; and (ii) has limited information about partner action. We also

assume that learning of a coordination strategy occurs through fictitious play (FP) [8], in which the agents play the game repeatedly, and at every round each agent determines its best response on the basis of their beliefs about how their opponents will play. The overall model is depicted in Figure 1. At each trial t, the i-th player selects an action, $u_i(t)$, on the basis of the partner's expected move (partner model), $x_i(t) = \hat{u}_i(t)$. Once the actions have been carried out, through their sensory systems both players collect information $y_i(t)$ about their partner's action. This information is then used to update their partner model, which will be accounted for when selecting the action on the next trial.

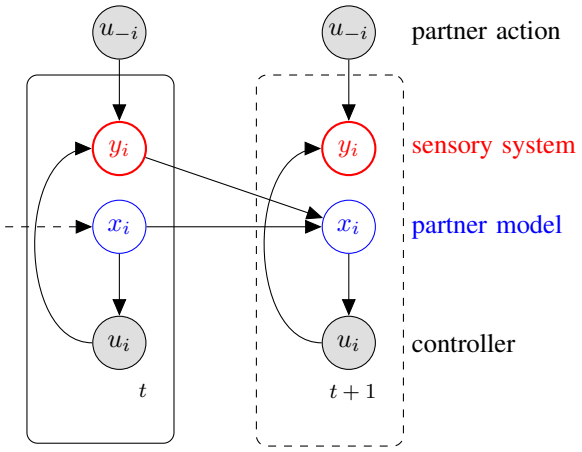

Fig. 1: Computational model. At each time step, each player's partner model (x_i) is used to select the actual action (u_i). Player i receives information about partner action (u_{-i}) through their sensory system (y_i). This information is used to predict the next action (u_i)

1) Joint task as a quadratic game: For each player i the task is specified by a quadratic cost function, which depends on both players' actions:

$$J_i(u_1,u_2) = \begin{array}{l} \frac{1}{2}\left[u_1^T R_{11}^i u_1 + 2\,u_1^T R_{12}^i u_2 + u_2^T R_{22}^i u_2\right] \\ + {r_1^i}^T \cdot u_1 + {r_2^i}^T u_2 + z^i \end{array} \tag{1}$$

where $i = 1, 2$ are the two players. Static games with infinite action space and quadratic costs are known as quadratic games. We assume that all R_{jk}^i are symmetric and positive definite. If this is the case, the Nash equilibrium is uniquely determined [7] as:

$$u^* = -R^{-1} \cdot r \tag{2}$$

where $u = [u_1^T\ u_2^T]^T$, $r = [r_1^1\ r_2^2]^T$ and:

$$R = \begin{bmatrix} R_{11}^1 & R_{12}^1 \\ R_{21}^2 & R_{22}^2 \end{bmatrix} \tag{3}$$

2) Sensory system: At each trial t, the sensory system of each player provides an estimate of the partner's action on that trial:

$$y_i(t) = H^i \cdot u_{-i} + L^i \cdot u_i + v_i(t) \tag{4}$$

where $v_i(t) \sim N(0, \Sigma_y^i)$ is a zero-mean sensory (measurement) noise of the i-th player, and Σ_y^i is its covariance.Parameters H^i and L^i reflect the structure of the sensory system. In particular, H^i and L^i respectively relate partner and own action and their observed features to their sensory consequences.

3) Partner representation: At each trial, t, each player optimally estimates their partner's next action by combining predictions and actual observations into a 'partner model'. Let $\hat{u}_{-i}^-$ and $\hat{u}_{-i}^+$ be the estimates of partner action, respectively before and after the sensory information is available, i.e. after the action has taken place (hereafter, 'prior' and 'posterior' estimates). The posterior estimate combines prior estimate and sensory information. The prior estimate propagates to the next trial by accounting for the player's retention rate. In conclusion, we have:

$$\begin{aligned} \hat{u}_{-i}^+(t) &= \hat{u}_{-i}^-(t) + K_i(t)\left[y_i(t) - H^i\hat{u}_{-i}^-(t) - L^i u_i^*(t)\right] \\ \hat{u}_{-i}^-(t+1) &= A^i \cdot \hat{u}_{-i}^+(t) + w_i(t) \end{aligned} \tag{5}$$

where $K_i(t)$ is calculated iteratively through the Kalman algorithm , which also provides time-varying estimates of the prior and posterior covariance matrices of $\hat{u}_{-i}^-$ and $\hat{u}_{-i}^+$, i.e. $P_i^-(t)$ and $P_i^+(t)$, and $w_i(t) \sim N(0, \Sigma_x^i)$ is a zero-mean process noise of the i-th player, and Σ_x^i is its covariance. Hereafter, we will refer to the prior estimate as the partner model: $x_i(t) \equiv \hat{u}_{-i}^-(t)$.

4) Action selection: The optimal action of player i at time t, $u_i(t)$, is the one which minimizes the expected cost $\bar{J}_i(u_i) = E\{J_i(u_i, u_{-i})\}$, where the average is calculated over the partner's action, u_{-i}. The partner model provides expected value ($x_i(t)$) and covariance matrix ($P_i^-(t)$) of the partner's action, so that the expected cost can be rewritten as:

$$\bar{J}_i(u_i) = \frac{1}{2}\left[u_i - u_i^*(x_i)\right]^T \cdot R_{ii}^i \cdot \left[u_i - u_i^*(x_i)\right] + q(x_i) \tag{6}$$

where

$$\begin{array}{ll} u_i^*(x_i) & = -{R_{ii}^i}^{-1} \cdot \left[R_{i-i}^i \cdot x_i + r_i^i\right] \\ q(x_i) & = -\frac{1}{2}{u_i^*}^T \cdot R_{ii}^i \cdot u_i^* + r_{-i}^i \cdot x_i + z^i + \\ & \frac{1}{2}\mathrm{tr}\left[R_{-i-i}^i \cdot P_i^-\right] + \frac{1}{2}x_i^T \cdot R_{-i-i}^i \cdot x_i \end{array} \tag{7}$$

Each player selects their next action u_i on the basis of the task and on their belief in partner state, x_i. However, a player may not behave in a perfectly optimal and deterministic way. To account for this, we assume that action selection is in fact a stochastic process.

$$p(u_i|\hat{u}_{-i}) \propto e^{-\frac{\bar{J}_i(u_i)}{\lambda^i}} \tag{8}$$

where λ^i reflects the 'temperature' of action selection. With greater λ^i leading to greater randomness – exploration. Eq. 8 implies that the action u_i is calculated as $u_i(t) = u_i^*(x_i) + \eta_i(t)$ where $\eta_i(t) \sim N(0, \Sigma_u^i)$, with $\Sigma_u^i = \lambda^i {R_{ii}^i}^{-1}$. For stable learning to occur, the

'temperature' parameter λ^i should decrease over trials. In the model, we specify the initial temperature, λ_1^i, and assume that it changes gradually over trials according to the following relation: $\lambda^i(t+1) = a^i \cdot \lambda^i(t)$, with $\lambda^i(1) = \lambda_1^i$ and $a^i < 1$.

5) Model identification: The model is completely specified by parameters $b^i = \left\{\Sigma_y^i, A^i, \Sigma_x^i, \lambda_1^i, a^i\right\}$. It can be used to simulate the evolution of a particular dyad, described by one specific parameter vector. It can also be used as analytical tool, to estimate the model parameters which best explain a specific subject behavior. Model parameters for a specific dyad can be estimated from the time series of players' actions $D = \{u_1(t), u_2(t) | t = 1, \ldots, T\}$. For parameter identification purposes, Player i model can be reformulated as

$$\begin{aligned} x_i(t+1) &= F^i(t) \cdot x_i(t) + G^i(t) \cdot u_{-i}(t) + w_i(t) \\ u_i(t) &= u_i^*(x_i) + \eta_i(t) \end{aligned} \tag{9}$$

where the true partner action $u_{-i}(t)$ is the model's external input, $x_i(t)$ is the internal state and $u_i(t)$ is model output. We estimated the model parameters by maximizing the expected log-likelihood of the above model [9].

B. Experimental Data and Statistical Analysis

We applied the model to study the mechanisms of joint coordination in a published study [4], in which two players are mechanically coupled through a pair of haptic interfaces; see Figure 2a. The players were required to perform reaching movements with the same start and end points, but different intermediate via-points. The experiment involved three groups of subjects, which differed for the amount of information available about their partner; see Figure 2c. The 2-VP joint action task can be summarized by the following cost function:

$$\begin{aligned} J_i(p_1, p_2) = \; & w_1 \left\| p_i(t_i) - \mathrm{VP}_i \right\|^2 + \\ & \tfrac{w_2}{N} \textstyle\sum_{n=1}^{N} \left\| p_1(t) - p_2(t) \right\|^2 + \\ & \tfrac{r}{N} \textstyle\sum_{n=1}^{N} \left\| F_i(t) \right\|^2 \end{aligned} \tag{10}$$

where $p_i(t)$ is the position of player i at time $t = T(n-1)/(N-1)$. Body dynamics can be approximated as $m_i \ddot{p}_i(t) + k\left[p_i(t) - p_{-i}(t)\right] = F_i(t)$, where $F_i(t)$ is the motor command. We assume that $p_i(0) = p_{start}$ and $p_i(T) = p_{end}$, and that player i crosses their own via-point, VP_i at time t_i. The whole trajectory $p_i(\cdot)$ can be approximated as a polyharmonic spline $p_i(t) = g(t) \cdot v_i$ where $g(t) = \left[|t-t^1|^3 \; \ldots |t-t^M|^3 \; t \; 1\right]^T$ and the coefficients $v_i = S \cdot u_i$ are specified by a small number M of nodes, $u_i = \left[p_i(t^1) \; \ldots \; p_i(t^M)\right]^T$. In this way, the trajectory of Player i is completely specified as a vector of node coordinates, u_i. Derivatives can be expressed in the same form, so that Eq.10 is transformed into a quadratic function of u_i and u_{-i}. For simulation purposes, we set $t_1 = 0.35 \cdot T$ and $t_2 = 0.65 \cdot T$ where the total movement duration was set to T=2 s. In parameter estimation, for each player, we took their average crossing times. Parameters w_1, w_2, and r were determined by the Bryson rule: $w_1 = 1/r_{VP}^2$, $w_2 = 1/d_{\max}^2$ and $r = 1/F_{max}^2$, where the VP radius is $r_{VP} = 2.5$ mm, the maximum between-subject distance is $d_{\max} = 1.5$ mm and the maximum force is $F_{max} = 0.1$ N. Using these parameters, the Nash equilibrium for this task is a joint trajectory in which both players cross both via-points - see Figure 2b. Further, in Eq. 4 we set $H^i = -L^i = I$ to reflect that what is sensed is the interaction force between the two players. We estimated the model parameters from 120-trial time series of trajectories of 15 dyads (30 participants) – five dyads per group. Parameters describe the learning behavior of each player in all dyads. For each parameter, we used a one-way ANOVA with Group as a factor. In case of a significant group effect, we used post-hoc analysis to identify group differences.

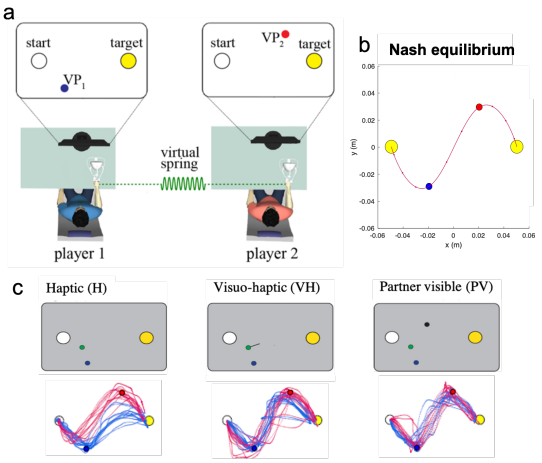

Fig. 2: The 2-VP task. a: Partners in a dyad were connected through a virtual spring. They were instructed to perform reaching movements in between the same start point and the same target point but through different via-points (VP). Each player could only see their own VP, but not their partner's. Both were instructed to keep the interaction force as low as possible during movement. b: Nash equilibrium for the 2-VP task. c: Trajectories at the end training for one representative dyad for each group. Information about partner actions was provided haptically, through the interaction force (Haptic group, H), by additionally displaying the interaction force vector on the screen (Visuo-Haptic group, VH) or by also displaying the partner's cursor (Partner Visible, PV).

III. RESULTS

A. Simulation

We used the model as a generative tool to simulate two dyads, which only differed in the magnitude of the sensory variance, Σ_y: small ($\Sigma_y = 4{\cdot}10^{-4}$ m^2) and large

($\Sigma_y = 4 \cdot 10^{-5}$ m^2). As in the actual experiments, for each model we simulated a sequence of 120 trials. The simulation results are summarized in Figure 3, in terms of the time series of the minimum distances of Player i trajectory to the j-th via-point (MD_{ij}). We observed that

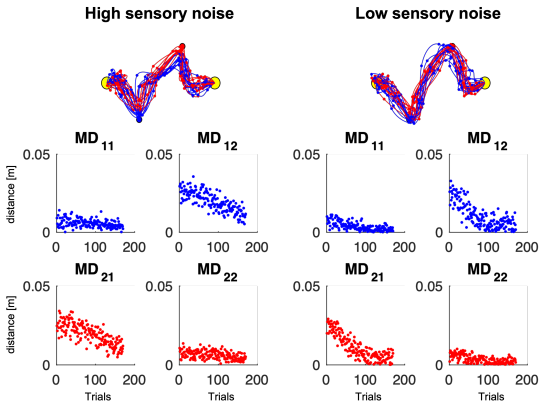

Fig. 3: Simulated trajectories, for large (a) and small sensory noise (b). Top: movement trajectories. Bottom: minimum distances from self and other via-points, for Player 1 (blue) and Player 2 (red).

consistently with experimental findings [4], with lower sensory noise players converged toward a shared solution which is close to the Nash equilibrium - figure 2b.

B. Parameters identification

We estimated the model parameters for each player and each dyad. As expected, and consistent with the experiment design, we found that the estimated sensory variance (Σ_y) decreases as the reliability of partner information increases (p = 0.0098) – see Figure 4. However, a significant group effect was also observed in the parameters which describe the action selection – greater λ_1 (p = 0.0308). Post-hoc analysis revealed a significant H-PV difference for measurement noise (p = 0.0072) and a significant H-VH for the initial exploration rate λ_1 (p = 0.0235).

IV. DISCUSSION

We presented a general computational framework to describe the mechanisms underlying the development of joint coordination. The model can be used to simulate joint action task and to analyze actual experiments. We demonstrated the model in the context of a joint coordination scenario (2-VP task) [4]. The analysis of the experimental observations in terms of the model parameters suggests that (as expected from experimental design), the measurement noise Σ_y decreases from the H to the PV group, consistently with experimental conditions [4]. In addition, the greater initial temperature λ_1 of action selection observed in the VH condition suggests that

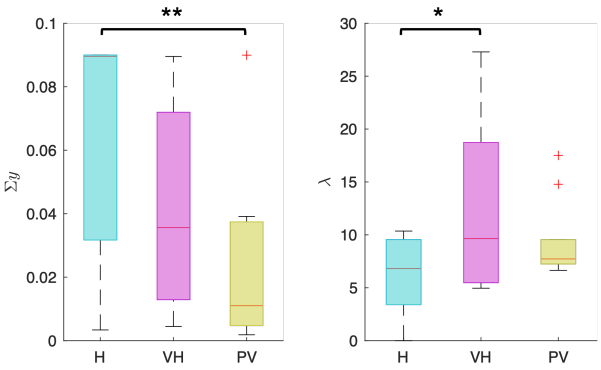

Fig. 4: differences in the estimated model parameters. Boxplots display median, 25th and 75th percentiles of the estimated parameters values, for H (light blue), VH (pink) and PV (yellow) groups. Post-hoc analysis: $*$: p < 0.05; $**$: p < 0.01

displaying interaction force as a vector tends to trigger extra exploration, possibly because the information is not immediately interpretable during movements. Overall, these findings confirm that model-based analysis of joint action experiments may provide valuable information on the underlying mechanisms. The modeling framework is general enough to be usable in a wide variety of joint action scenarios. It can also be used to characterize situations in which social behaviors are defective, as in autism spectrum disorders.

Fast path replanning in a dynamic environment in percutaneous cardiac interventions

A. Peloso[1], R. Damiano[1], E. Votta[1] and E. De Momi[1]
[1] *Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy*

***Abstract*— Percutaneous interventions for structural heart diseases allow for a less invasive approach in elderly or high-risk patients. Great research interest arises in the field, working towards the robotization of current manual procedures. Usually, a catheter is guided by the surgeon from a peripheral vein access towards the relevant intracardiac target. Autonomous intracardiac navigation would require precise planning of the path to safely lead the catheter avoiding collisions. From this standpoint, one of the main challenges is to account for motion of the heart structures. To comply with a dynamic environment, fast replanning needs to be considered to obtain reliable and safe paths in case of moving targets or possible impacts with moving obstacles. In this work Imitation Learning is adopted in a static and dynamic simulation environment. Performances are preliminarily assessed in terms of rate of success in reaching the target and angle of impact against the target. The proposed planner reaches good performances in a dynamic environment, with a success rate of 75% and respecting the maximum bending angle of 20°.**

I. Introduction

Percutaneous interventions in the frame of mitral valve (MV) repair involve a steerable tendon-driven catheter which is manually advanced from a femoral vein access towards the heart [1]. From the right atrium, through a transeptal puncture, the catheter reaches the left atrium, where it is led to the MV to position a clip to restore MV leaflet coaptation. In this field, reaching autonomous procedures is a matter of great research interest, leading to help surgeons during interventions, as well as reduce the learning curve for new operators and standardize the outcome of the procedure. To reach an autonomous procedure, the actuation must follow a safe trajectory along the way, assuring obstacle avoidance while reaching the target. Indeed, in an intra-operative scenario, the need of a suitable planner able to comply with dynamic anatomical structures and adjust the path in real time is substantial.

Sampling-based approaches have been largely explored for real-time path replanning in a dynamic environment [2]. Although providing a fast and easy to implement approach, traditional methods require further adjustments to find the best trajectory among the possible solutions [3]. Learning based methods, instead, allow for a more comprehensive investigation in complex environments. Reinforcement Learning (RL) has gained credibility in several contexts [4], [5], [6] as a suitable method for estimating the policy that defines the agent's behaviour, such that a reward function is maximized. In the context of path planning, RL enables optimal path definition by directly considering kinematic constraints, path length constraints, and distance to obstacles without any subsequent refinement, thus representing a viable approach for intra-operative dynamic scenarios. Reference [7] implemented a RL algorithm to automatically control a catheter into the heart using Dueling Deep Q-learning method. Another example can be found [8], where robotic trajectories for endovascular procedures are optimized through RL to avoid the contact between catheter's tip and the vessel wall, adapting to complex flow dynamics.

When RL is implemented for complex environments, the design of the reward function becomes very complex. In those cases, Imitation Learning (IL) is a promising technique that might achieve better results [10]. In the framework of IL, the agent learns a policy to perform a task in the environment based on demonstrations by experts. Some methods directly estimate the policy from demonstrations, others instead estimate a reward function and, from there, indirectly estimate the behavioural policy [12]. Reference [13] already adopted this approach to address path replanning in an intra-operative scenario for steerable needles in keyhole neurosurgery.

In this framework, the aim of the present work is to develop an accurate path planner in a dynamic environment, exploiting IL to react to MV motion. We relate to a previous implementation [14], optimizing for a realistic and dynamic intracardiac environment.

II. Materials and Methods

The aim of path planning [15] is to find a set of configurations from a starting pose to a target pose, defining a suitable path for an agent in the free space, i.e., all possible configurations the agent can assume without hitting any obstacle. In the intracardiac environment, we defined as starting configuration a pose in the septum, and we set the target pose along the coaptation line of the MV (Fig 2). A cube encompassing the coaptation line was defined; at each expert demonstration, the target was represented by a point within the cube. This setting allowed for generalizing the problem for any possible site of application of the clip on the MV. The scene was implemented in *Unity3D*, with the main regions of interests derived from the 3D reconstruction of a patient computerized tomography scan.

A. Imitation Learning algorithm

The performed training is based on IL. Two approaches were used together: Generative Adversarial Imitation Learning (GAIL) [12] and Behavioural Cloning (BC) [17]. GAIL algorithm is based on two antagonistic networks: the generator and the discriminator. While the generator proposes new actions, a(t), for the agent on the basis of a RL algorithm (Proximal Policy Optimization), exploiting a given set of

rewards (R_{ext}), a discriminator is embedded to distinguish the generated actions from experts' demonstrations, giving the agent an intrinsic reward (R_{int}). To enhance experts' behaviour mimicking, BC is included: the agent learns a behavioural policy, π, like in a supervised learning problem in which expert's demonstrations represent the ground truth. A descriptive flow is reported in Fig 1. R_{ext} were given based on an empirical analysis: -1 in case of collision with sensible anatomical structures, ending the episode without reaching the target; +0.75 in case of reaching the target point. Since the procedure requires to arrive perpendicularly at the target, a control for the hitting angle was also included, adding a +0.25 reward in case of hitting angle inferior to 20° and -0.25 otherwise. To train the model, the ML-Agents package [18] was integrated in Unity.

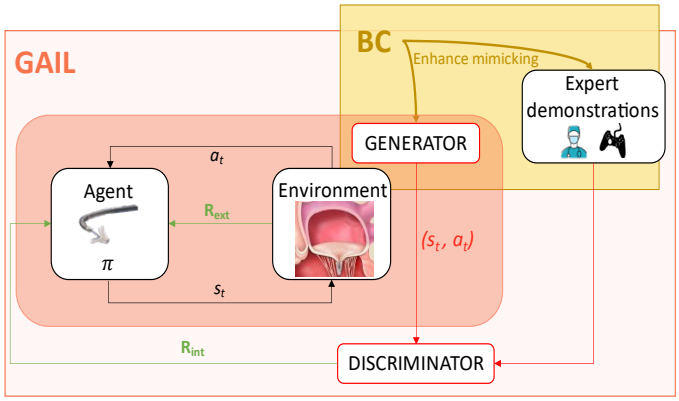

Fig 1 *Description of the algorithm: GAIL and BC*

B. *Mitral valve movement*

To make the environment more realistic, we introduced the dynamics of the MV. We defined the movement by accounting for MV annular plane motion while neglecting leaflet motion, which is not relevant to our specific goal. At each cardiac cycle, the mitral annular plane undergoes a shift towards the apex of the heart due to the contraction of the atria (atrial systole), and then returns to its starting position during the contraction on the ventricles. The motion of the MV annular plane was defined based on typical values of mitral annular plane systolic excursion (MAPSE), which represents the amount of displacement of the mitral annular plane along the heart long-axis towards the apex. As reported in [16], normal values of MAPSE are reported to range from 12 mm to 15 mm. Focusing on MV dysfunctional patients, to train the algorithm we considered 12mm as a reliable estimation of the maximum excursion of the MV annular plane.

The points representing the base and the apex of the heart were manually identified: the base was set in the centre of the MV orifice while the apex as the point of maximum curvature in the left ventricle wall, at the opposite side of the base. The direction of the target's movement was then obtained as the direction of the vector connecting base and apex (green arrow, Fig 2). To define the systolic time-dependent displacement, a *sin* wave was considered for 1/3 of the cardiac cycle duration, while motion was considered absent in diastole, as reported in Eq.1:

$$MV_{shift}(t) = \begin{cases} 12\sin(2\pi f_{systole} t) & 0 < t < t_{systole} \\ 0 & t_{systole} < t < Tcycle \end{cases} \quad (1)$$

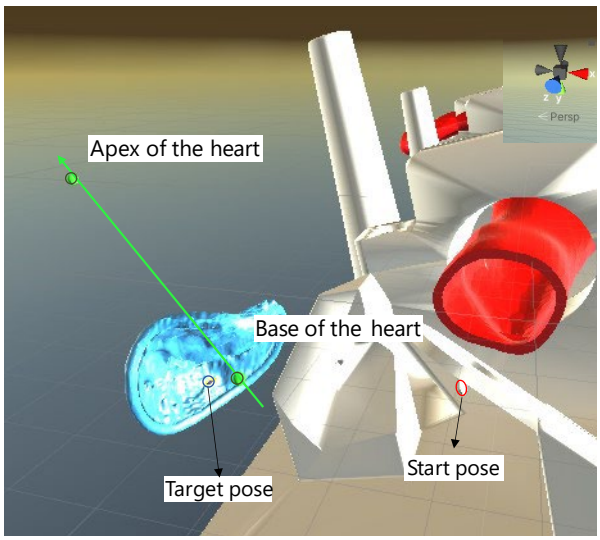

Fig 2 *Intracardiac environment: starting point in the septum and target point in the valve – along coaptation line*

C. *Experimental protocol*

We trained two different models, one with a static environment, and one introducing the movement of the MV. A set of 110 demonstrations was recorded with a joystick both for the static and the dynamic model, with mean reward of 0.85 and 0.8 respectively. 10000 training steps were performed. The model was trained to reach the target sampled from the cube positioned along the coaptation line with a tolerance of 2 mm. The two models were compared in terms of success rate, defined as the number of successful events over 100 attempts and expressed as percentage (SR [%]), of time to compute the path and get to the target (t [s]), and of angle with which the catheter reaches the target ([°]).

III. Results and Discussion

The training in the static environment yielded a SR of 62%, with median time to compute the path and get to the target of 12.8 s and a median angle value of 10.4°. The planner in the dynamic environment, instead, showed a SR of 73% and median values of time and angles equal of 15,8 s and 18.5° respectively. The increase in time metric and in the inaccuracy on target hitting angle in the dynamic setting, compared to the static setting, could be expected, given the higher complexity of the dynamic task. Overall, the time to reach the target is acceptable compared to previous work [14]. On the contrary, the lower SR in the static environment might suggest margins for refinements of the environment setting.

IV. Conclusion

This work investigated the introduction of a dynamic environment for a path planning module in the framework of percutaneous interventions for mitral valve repairment. Although these preliminary achievements showed promising

results of dynamics inclusion in path replanning, several adjustments are needed. One first thing to address is enhancing the training step to assess the stability of the algorithm. Moreover, the model may have suffered sub-optimal demonstrations: the impact of manual dexterity using a joystick might have played a part in the low SR for both models. The unexpected lower SR of the static model with respect to the dynamic one, instead, could be explained given the fact that, thanks to the motion of the valve in different planes, the agent had the possibility of reaching the target in different positions. This increased the possibility of getting to the target (higher SR in dynamic environment), with the consequence of a major angle of impact. One last remark regards the need for physical constraints of the agent: being a tendon-driven catheter, kinematics must be considered in further developments.

Nonetheless, these are the first steps toward a path planning module accounting for the movement of the MV. As a matter of fact, in the real time environment, it becomes extremely important to synchronize the advancement of the catheter inside the left atrium with the MV movement itself. Hence, the need for a continuous correction and replanning to reach the moving target is indispensable to obtain a reliable simulation transposable in real robotics applications.

***Abstract*—Social robots are very promising in therapies with ASD children as they have the potential to promote communication and attention skills of these children. Attention plays a critical role in almost every area of life, allowing people to focus on information. In literature, several authors measured attention through the manual labelling of videos, which is labour-intensive and subjective. However, new algorithms objectively quantify the progress of the child during therapy. This work aims to develop and test an attention measurement system to evaluate a novel robotic therapy for ASD children. First, in cooperation with IRCCS Fondazione Don Carlo Gnocchi, a new protocol focused on eliciting the child's attention through the use of the social robot NAO was developed. The sessions were recorded with a Microsoft Kinect camera for offline analysis. We used Gaze 360 and we implemented a bottom-up solution to compensate for offsets in gaze signal reconstruction caused by subject position, target position, gaze value, and light. The final algorithm included two neural network architectures to classify to which target the subject was looking. In a sample of 5 healthy adults, we obtained a final accuracy of 88%, showing the promising results of our system. In the future, we will test the developed protocol with healthy and ASD children to understand its sensibility to capture the differences between the two groups and to verify its consistency in children.**

***Keywords*—Autism Spectrum Disorder, Deep Neural Networks, Attention classification**

I. INTRODUCTION

Autism spectrum disorder (ASD) is a group of neurodevelopmental disorders characterised by difficulties in social interaction, social communication and the presence of restrictive and repetitive behaviours. There is no standard therapy, but early interventions lead to a better prognosis. Several works showed the advantages of using social humanoid robots for the therapy of ASD children [2]. However, these therapies are still not used in daily practice because the evidence of their impact on children is still missing. One of the principal causes for this lack of evidence is the reduced number of quantitative outcome measures validated with clinical scales, which prevents comparison among studies.

In terms of clinical scales, the ADOS in combination with the Autism Diagnostic Interview-revised are considered the gold standard questionnaires for autism diagnosis [5]. However, since they are diagnostic scales they are not able to collect small changes caused by a therapy. A solution could be the Early Social Communication Scale (ESCS) that was developed to assess individual differences in nonverbal communication skills, namely attention, through 25 semi-structured situations that encourage interactions between the tester and the child [6]. Attention is one of the principal measures analysed in these therapies and can be obtained manually (e.g. therapists analyse the frames recorded during the sessions) or automatically [7], using non-intrusive devices (better for ASD children) such as cameras.

Alnajjar et. al [1] use the camera of a NAO robot to construct an autonomous assessment system of attention based on attention cues. In this study, to generate attention's score, the frequency of detecting a face was analysed during protocol. Instead, Di Nuovo et al. [2] preferred to use a deep learning method to automatically estimate if ASD children focus their visual attention on the robot during a therapy session. They used the facial landmarks extracted from a video recorded by NAO and a Convolutional Neural Networks (CNN) to classify the behaviour of the child. The labelling was considered "Attention" when the child was monitoring the robot and "Distraction" otherwise. In both methods, the children could be facing the camera but looking otherwise, not being a precise measure of attention.

In the context of previous work, we developed a therapy for training of gestures through turn-taking games between a robot, a child and a therapist (IOGIOCO protocol [3]). In the several games, the robot mirrored the participants using a Kinect camera and gave feedbacks about their performance. For measuring the attention of children during this protocol, we developed an automatic system using gaze [7], considered a good proxy of attention. In this system, we used the frames recorded with a Kinect camera to obtain the azimuth gaze angle of the child from an algorithm named Gaze360 [4]. Associating this gaze angle with the positions of our targets, we determined where the subject was looking at, in each moment. The mean accuracy obtained for two ASD children during two sessions was 59%. This low performance was related to the poses that the children and the therapist took during the therapy sessions [7]. Therefore, we had two main

goals: the development of a protocol for a correct evaluation of the improvement of children doing a robotic protocol and the implementation of an objective, accurate and precise attention classifier to evaluate a robotic protocol for ASD children.

II. Methods

A. Robot-mediated evaluation protocol

From a collaboration with Fondazione Don Carlo Gnocchi, we have decided to depart from a Clinical Scale so that we could compare clinical results with the results of our automatic system. We have chosen the Early Social Communication Scale (ESCS) as the starting point for the development of the new evaluation protocol. This scale has as main goal the assessment of nonverbal communication skills which was aligned with ours and it was quite fast to administer (15-25min).

In order to develop our new protocol, we chose three tasks from the ESCS: *object spectacle task*; *gaze following task* and *book presentation task*. Then, we adapted each task to include the robot NAO, obtaining a setup more similar to our therapy protocol (*IOGIOCO* protocol). In this setup, we also included the table of the ESCS and a Microsoft Kinect camera to record our sessions (Figure 1).

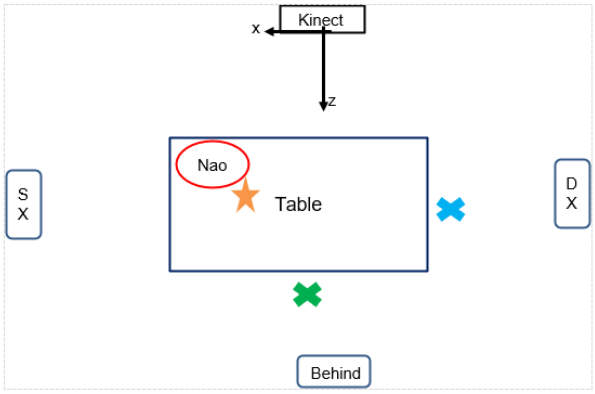

Fig. 1: Protocol setup. The orange star represent the mechanical toy; DX, SX and Behind are the three posters on the wall. The forth poster was below the Kinect camera. The blue x represent the therapist, the green one the child.

The protocol starts with the therapist and child exploring the robot in a kneeling position. After, NAO presents itself and starts the *object spectacle task*, pointing to a small mechanical toy placed in front of it and asking the child if she/he wants to play. As in the ESCS, the therapist shows the toy and then gives it to the child to assess his behaviour during free play. While the child is playing or distracted, the therapist turns on NAO's LEDs, dragging the child's attention to the robot. After the *gaze following task* starts, where first the robot turns its head to one of the four posters present in the room waiting for the child to follow with his/her gaze, and secondly, points and makes a comment on the poster to explicitly call the attention of the child. In the final task (*book presentation task*) NAO points to one of the children's books that the therapist holds. The therapist waits for the answer from the child and then takes one of the books to show it to the child while interacting with him and keeping the child's attention.

B. Attention estimation

After establishing the evaluation protocol, we implemented an attention classifier. As a starting point, we adapted the automatic system described before (Section I), and we chose to test the system in more stable conditions than the ones of the final protocol but with the same setup. We selected five targets that elicit attention behaviours easily: NAO, Kinect and three posters.

In order to have a controlled scenario and to understand the system's performance, we did four tests with four pairs of adults (27 ± 5 years), acting as the child and the therapist of our final protocol. In these tests (protocol S), the subjects sat in the positions represented in Figure 1 and changed the gaze's direction by alternating between the camera and a target every 5s. In all videos, there was one common subject (Subject 1), so in total, we had five subjects.

In order to compute the system's performance, we manually labelled the videos indicating where the subjects were looking. Then, we compared these results with the estimations obtained by the system to calculate the accuracy and precision.

The analysis of protocol S revealed a low precision (18%) for the purpose of the project. Thus, we decided to add the elevation angles, extracted from the Gaze 360 algorithm, to the attention classifier. Following the methodology proposed in the *IOGIOCO* project for the azimuth angle [7], we started by calculating the expected gaze angles (standard angles) for each of the targets and defined an area of interest (AOI) around them, for each frame. Then, we filtered both the azimuth and elevation gaze estimations from the Gaze360 algorithm to reduce the noise. After, if the azimuth estimation was inside the AOI range of angles for a given duration (> 400 ms), we checked the same in the elevation direction. When this occurred, we considered that the subject was looking at the target and we called it a fixation.

Despite the accuracy improvement with this new method, the result was not yet sufficient. We found that this was caused by the presence of offsets between the standard angles and the estimated Gaze360 angle (an example is shown in Figure 2, for the Kinect where the expected gaze value is 0rad, by definition of the Gaze360 algorithm, see [4]). We developed and tested different acquisition protocols to selectively identify the possible different origins of these offsets. From these protocols, we observed that several factors influenced the offsets in a non-linear way, such as light, subjects and targets coordinates, gaze value, and confidence error angle (a measure of the reliability of the gaze outputted by Gaze360).

We developed an explicit and an implicit method for calculating the offsets and then removing them. We tested both solutions on four protocols: protocol S and three other protocols with the same subjects, in which they looked to the same targets as in protocol S but standing. For each protocol (now on called protocol x,y,z), the two adults assumed two

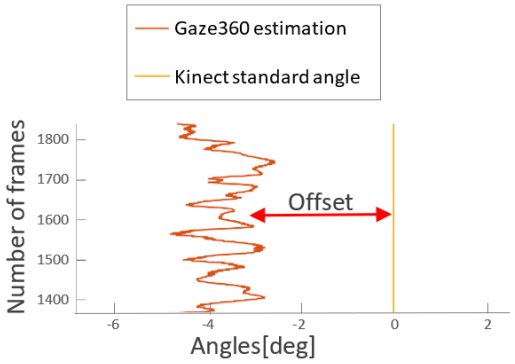

Fig. 2: Example of offset between predicted Gaze360 and standard angle for Kinect camera in azimuth direction

positions and moved only in one direction (x, y, z directions of the Kinect camera, respectively).

1) The explicit method: In this method, we calculated the offset between the estimated gaze and the standard angle explicitly, using the following hypothesis: when the subject looks at a target, the offset for that target is less than for all the other targets. Therefore, the correct offset (O) at each moment could be given by the minimum difference between Gaze360 estimation (γ) and the standard angles (α) of the different targets (Equation 1). This calculation was done separately for the azimuth and the elevation.

$$O(t) = \min_{\forall target} \gamma(t) - \alpha_{target}(t) \quad (1)$$

The chosen offsets were then added to the lower and upper limits of all the AOIs in that frame. Then we computed the fixations as previously mentioned and compared them with our ground truth.

2) The implicit method: Given the wide variety of factors influencing offsets, we decided to apply a bottom-up approach and constructed a deep learning method to predict towards which target the person was looking. In this way, the correction of the offset was implicit in the method.

We chose as input the azimuth and the elevation angles estimated by Gaze360, the x, y, and z coordinates of the head of the subject, the confidence error, the four vertices of the bounding box estimated by Yolo algorithm, and the respective image with the selected face [7]. The output should be a classification in one of the six possible classes corresponding to the different targets: Kinect, NAO, three posters and elsewhere.

In terms of architecture, for extracting the best features of the images, we used a convolutional neural network (CNN), more specifically, a pre-trained EfficientNet architecture [8] associated with two fully connected layers. Regarding the other inputs, we constructed a Multi-Layer Perceptron (MLP) with two fully connected layers. Then three architectures were trained and tested: MLP, CNN and MLP+CNN. In this last architecture, first, there was a pre-training of the weights of each architecture, and then, they were fine-tuned considering the complete network. For the training of the different architectures, we minimised the loss between the predicted and the true class (given by manual labelling of the videos). We tested the MLP and CNN with different hyperparameters keeping the validation set (containing Subject 3 data) fixed. Since we had few subjects, we calculated the mean of the cross-validation process (using four subjects to train and another to test) as a final result.

III. Results and Discussion

From the analysis of protocol S, using just the azimuth, we obtained a mean accuracy of 77% and a mean precision of 18%. With the inclusion of the elevation angle, the mean accuracy improved to 81% and the mean precision to 34%. The improvement was obtained thanks to the fact that some targets (ex: NAO and the Kinect) had similar azimuth directions not distinguishable by the original algorithm. The still low precision was caused by the presence of offsets, as previously mentioned. These offsets are influenced in a non-linear way by several factors. Thus, we developed the two different solutions explained.

In order to have comparable results, we decided to analyze also the protocols x, y, z with the original algorithm and with the addition of elevation (Table I). We verified that the results decreased in relation to protocol S. These lower results can be related to the presence of more noise in these new protocols since the subjects are walking through the room instead of being seated as in protocol S.

TABLE I: Accuracy and precision of the original algorithm and of the original algorithm with the elevation computation

	Original algorithm		**Add of elevation computation**	
Subject	**Precision**	**Accuracy**	**Precision**	**Accuracy**
1	0.09	0.74	0.21	0.78
2	0.17	0.76	0.24	0.78
3	0.20	0.77	0.23	0.78
4	0.11	0.74	0.17	0.76
5	0.18	0.76	0.52	0.86
Mean	0.15	0.76	0.28	0.79
St. deviation	0.05	0.01	0.15	0.04

A. The explicit method

Using an explicit method to correct the offsets, we observed that both precision and accuracy improved (Table II). However, it was not the optimal solution for our system since the lower offset was not always the correct one.

We observed two major problems. First, when two targets had similar coordinates in x or y, their offsets (in azimuth and elevation) were also similar, and the correct offset could not be the chosen one. Second, for the target behind, when the subject looked at that target, his/her face was no longer detectable by the Kinect, which led to a signal with more noise and higher offsets that through this method were not found. However, we decided with therapists not to remove this target, despite a possible decrease in accuracy. Indeed, from a clinical point of view, the child's ability to focus attention even on targets out of his visual field following therapist indications is considered a high-level attention task [6].

TABLE II: Accuracy and precision of explicit method solution

Explicit method		
Subject	**Precision**	**Accuracy**
1	0.58	0.88
2	0.45	0.84
3	0.40	0.83
4	0.44	0.84
5	0.59	0.88
Mean	0.50	0.86
St. deviation	0.04	0.14

B. The implicit method

As explained in II-B2, given the wide variety of factors influencing offsets, we decided to apply a deep learning method to predict towards which target the person was looking.

In terms of hyperparameters, we found that the best loss was the mean square error loss function for both individual architectures. The ideal training time was 80 epochs for the MLP and 30 epochs for the CNN. Regarding the effect of the inputs on the MLP performance, we verified that the head boxes worsened the final precision.

With these parameters, the CNN (precision: 66%) had a lower precision than the MLP (precision: 78%). Thus, we excluded CNN alone from further analysis but added it to the MLP to see if it could improve its performance. In Table III are shown the obtained results for the tests of the MLP and MLP+CNN networks. We noticed that the mean precision and accuracy improved in relation to the explicit method (Table II).

Furthermore, CNN helped to improve model prediction when validating with Subject 1 and Subject 5. The first one was the subject associated with the larger quantity of data. When the data from this subject was used for validation, the training dataset became smaller than the validation set. In the absence of a large quantity of data, the features provided by the CNN were important to improve the overall result. The second one was a subject of the same gender (male) of the subject that we used to determine the best hyperparameters, and, probably, that is why we obtained a good result with him. Nevertheless, in order to take more significant conclusions, the number of subjects should be increased.

TABLE III: Accuracy and precision obtained for all subjects for MLP. In $Subject$ column the additional information of the gender: male (M) and female (F).

Implicit method				
	MLP		**MLP+CNN**	
Subject	**Precision**	**Accuracy**	**Precision**	**Accuracy**
1 F	0.40	0.80	0.48	0.83
2 F	0.60	0.87	0.47	0.82
3 M	0.78	0.93	0.76	0.92
4 F	0.75	0.92	0.67	0.89
5 M	0.64	0.88	0.78	0.93
Mean	0.63	0.88	0.63	0.88
St. deviation	0.15	0.05	0.15	0.05

IV. Conclusion

With this work, we have shown that neural networks are promising to analyse a person's gaze and thus measure his/her attention. Thanks to this method, we achieved an accuracy of 88% improving by 13.7% in comparison to the original algorithm.

One of the major study limitations was the low availability of data for analysis, which prevented the choice of the best architecture. The networks need a large amount of data to train optimally, particularly the CNN. Moreover, we did not include the mechanical toy, which is part of the standard ESCS protocol, in our attention classifier as a target object of attention to simplify the protocol. Therefore, a method for real-time tracking of moving targets should be included so that the position of the mechanical toy could be integrated as input of the deep learning method.

In the future, we will test the developed protocol first with neurotypical children and then with ASD children to understand its sensibility to capture the differences between the two groups. Simultaneously, the attention classifier should be tested to verify its consistency in children. It is anticipated that there will be a minor reduction in accuracy, particularly among children with ASD, due to their inability to remain motionless in fixed postures. Nevertheless, measures similar to the ones used by the clinicians for the ESCS scale should be created to compare our automatic measures with validated clinical measures. In this way, this work will have a two-fold impact: it can be used to test the effect of the $IOGIOCO$ protocol on the improvement of children skills, if any, and it provides a quantitative framework for the qualitative clinical scales being applicable not only for Autism but also for other pervasive developmental disorders.

A safe robot control for semi-autonomous pedicle tapping

C. Lauretti[1], F. Cordella[1], I. Saltarelli[1], and L.Zollo[1]
[1] *Unit of Advanced Robotics and Human-Centred Technologies, Campus Bio-Medico University of Rome*

***Abstract*—The objective of this paper is to propose a novel safe control for robot-aided pedicle tapping that is able to identify the bone layer transition and stop the tool-tip before propulsion of the bone boundaries. The proposed control for pedicle tapping consists of : i) a hybrid position/force control loop that allows the surgeon to move the surgical tool along a pre-planned axis and ii) a velocity control loop that allows him/her to finely tune the tool rotational speed by modulating the tool-bone interaction force along the same axis. The velocity control loop integrates also a bone layer transition detection algorithm that stop the tool bit before propulsion of the the bone last layer. The approach was tested on the Kuka LWR4+ provided with an actuated surgical tapper which was used to tap a wood specimen simulating the bone layer density characteristics. The study demonstrated high capability of the proposed approach to i) promptly detect transition among the specimen layers and ii) stop the tool rotation as the transition to the last bone layer is detected.**

I. INTRODUCTION

In clinical practice, the pedicle screw is the implant of choice for treating patients with spinal deformity or spondylolisthesis [1].

The risk of screw misposition can be considerably decreased by tapping the screw path prior to screw installation [2] also thanks to the use of robotic devices that have been recently employed, in spine surgery, to make the screw fixation more repeatable and increase precision between the preoperative planning and postoperative position of the screws.

Commercial spinal robots are generally used to constrain the orientation and position of the surgical tool providing the surgeon with mechanical guidance [3], [4] during the surgical instrument use.

Although there has been a noticeable improvement in screw placement accuracy, movements along or around the tapping axis are still manually performed by the surgeon, who has to pay great attention while controlling the penetration of the surgical tool into the bone layers and stop its movements based on the visual feedback from the navigation system or, worse yet, on the perceived interaction force.

Therefore, the objective of this paper is to propose a novel safe robot control for pedicle tapping that is based on a bone layer transition detection algorithm [5] and is able to stop the tool rotation before propulsion of the last bone layer, hence preventing the underlying tissues from being damaged and making the procedure safer for the patient.

In addition, the proposed safe robot control for pedicle tapping has the following advantages: i) allows moving the surgical tool along a pre-planned axis, by simply exerting controlled forces on its handle, and ii) allows finely modulating the rotational speed of the surgical tapper by modulating the tool-bone interaction force along the same axis [6].

The proposed control was evaluated, at 6 thrust forces, on a wood specimen made of different materials that simulate the bone layers (i.e. cortical and spongy layer). Moreover, to assess performance in terms of success rate of the tapping execution and the readiness of the control strategy, a volunteer was asked to try the overall platform.

II. MATERIALS AND METHODS

A. The proposed Safe Control for pedicle tapping

The proposed safe control for robot-aided pedicle tapping is shown in the block scheme of Fig. 1. The following steps describe a typical robot-aided pedicle tapping procedure involving the use of the proposed control:

- Robot autonomous positioning: the robot is automatically positioned so as the tapping tool is aligned to the tapping axis, whose orientation is a priori computed based on pre-planned trajectories and thanks to the real-time information provided by an image-guided navigation system.
- Robot-aided tapping: the surgeon manually operate the robot end-effector along the tapping axis and enable the

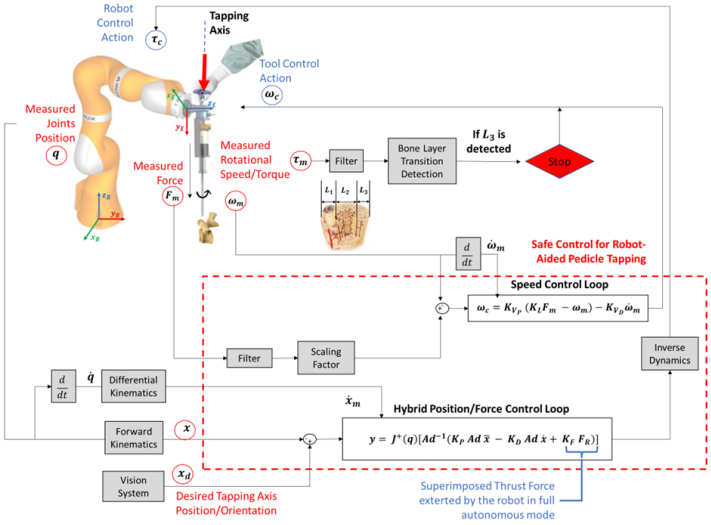

Fig. 1: Scheme of the proposed safe control for robot-aided pedicle tapping

tool rotation by finely tuning the force exerted onto the tool handle.
- Automatic tool stop: During the pedicle tapping, a Bone Layer Transition Detection is used to automatically stop the tool bit before going through the boundaries of the bone.

The following paragraphs report details about i) the robot control loop, ii) the tool motor control loop and iii) the bone layer transition detection algorithm.

B. Robot control Loop

The robot control law is described by the following equations

$$\tau_c = \hat{\mathbf{B}}(\mathbf{q})\mathbf{y} + \hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}}) + \hat{\mathbf{g}}(\mathbf{q}) \tag{1}$$

$$\mathbf{y} = \mathbf{J}^{\dagger}(\mathbf{Ad}^{-1}(\mathbf{K}_P\mathbf{Ad}\tilde{\mathbf{x}} - \mathbf{K}_D\mathbf{Ad}\dot{\mathbf{x}}_m + \mathbf{K}_F\mathbf{F}_R)] \tag{2}$$

where $\hat{\mathbf{B}}(\mathbf{q})$ is the estimation of robot inertia matrix, $\hat{\mathbf{C}}(\mathbf{q}, \dot{\mathbf{q}})$ accounts for the estimation of the Centrifugal and Coriolis effects, $\hat{\mathbf{g}}(\mathbf{q})$ is the estimation of the gravity contribution, $\mathbf{J}^T$ is the geometric Jacobian transpose, $\mathbf{q}$ and $\dot{\mathbf{q}}$ are the robot joint position and angular velocity, respectively, $\boldsymbol{\phi}$ is the command torque, $\mathbf{J}^{\dagger}$ is the robot geometric [7] Jacobian right pseudo-inverse, $\tilde{\mathbf{x}} = [\tilde{\mathbf{p}}; \tilde{\varphi}]$ is the position error expressed in the base reference frame $[\mathbf{X}_B, \mathbf{Y}_B, \mathbf{Z}_B]$ and $\dot{\mathbf{x}}$ is the robot Cartesian velocity expressed as $\dot{\mathbf{x}} = \mathbf{J}(\mathbf{q})\ \dot{\mathbf{q}}$ (see Fig. 1).

Matrix $\mathbf{Ad}$ in (2) is the adjoint matrix that transforms the velocity error $\dot{\tilde{\mathbf{x}}}$ and the position error $\tilde{\mathbf{x}}$ from the base frame $[\mathbf{X}_B, \mathbf{Y}_B, \mathbf{Z}_B]$ to the end-effector frame $[\mathbf{X}_{ee}, \mathbf{Y}_{ee}, \mathbf{Z}_{ee}]$. It is defined as

$$\mathbf{Ad} = \begin{bmatrix} \mathbf{R}_{ee}^{B} & \hat{\mathbf{p}}_{ee}\mathbf{R}_{ee}^{B} \\ \mathbf{O}_{(3x3)} & \mathbf{R}_{ee}^{B} \end{bmatrix}^T \tag{3}$$

where $\mathbf{R}_{ee}^{B}$ is the rotation matrix that expresses the end-effector orientation with respect to the base frame and $\hat{\mathbf{p}}_{ee}$ is the skew-symmetric matrix of the end-effector Cartesian position $\mathbf{p}_{ee}$.

$\mathbf{K}_P$ and $\mathbf{K}_D$ are the proportional and derivative control gains that are defined as 6×6 positive diagonal matrices $\mathbf{K}_P = diag(k_{P_1}, k_{P_2}, k_{P_3}, k_{P_4}, k_{P_5}, k_{P_6})$ and $\mathbf{K}_D = diag\{k_{D_1}, k_{D_2}, k_{D_3}, k_{D_4}, k_{D_5}, k_{D_6}\}$ where k_{P2} was chosen to be equal to zero so as the position control action has no influence along the Y direction, i.e. the tapping axis.

Conversely, $\mathbf{K}_F$ is a 6×6 identity matrix and $\mathbf{F}_R = [0, f_R, 0, 0, 0, 0]$ is a superimposed force exerted by the robot in an autonomous control mode, or by the surgeon in a semi-autonomous control mode.

C. Tool motor control loop

In the semi-autonomous mode, $\mathbf{f}_R$ is set to zero and the thrust force along the tapping axis is exerted directly by the surgeon. The surgeon can fine-tune the angular velocity of the tool according to the following control law

$$\omega_c = K_{V_P}(K_L F_m - \omega_m) - K_{V_D}\dot{\omega}_m \tag{4}$$

where F_m is the force supplied by the surgeon along the tapping axis (measured by the force/torque sensor put between the tool handle and the motor), K_V is the control gain factor, ω_m is the measured tool rotational speed and K_L is a gain factor used to scale the measured force after filtering.

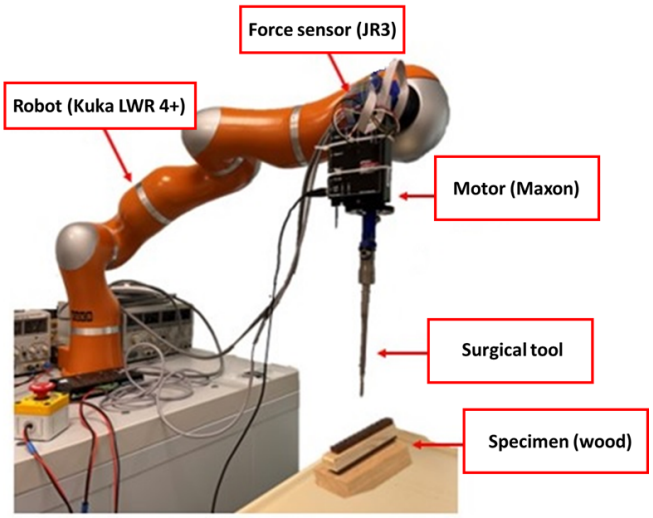

Fig. 2: Experimental setup

D. Bone Layer Transition Detection

Transition among each bone layer is detected on the basis of the the tool torque/current according to the following rules,

$$L = \begin{cases} L_1 & for \quad F(t) < C_1 P \\ L_2 & for \quad C_1 P < F(t) < C_2 P \\ L_3 & for \quad F(t) > C_3 P \end{cases} \tag{5}$$

where C_1, C_2 and C_3 are gain parameters experimentally retrieved, P is a scaling factor that is characteristic for each subject and is the first peak magnitude of the filtered torque and $F(t)$ is a feature function computed on the filtered torque signal as follows,

$$F(t) = \begin{cases} P & for \quad \frac{\tau_F(t) - min(\tau_F)}{P} > 1 \\ P\left(\frac{\tau_F - min(\tau_F)}{P}\right)^3 & for \quad 0 < \frac{\tau_F - min(\tau_F)}{P} < 1 \\ 0 & for \quad \frac{\tau_F(t) - min(\tau_F)}{P} < 1 \end{cases} \tag{6}$$

E. Experimental setup

The experimental setup used to test the proposed safe control for pedicle tapping is shown in Fig. 2. It consists of the following components:

- KUKA LWR 4+: a robotic arm provided with 7 Degrees of Freedom (DoFs) and position and torque sensors enbedded in its joints [8] [9] [10]. Robot Operative System (ROS) ensure the communication between the Kuka controller and a remote PC (UDP communication protocol with a frequency of 500 Hz)
- JR3 force/torque sensor: 6 DoFs force/torque sensor, used to measure the force applied by the surgeon or robot

along the tapping axis. Data acquisition is guaranteed by the DAQ NI USB-6008 device and signal recording and analysis is performed on a workstation under Labview environment
- MAXON EC-max Ø40 mm, brushless, 70W, with Hall sensors: electronically commutated DC motor that is speed-controlled via EPOS2 50/5 which is a modular digital positioning controller. The integrated sensors allow the acquisition of the current signal used for indirect torque measurement
- Surgical tool: used to tap the pedicle screw path. It is provided with a handle on which the user, i.e. the surgeon, can exert a direct force along the tapping axis
- Specimen with similar bone conformation characteristics. The specimen is composed of three layers, namely Upper Layer (UL), Middle Layer (ML) and Lower Layer (LL) whose characteristics are reported below:
  - UL: high density wood material of $8mm$ thickness, reproducing the bone Upper Cortical Layer
  - ML: Low density wood material of $19mm$ thickness, reproducing the bone Middle Spongy Layer
  - LL: high density wood material of $8mm$ thickness, reproducing the bone Lower Cortical Layer

F. Experimental Protocol

The experimental tests were aimed at assessing the capacity of the proposed method to promptly detect transition among different bone layers (measured in terms of time delay between the actual state transition and the detected one) and stop the tool bit before propulsion of the bone.

In a first experimental session, tests were carried out at 6 different thrust forces exerted onto the tool. To guarantee a constant thrust force, the robot again for these trials was piloted in autonomous mode, i.e. the force exerted by the surgeon was simulated by the robot.

In a second experimental session, a human operator was required to perform the specimen tapping by exerting a thrust force along the tapping axis (the orientation of the axis was a priori set to be parallel to the gravity axis). By means of this control modality, the user was able to indirectly tune the tool rotational speed by finely modulating the thrust force. Moreover, thanks to the Bone Layer Transition Detection algorithm, the tool rotation was promptly stopped as the transition between the middle and lower layer was detected.

G. Performance indicators

Three quantitative indicators were computed to assess the system performance in terms of i) capacity of the proposed method to promptly detect transition among different bone layers and ii) capacity of the proposed approach to stop the tool rotation as the transition among the middle and lower layer was detected. They are listed below.

Transition Detection Delay Index: The Transition Detection Delay (TDD) index is calculated as follows

$$TDD = \frac{t_d}{t_p} \tag{7}$$

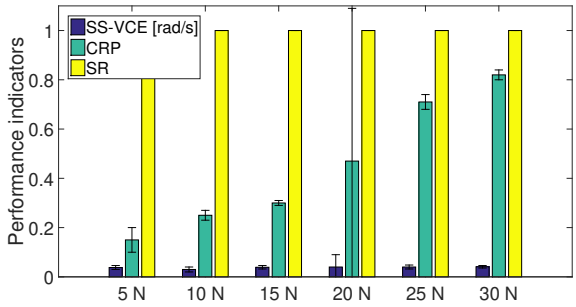

Fig. 3: Results obtained for the 1^{st} experimental session

where t_d is the time elapsed between the time instant when the transition among different specimen layers occurs and the time instant when the proposed Control detects the transition and t_p is the time the tooltip takes to project over the last cortical bone boundaries. t_p is defined as,

$$t_p = \frac{d}{v_t} \tag{8}$$

where d is the thickness of the bone cortical layer (in an adult of medium height this parameter is $2.9mm$ [11]) and v_t is the tool linear velocity.

Control Robustness to Perturbation: The Velocity Control Robustness to Perturbation (CRP) is calculated as follows

$$CRP = \frac{t_c}{t_p} \tag{9}$$

where t_c is the time elapsed between the time instant when a perturbation is given to the control input (i.e. a change in the tool velocity gains due to transition among bone layers) and the time instant when the motor control error reaches $0.05\ \frac{rad}{s}$.

Steady State Velocity Control Error: The Steady State Velocity Control Error (SS-VCE) is used to evaluate the accuracy of the proposed control to track the desired velocity when the thrust force gain parameters are modified according to the bone layer density (in a steady state condition). It is defined as follows,

$$SS - VCE = \|K_L F_m - \omega_m\| \tag{10}$$

Success Rate: The Success Rate (SR) of the tapping execution is evaluated as

$$Success\ rate = \frac{N_{succ}}{N_{tot}} \tag{11}$$

where N_{succ} is the number of trials successfully accomplished and N_{tot} is the number of all the performed trials. A tapping task is considered as successfully accomplished if all the following conditions are satisfied:

- $TDD + CRP < 1$
- $SS - VCE < 0.05\ \frac{rad}{s}$

III. Results and Discussions

Fig. 3 shows the results of the 1^{st} experimental session, i.e. mean value and SD of the CRP, SS-VCE and SR for each of the 6 tested thrust forces. As evident from the figure, the proposed control performance in terms of SS-VCE does not vary significantly as the thrust force increase; comparable errors have been obtained for all the tested forces. Moreover, it is worth noticing that the CRP is always lower than 1, meaning that the time required for the motor to stop is always lower than the time that tooltip takes to project over the specimen boundaries, at a given velocity. Hence, the tapping procedure could be considered successfully accomplished for all the tested forces, resulting in a success rate of 100%.

The results are also confirmed by the ones obtained during the 10 trials performed by the recruited subject ($SS-VCE = 0.06 \pm 0.09\ rad/s$; and $CRP = 0.19 \pm 0.07$) who exerted a mean thrust force of $15 \pm 5N$ during the 10 trials.

IV. Conclusion

In this paper, a Safe Robot Control for pedicle tapping based on bone layers transition detection has been proposed. The proposed approach is able to detect the bone layer density and promptly stop the surgical tool movements before projecting over the bone boundaries.

The ability of the proposed method to detect transition among different bone layers identification has been evaluated in terms of elapsed time between the time instant when the transition is detected and the time instant when the transition actually occurs. This delay has been compared to time that tooltip takes to project over the bone boundaries in order to evaluate the success rate of the tapping execution. A success rate of 100% has been achieved for all the tests.

Evaluating Spatial Hearing in Virtual Reality Environment

***Abstract*—Experimental protocols used in multisensory studies are typically simplified with basic stimuli, in contrast with the complexity of real-world situations. Virtual Reality (VR) and binaural audio technologies pose an opportunity to provide multisensory stimulation in ecological conditions and in a controlled way. The Head-Related Transfer Function (HRTF), which describes the interaction of sound with head and torso, is the most common used binaural spatialization technique. However, non-individual (or generic-) HRTFs are typically used leading to incorrect perception of sound locations. In such context, a common selection procedure of the subjective optimal HRTF is needed. In that work, we investigate the auditory spatial perception with two generic HRTFs in a sound localization task. Moreover, the perceptual similarities between two HRTFs, at individual level, was discussed. Results suggest no statistical significance difference between two chosen HRTFs set in the tested group.**

***Keywords*—Spatial Audio, Binaural Audio, HRTF, Multisensory integration, Virtual Reality.**

I. Introduction

Our brain is able to construct a robust interpretation of the space surrounding us by merging stimuli of different nature (visual, haptic, auditory, etc…). Understanding the underlying mechanisms is one of the key objectives in different fields such as rehabilitation in sensory deficit [1]–[2], neuroscience [3], etc. However, actual experimental paradigms use simplified protocols with basic stimuli, which are unable to capture characteristics of real-world situations that typically are three dimensional, dynamic and complex.

In this context, Virtual Reality (VR) technology represents an opportunity to investigate cross-modal interaction processes that occur in naturalistic environment in a controlled way. More precisely, the use of VR has the advantage to build scalable and reproducible experimental situations with high level of realism and immersivity by employing a relatively low-budget technology [11]-[12]. Recent developments have enriched the virtual experience making use of spatial audio tools (known as Binaural Audio), that allow the creation of three-dimensional soundscapes simply using a pair of headphones as a playback device. A widely used technology consists in the so-called Head Related Impulse Response (HRIR; or its equivalent in frequency domain: Head Related Transfer Function, HRTF), in conjunction with the Binaural Room Impulse Response (BRIR). More in detail, the HRTF is used to describe the change in sound spectrum due to the interaction of sound waves with the listener's torso, head and pinna [5] which embeds localization cues–such as Interaural Time Differences (ITDs), Interaural Level Differences (ILDs), and spectral cues–within the original sound stimuli [6]. The BRIR incorporates in the virtual simulation the acoustical properties of an indoor environment (e.g., reverberation). Because measurements of individual-HRTF are costly and difficult procedures, generic-HRTF are typically used [7], although they provide a worse spatial perception in terms of localization accuracy [8] and confusion over auditory source location [9]. However, the results regarding such limitations are mixed, and other cues, such as reverberation, head movement, and vision, may be more critical factors for robust auditory spatial perception [10].

The aim of this work is the characterization of the individual's auditory spatial perception in a 3D soundscape rendered using binaural audio. In particular, we evaluate the accuracy in localization of a virtual sound source synthesized using non-individual HRTFs: a commonly used evaluation method [13]—[14]. Finally, to select the best HRTF in terms of spatial perception, the perceptual differences within two non-individual HRTFs from IRCAM Listen database (Ircam listen HRTF database, [14]) was investigated.

II. Materials and methods

A. Experimental Setup

The system consists of VR Headset (HTC VIVE Pro), hand VIVE controller and a pair of headphone Sennheiser HD 280 Pro. The VR system is real-time tracked by means of two infrared cameras fixed at the corner of the experimental area. Such tracking system allows to the participant to freely interact in the virtual environment with head and hands movements. The application has been developed by means of Unity 3D; SteamVR 2.0 system was used to define custom behaviour of VIVE controller during the experiment.

As regards the spatial audio engine, the Unity Wrapper of the open-source toolkit 3D Tune-In Toolkit [17] was employed. More in detail, sounds were spatialized using two HRTFs, from the IRCAM Listen database, and a generic BRIR filter synthesized for an empty room of 7x7x3m. Two employed HRTFs correspond to subject IDs IRC0008 and IRC0013 within the database. Active listening is supported by spatial audio engine and real-time tracking system.

Finally, custom-written MATLAB (MATLAB R2021b) scripts were used to generate auditory stimuli.

B. Experimental protocol

Eight participants with normal hearing (mean age 27 y, range 25–29 y) were tested in a sound localization task. During the experiment participants sat on an office chair, in a silent room, listening to the binaural recordings over headphones. Experimental procedure consists in two subsequent sessions: familiarization (see Fig.1) and test, both with no fixed time duration. In the first phase, a set of interactable loudspeakers were located inside the room

around the virtual listener, each one at different location, to familiarize with auditory space. In the next phase, sound localization task with no visual targets was performed. A virtual button positioned in front of the user was used to initiate playback of a complex auditory stimuli, randomly chosen within a set of 19 radio-like communications with time duration of 1.6s. More in detail, the structure of the stimulus consisted in a pink noise burst of 200ms, followed by 1s of female English speech with low level pink noise (SNR equal to 25dB), an another 200ms pink noise burst and, a final, 1kHz tone of 200ms, as described in [16]. Instructions of the experiment was conveyed to the player using a Head-up Display (HUD).

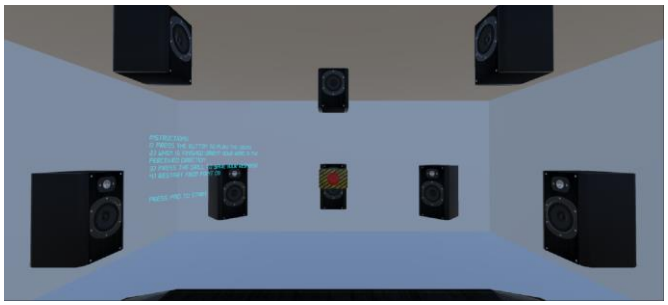

Fig. 1: Screenshot of virtual player view in the virtual reality room during familiarization phase. Virtual button (ahead) initiated playback of spatialized stimulus. Head-up display (HUD) on the left was used to convey instructions to the player

Participants were instructed to start each trial by means of the virtual button and, when the stimulus is finished, orient their head in the perceived direction. Response is saved by pressing a VIVE controller button.

During test block, the two generic HRTFs were switched randomly at each trial. For each one, stimuli were presented in a casual order along twelve different orientations around listener head, each one repeated for $n = 10$ times. Eight were defined at 0° elevation, with azimuths steps of 45°. A further four orientations were defined at 45° elevation with azimuths equal to 45°, 135°, 225° and 315°. Distance from head subject of each trial was chosen randomly between 0.8, 1.4 or 2.0 meters. In summary each subject was tested on $2 * 12 * 10 = 240$ trials.

C. Data Analysis

Data were analysed in MATLAB R2021b, removing outliers meant as trials in which the orientation of the head-mounted display deviated by more than 6° in any direction. Spatial locations are represented in a single-pole coordinate system. More in detail, horizontal location are identified by azimuth θ, defined as the right-handed rotation around vertical axis that passing through the centre of the HMD position with 0° being forward direction; the vertical location are specified by the elevation angle ϕ, that referrers to the angle subtended at the center of the head relative to the horizontal plane, with 0° being horizontal orientation and 90° being vertical orientation.

To evaluate sound localization accuracy two localization unsigned error are used. The former is the **polar error**, defined as the absolute value of the difference between target horizontal location and response horizontal orientation of the head. The rate of trials in which polar error is greater or equal to 60° is defined as *front-back confused* trial. Front-back confusion is the rate of front/back confused trials. The latter, **spherical error**, is defined as the absolute difference between target and response location.

III. Results

Front/back confusion rate is similar within group for two HRTFs (IRC0008, mean = 25.73%, SD = 3.32; IRC0013, mean = 23.44%, SD = 3.71). Fig.2 shows the mean localization error (spherical (a) and polar (b) error) pooled across all participants, as a function of target azimuth, for both conditions (IRC0008 and IRC0013).

The largest accuracy in localization error was observed when the virtual sources were placed laterally, as opposed to the frontal and rear positions resulting in the lowest accuracy, with both HRTFs.

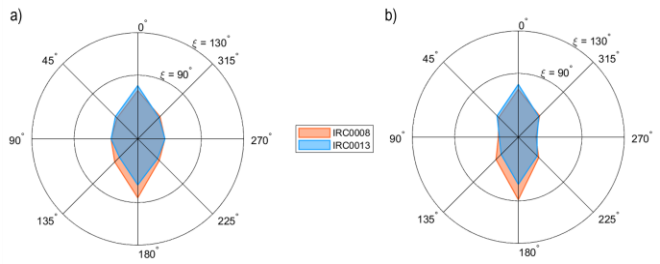

Fig.2: Mean spherical and polar error averaged across participants for the two HRTFs

Subsequently, to investigate individual perceptual dissimilarities with two HRTFs, a one-way ANOVA was conducted. Such analysis indicates no statistically significant difference in localization error distribution within two HRTFs in any subject: F(1,1918) = 2.24, $p = 0.135$ (spherical error) and F(1,1918) = 1.91, $p = 0.167$ (polar error). Fig.3 shows spherical (a) and polar (b) error distribution in both conditions and for each participant.

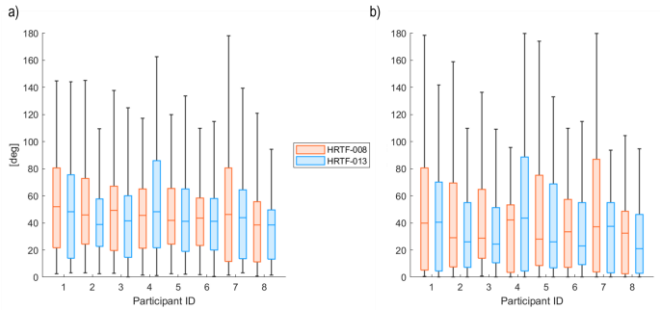

Fig.3 Spherical (a) and polar (b) error distribution for both HRTFs (red: IRC0008, blue: IRC0013) in each participant

IV. Conclusion

A preliminary analysis on sound localization task in virtual reality with two distinct generic-HRTFs has been conducted. Overall, the level of directionality perception and front/back confusion, supports previous findings of several similar studies (see [9]-[16]). Moreover, we investigated the perceptual differences in terms of localization error, within two non-individual HRTFs set from IRCAM Database. No

significant statistical differences were found in any subject suggesting that the two chosen HRTFs are close in terms of perceptual similarities. However, because of the small size of data set, further and more accurate analysis is required. In fact, to investigate the perceptual equality of two HRTFs some metrics can be employed to evaluate spectral differences between two HRTFs such as spectral distortion [20] and auditory models for human sound localization [19].
Moreover, a potential improvement in evaluate sound localization accuracy could be obtained by means of a different coordinate system inspired by binaural hearing (known as interaural-polar coordinate system [16]), that employs coordinates related to localization cues.
Future perspectives consist in improve the acoustic individual realism of the virtual environment. In the recent years, several methodologies have been proposed such as HRTF personalization [7], training paradigms [16] or generic-HRTF recommendation based on perceptual similarities and anthropometric features [18]. The key idea is to employ such technology in a multimodal virtual reality platform to study multisensory integration processes in ecological and controlled situations.

***Abstract*—Subjective cognitive decline (SCD) and Mild Cognitive Impairment (MCI) are receiving increasing attention as risk factors for incident dementia. Cognitive training has been reported to delay and/or counteract cognitive decline. During the last years, software applications have been increasingly used to support cognitive training. Here we describe a mobile platform which has been specifically designed for cognitive training and assessment. Subjects use the application to play a variety of exergames and all their actions and performance are recorded into a cloud database. Therapists can monitor subjects performance using the database interface. The application currently focuses on training attention, memory and executive functions, which are some of the functions mostly involved in deterioration. We carried out two preliminary studies. The first study involves healthy subjects of different ages (15-19, 20-30 and 50-65 years old). We also ran a preliminary acceptance study, involving persons with SCD. In all games, performance varies with age. We also found that there is a good acceptance of the application in persons with SCD. We conclude that the application is a promising tool to assess cognitive functions.**

***Keywords*—Cognitive training, mobile health, telehealth.**

I. INTRODUCTION

Dementia is defined as a deterioration of cognitive function – usually of chronic or progressive nature – 'beyond what might be expected as a consequence of biological ageing'. In the last ten years, research has been focused on identifying early predictors of dementia onset.

Persons experiencing a subjective decrease in cognitive functions, with no evidence of objective complaints – Subjective Cognitive Decline (SCD) [1] – exhibit an increased risk of subsequent objective cognitive decline, which may progress into Mild Cognitive Impairment (MCI). From [2], the annual conversion rate from SCD to MCI is 6.6%, while it is 2.3% to dementia, compared with 1% in those without subjective decline. These results have recently been confirmed by [3], a meta-analysis addresses to evaluate the rate of incidence of MCI and dementia in persons with SCD, and also factors which might influence the relationship between SCD and the risk of future decline. After the onset of the COVID-19 pandemic in 2020, the incidence of people with cognitive impairment has been reported to increase [4]. Attention, memory, language and executive functions are the aspects of cognitive functions that are most frequently involved in SCD.

Training strategies have been designed to enhance individual capacity to process and interpret information. While there are no effective treatments for dementia, evidence suggests that cognitive training may have a long-term impact and might enhance cognition in face of future brain changes. For instance, sustained effects of cognitive training have been demonstrated on ageing [5]. As cognitive training programs must be intensive and prolonged over time, information and communication technologies have been increasingly regarded as potentially effective options to support cognitive rehabilitation [6].

Several recent reviews have summarized the most widely used applications. Reference [7] examined different studies on seven commercial training programs within two separate populations: healthy older adults and older adults with MCI. Findings suggest that improvements in cognitive functions using training strategies were limited to tasks similar to the proposed training game. References [7] and [8] analyze individual cognitive domains for healthy subjects and yielded effects for some cognitive functions such as executive functions, memory and processing speed, but not objective measures for attention.

As these applications were not specifically designed for clinical studies, participants' strategies and performance games were not considered in the analysis, which mostly focused on general outcome measures before and after training (for a review see [9], [10]). A more controlled setting may potentially provide information on how cognitive decline affects player performance and evolve over time.

Here we present a novel mobile (Android) application, specifically aimed at telemonitoring of cognitive performance of the outpatients of the Center for Cognitive Disorders and Dementia of the Galliera Hospital, Genoa with SCD episodes. The app – Allenamento Personalizzato Preventivo, or Personalized Preventive Training (APP Galliera) – has been originally developed as a substitute for in-presence periodic assessments during the COVID-19 pandemic, and has been specifically designed to train attention, memory and executive functions. The app makes games available to users and records both game performance and individual moves during each game. This information is stored into a dedicated cloud-based database. Through a custom dashboard, therapists may provide individual users with specific training prescriptions and can monitor game use and ongoing performance, so that changes in performance can be promptly identified. We also present preliminary results from game use in two populations

of subjects: (i) persons with no signs of cognitive decline, stratified by age groups; (ii) persons with SCD.

II. Materials and Methods

A. Platform architecture

The platform consists of an Android application connected to a cloud database where game data is stored; see Figure 1. The application includes different exergames, which are developed to assess – and train through repeated performance – a specific cognitive function. Individual game records are collected into a Cloud Firestore (Firebase) database – a non-relational document database, which allows more flexibility in representing game-specific information. The cloud-based database is compliant with the EU General Data Protection Regulation (GDPR) legal framework. The database keeps track of the list of authorised application users and records performance for each game, and each move within a game. All data are made available to the therapist through the standard web-based interface. Every time the application is run, the user must authenticate through a one-time password (OTP). A cognitive training session typically involves playing different games, possibly multiple times. The application has been developed using Android Studio IDE. The games have been implemented using the LibGDX game engine.

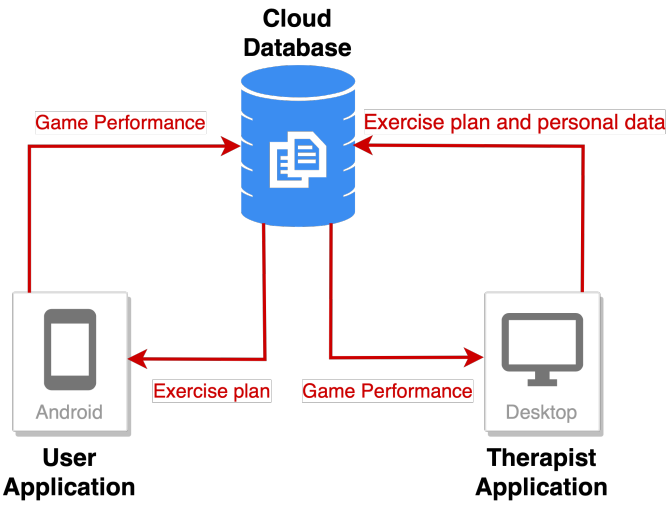

Fig. 1: System architecture. The platform involves a user application, a cloud database and a therapist dashboard

B. Cognitive training games

The application currently offers five games (see Figure 2), each aimed at a specific cognitive domain. Games have been designed to recall daily life activities.

1) Bird: The game focuses on attention and is inspired by the Attention Network Test (ANT)[11]. A flying bird (a swallow) is displayed on the screen. Players must indicate whether the bird is flying by pressing the arrow buttons placed in the bottom region of the screen. There are three difficulty levels: (i) the stimulus (bird) is displayed in isolation, or with other birds (flankers) flying (ii) in the same (congruent) or (iii) opposite (incongruent) direction. The response time (time delay between stimulus onset and user response) is taken as a measure of attention. Errors and flankers are also recorded, so that it is also possible to quantify the effect of flankers on response time.

2) Waste Sorting: In this game – focused on executive functions – the goal is to sort the garbage items that appear on the screen, by putting them into the right trashcan (plastic, glass, paper, and compost waste). There are two levels of difficulty: the garbage items are displayed in the same colour as the correct trashcan, or they are displayed in their natural colour. As before, performance is measured in terms of response time and errors.

3) Key: In this game – also related to executive functions – the goal is to open the door by matching the keyhole with one among the available keys. Response time is taken as a measure of performance; errors are also recorded.

4) Cart: In this game, the action takes place in a supermarket. A list of ingredients is displayed first. The goal is to move a cart in order to catch the items falling down from a shelf. The food items that are not part of the recipe must be ignored. There are different difficulty levels, corresponding to different fall velocities. The game relates to attention and executive functions. Performance is measured by the number of correct catches, which must be put in relation to game difficulty.

5) Memory: The game is an implementation of the popular card game known as Memory or 'concentration' and is related to working memory. A deck of $2n$ cards is displayed (covered) on the screen. Players must turn pairs of cards. If the cards are identical, they are left uncovered and one point is scored. Otherwise, they are covered again. Game performance is related to the number of moves needed to uncover all pairs of cards. Response time is also recorded. Depending on game performance, the number n of card pairs could vary in the next game ($n = 3, 4, 6, 8$). The number of moves required to end the game is related to memory span – the amount of items a player can simultaneously remember. For each move in a game, the application records the value and location (row, column) of the cards selected in a trial, whether the match is correct and the time elapsed from the selection of the first and second cards. It should be noted that different from the other games, performance is not only determined by the skill of the player but also has a chance element – depending on the location of the matching pairs[12].

During a game, game-specific information is saved in the database, which belongs to two broad categories: (i) Context data: all attributes of a single trial of the game, e.g. game modality, difficulty level, etc; (ii) Action data: description of user moves and game performance.

C. Experiments

1) Study 1: age-related differences in game performance: A total of 15 subjects with no evidence of cognitive and motor impairments, were assigned to three age groups: age 15-19 (4M+1F); 20-30 (3M+2F); and 50-65 (2M+3F). Participants

Fig. 2: Game screens. The application includes five games, from the left: bird, waste sorting, cart, key and memory.

were required to play all games once a day for five consecutive days.

2) Study 2: user experience: The study involved seven subjects (2M+5F) with age 59-82 and early signs of cognitive impairment (SCD: 6, MCI: 1). Participants were free to use the application whenever they wanted during the first week from installation.

III. Results

A. Study 1: age-related differences in game performance

One 15-19 subject did not complete the experimental protocol and was excluded from the analysis. In each game, the first answer of the first time playing was excluded from the evaluation.

1) Bird: Game performance (response time of correct answers, in different conditions and age groups) is depicted in Figure 3. Response time is consistently greater when age increases. Inconsistent with ANT outcomes, we observed a decrease in the response time from the simpler (no flankers) to the more complex condition (incongruent flankers). This effect could be explained with the progressive nature of the game – subjects played with the highest level of difficulty always after training with the lower levels.

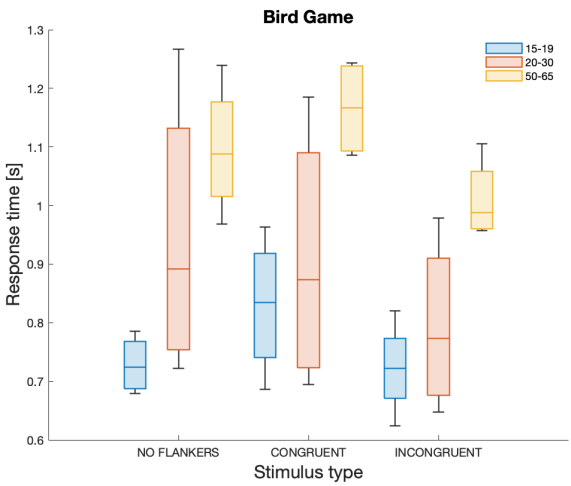

Fig. 3: Bird Game: Response time (correct answers only) for different stimulus types, per age group.

2) Waste Sorting: This game also involved different situations. In trials with no colour cue, the response time was generally shorter – possibly a learning effect as the colour cue was only provided in early trials. Or, colour cues actually made identification of the garbage item more difficult (performance data not shown).

3) Key: We found a degradation of performance (greater response time) in the 50-65 age group; see Figure 4.

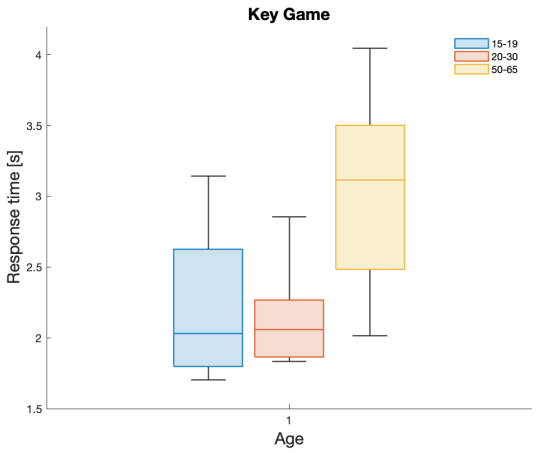

Fig. 4: Key Game: Response time per age group.

4) Cart: Performance (mean number of correct answers, i.e. the number of items that were in the recipe and were taken, plus those that were not in the recipe and were not taken) decreases with age (results no shown).

5) Memory: The mean number of moves suggests no clear group difference when looking at the late performance (the

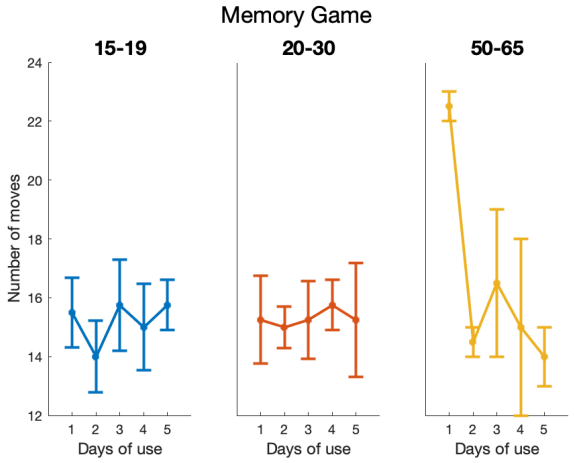

Fig. 5: Memory Game. Number of moves (Mean ± SE) per age group, across days of use.

fifth day of usage). However, across days, a learning effect seems to be only observed in the 50- 65 group (results no shown). Because of the chance element, the number of moves for a given skill (memory span) is a random variable. Theoretical analysis of optimal performance [12] predicts that in the case of perfect memory (infinite memory span), the average number of moves to complete the game is $1.6n$ where n is the number of pairs. In contrast, with no memory (zero memory span) the game is completed on average in n^2 moves. In the experiment, we set $n = 8$, corresponding to a number of moves ranging from 12.8 (perfect memory) to 64 (no memory).

B. Study 2: user experience

Figure 6 summarises the user activity during the first week of use. More than 70% of users actually used the platform at least once (Large and Medium Users), and 57% used it more than three times. This figure suggests that there is an interest in using the platform. A more thorough analysis, involving questionnaires on user experience is currently under way.

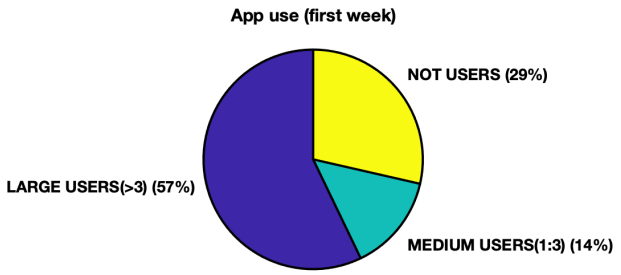

Fig. 6: App use during the first week from installation. Large users played more than three times, medium from one to three times, not users didn't use it.

IV. Conclusion

We have developed a mobile platform for cognitive training, intended for monitoring and counteract cognitive decline. The medical staff at the hospital can monitor the performance of the subjects using the interface of the cloud database where all data is saved. Preliminary results suggest that games developed are able to detect age-dependent differences in cognitive performance. Early results also suggest partly divergent requirements for monitoring and training functionality. While monitoring of multifaceted functions like attention requires randomization of stimulus conditions (i.e. congruent vs incongruent stimuli), promoting engagement requires a gradual increase of exercise difficulty, which may introduce learning effects that need to be acknowledged when interpreting performance. Preliminary results also suggest that the use of the application with persons with SCD/MCI is feasible and well accepted. A full clinical study is under way. The current version of the app has five exercises which target different cognitive functions and a basic therapist interface, but the platform can be easily extended to cover additional cognitive functions, like language processing, and the further development of the therapist interface, equipped with a dashboard to monitor the performance of multiple patients and with the option to set-up personalised exercise schedules.

***Abstract*— People with severe body paralysis mainly rely on the use of powered wheelchairs to move autonomously without the assistance of a caregiver. Nowadays powered wheelchairs offer a large variety of controllers, which span from the most common joystick to more sophisticated systems such as the sip-and-puff or the head array. Most of this device use a discrete variable as control inputs, while little effort has been devoted to investigating the possibilities offered by continuous control. Only recently, a powered wheelchair control interface that uses instantaneous upper body-configuration signals to generate powered wheelchair commands was developed, through the application of linear dimensionality reduction (DR) methods. However, DR methods may not be able to capture the non-linear nature of the input data, leading to overestimation of their actual dimensionality. Therefore, in this work we propose a possible solution to overcome the abovementioned restriction based on employing non-linear DR techniques, which could be more efficient in capturing the structure of the input data and, therefore, might improve the control of the devices. In particular, we developed a non linear autoencoder network using the units of its bottleneck as control commands for the powered wheelchair. Such interface was tested with a proof-of-concept experiment involving a single subject successfully performing a variety of tasks while controlling a real powered wheelchair. Our findings suggests that non linear DR methods could lead to a more efficient control for a powered wheelchair interface compared to linear DR methods.**

I. INTRODUCTION

Body Machine Interfaces (BoMIs) define a way to interact with different types of devices, allowing their users to overcome the limits of their motor abilities by exploring their body's redundancy. Among the many different types of devices that can be controlled through a BoMI, this paper focuses on powered wheelchairs. These represent one of the most effective ways to move autonomously for people who are unable to self-propel a manual wheelchair, for example, people with both lower and upper-body paralysis deriving from a high-level Spinal Cord Injury (SCI). The remaining upper extremity function in these individuals depends on the injury level. For example, people with a cervical lesion between C2 and C4 generally have no arm and hand muscle function, but preserve shoulder elevation and some neck muscle control [1] or in the most severe cases cannot move anything else other than their tongue and face. Therefore, in the former situation, there is still some retainment of movement that can be redirected towards the generation of an efficient control signal. In the latter situation, for the most severe cases a tongue computer interface has been designed to provide real-time discrete and proportional control for computers and for operating a powered wheelchair [2], [3]. While, for SCI people with some residual movements of shoulders and arms it has been previously demonstrated that such signal can be used to successfully control the speed and direction of a powered wheelchair [4]. More specifically, the interface developed in the aforementioned study included Inertial Measurement Unit sensors (IMUs) to detect and measure shoulder movements which were mapped to powered wheelchair control commands for people with cervical SCI. The powered wheelchair commands were obtained by applying a linear DR method to the recorded IMU data: Principal Component Analysis (PCA). PCA reduces the dimensionality of the input creating a map that consists in a low-dimensional, latent space that maximizes the input variance [5], and whose directions are identified by the Principal Components (PCs). Only the first two PCs (which by definition explain the most variance of the input data) were used to control the powered wheelchair velocity.

Although PCA is a computationally straightforward and inexpensive procedure, it presents some limitations imposed by its orthogonality and its ability to only account for linear relationships in the input signals [6]. To account for the non-linear features of shoulder movements, this paper considers a non-linear DR method based on Autoencoder Networks (AEs). The efficacy of AE was previously demonstrated in a study regarding prosthetic hand control [6]. The aim of such research was to find a parsimonious representation of hand kinematics data that could facilitate prosthetic hand control by comparing PCA and AEs in their ability to accurately capture a wide range of hand gestures and actions. According to this study, the AE exhibited higher performance than PCA in its ability to reconstruct hand kinematic data from its latent space, and was able to produce a manifold of more separable movements as well. AEs also showed to be an effective control platform to operate a computer cursor ([6], [7], [8]), or a 4D virtual robotic manipulator [9]. Here, we wanted to extend the use of AEs and verify whether they could also be used as a means to control a powered wheelchair. Therefore, the aim of this study was to test the feasibility of BoMI based on a nonlinear map between the input and output signals to control a power wheelchair.

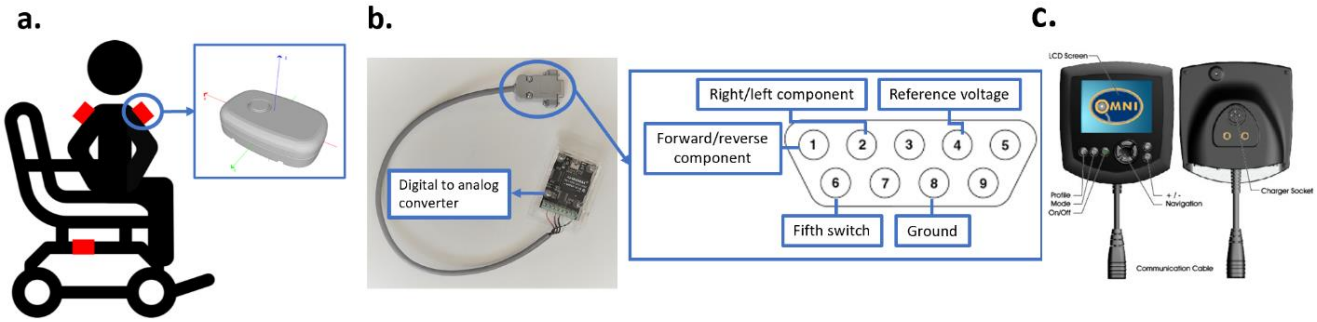

Figure 1: Experimental set up and hardware components: **a.** Experimental set up: Inertial Measurement Unit sensors are represented in red: two are placed on the subject's shoulders and a third one on the wheelchair; **b.** Digital to analog converter connected to 9 way D-Type connector; **c.** OMNI Wheelchair' interface.

II. MATERIALS AND METHODS

A. *General description of the system*

The objective of the BoMI developed in this study was to use high dimensional shoulder movements in order to control, in terms of velocity, a powered wheelchair through the application of non-linear dimensionality reduction methods. In more detail, three IMU sensors (Fig 1a, BNO055 orientation sensors, Bosch Reutlingen, Germany, the same sensors used in [10]) were used to detect the subjects' shoulders movements. The IMUs data was recorded with a sampling frequency of 50 Hz. Similarly to [11], two of the three sensors were placed on the shoulders and attached to a vest, which was worn by the subjects during experimental testing (Fig 1a). The third sensor, was placed on the wheelchair, as a means to subtract the contribution of the wheelchair's acceleration and velocity (during the driving phase) from the signals acquired from the shoulders; and to separate intentional movements (coming from the individuals controlling the wheelchair) from unintentional ones, which could result from uneven surfaces on the road. The data acquired from the IMU was sent via Bluetooth to a computer onboard the wheelchair, which contained the software developed in C#, as a Windows Form Application, to acquire the signals from the IMUs and preprocess them as mentioned above. The processed IMU data recording shoulder movements was then mapped via an AE into a 2D vector that specified the position of a computer cursor, whose coordinates were converted in real time into two digital voltage values. These digital voltage values were finally converted into analog voltages using a digital/analog converter (Phidget Analog 4-Output, Fig. 1b) and were directly sent as input, via a 9 way D-Type Connector, to the wheelchair's interface OMNI (Fig. 1c).

B. *Acquisition and mapping of shoulder kinematics*

Two IMUs were used to acquire shoulder kinematics. Each sensor measured the orientation in quaternions format. Differently from the previous work [11], we did not derive orientation using Euler angles because quaternions are able to overcome the "Gimbal lock effect" [12]; therefore the recorded signal from the body of the subject was a 8-D vector.

The first step of the data acquisition consisted in an initial calibration. Subjects were asked to perform a 1 minute "dance", during which she had to freely move the shoulders within a range of motion that was comfortable for her. The signals acquired during the calibration represented the dataset used to train the AE before using it for operating the BoMI.

The AE is an artificial neural network composed of two networks: an encoder that projects the input data into a latent space, that in the BoMI is the control space for a computer or an external device like the powered wheelchair and a decoder that projects data in the latent space back to the output space, with the same dimensionality as the input. The AE structure used for this project (same as the one found here [6]) included input and output layers of 8 units and a total of three hidden layers, the middle one being the bottleneck layer (Fig.2). The bottleneck layer had two latent units, which were used to control the *x*, *y* coordinates of the computer cursor that would ultimately move the powered wheelchair, respectively; while the first and third hidden layers were composed by 8 units. Similarly to the original AE proposed by Kramer in 1991 [13], we chose a non-linear activation function, a hyperbolic tangent, for the first and third hidden layers, and a linear activation function for the bottleneck. The use of both linear and non-linear activation functions has been shown to help increase the ease with which the network learns linear relationships in the data [14]. In order to train the AE we split the kinematic data recorded during the calibration (3000 samples, 1 minute dance with a sampling frequency of 50 Hz) into 80% of training points (2400) and 20% of test points (600) and a full-batch gradient descent was used.

C. *User interface and Analog powered wheelchair commands*

The screen displayed a circle divided into nine sections by a grid (Fig. 3), corresponding to different wheelchair

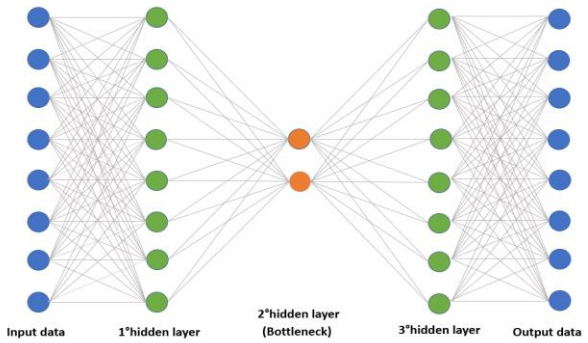

Figure 2: The non-linear Autoencoder (AE) structure used in this study. The AE has an input and output layer of 8 units and a three hidden layers, the middle one is the bottleneck. The bottleneck layer had two latent units, used to control the computer cursor and move the powered wheelchair

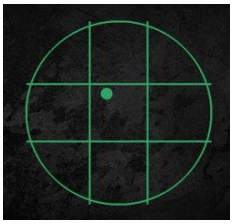

Figure 3: The driving interface shows the circle divided in nine sections in which the subjects can control the cursor on the screen in ordered to move the wheelchair in the desired directions.

commands. We designed such commands to mimic a typical joystick controller. When the cursor was in the center of the screen, the powered wheelchair was stationary. As the cursor moved up or down, the speed increased (wheelchair moving forwards) or decreased (wheelchair moving backwards), respectively. Similarly, as the cursor moved left or right the rotational command changed to cause the powered wheelchair to turn left or right respectively. Therefore, each *x* and *y* cursor's coordinates would be linearly converted into first digital and then analog voltage values compatible with the wheelchair's commands, which ultimately allowed subjects to move the wheelchair. The voltage values assigned varied linearly, progressively increasing as the cursor was moved away from the center of the grid. Overall, the total of voltage values sent to the wheelchair were four (Fig. 1e), corresponding to:

1. Forward/reverse movement component (pin 1);
2. Right/left movement component (pin 2);
3. Reference voltage value (6 V) (pin 3);
4. "Fifth switch" voltage value (pin 6). This output functioned as an emergency button: therefore its value was always maintained at 2.5 V, except in case of an emergency, when it was brought to 0V. In this scenario the wheelchair would stop immediately.

Once the digital voltage values were converted into analog voltage values by the digital/analog converter, such values were sent to the OMNI wheelchair's interface (Fig. 1e). The wheelchair used in this study was provided by Ottobock, Genova, IT

D. Experimental protocol

To assess the correct functioning of the entire system, we designed a protocol that could also be used for potential future experimental testing. In addition to the initial 1-minute initial calibration ("dance" mentioned in section *B*), we included exercises that consisted of a first familiarization phase w BoMI, where the subject was trained to control only a cursor on a computer screen, and a second phase, where the subject was trained to control the powered wheelchair. In the first phase, the subject seated on the non-moving wheelchair performed center-out reaching tasks by controlling the cursor on the laptop's screen using shoulder movements. This exercise was designed to enable the subject to find the best and most comfortable strategy to control the cursor. In this task there were six external targets placed on a circumference centered in the middle of the laptop's screen, with a 5 cm radius, and a central target placed in the center of the screen, corresponding to the "dead zone" of the BoMI wheelchair driving. The subject was required to complete five series of center-out reaching tasks on the screen, with each task consisting of a total of sixteen movements, before proceeding with the second phase of real powered wheelchair driving. In this phase, the subject was instructed to complete different maneuvers with the wheelchair, including: performing a real center-out reaching task, where the subject drove the wheelchair from a starting point to three real targets placed 1.5 meters away (this was repeated three times); going up a ramp with a slight slope (in this case ~5% and 7 m long); perform a slalom around 3 obstacles placed on a straight line every 2 meters. To track the movement of the wheelchair we also integrated an Intel Realsense Depth and Tracking camera, that was attached to one of the armrests of the wheelchair and from which we were able to extract the wheelchair's trajectory.
A preliminary test of the full experimental protocol was conducted on one pilot subject (24 years old unimpaired female).

E. Dimensionality reduction metric

We compared the difference between a linear approach based on PCA and the AE network in terms of variance accounted for (VAF) by the respective 2D latent spaces using as dataset the one of the dance. The VAF measures the difference between the reconstructed output and the original input, therefore it represents a measure of the information preserved by the dimensionality reduction method applied to the original data (equation below, for more details on VAF see [4]).

$$VAF(\%) = \left(1 - \frac{var(Y-\hat{Y})}{var(Y)}\right) * 100$$

Where Y is the original data and $\hat{Y}$ is the reconstructed data.
A VAF of 100% means perfect reconstruction.
First we compared the VAF of the 2D latent space obtained with both PCA and AE, and then we compared the VAF computed on each one of the two dimensions of the latent spaces for PCA and AE.

III. RESULTS

A. Dimensionality reduction methods

In order to compare the performance of PCA and AE we chose to analyze the VAF explained by the above dimensionality reduction methods (as previously mentioned in section *E*). Consistently with the results obtained in the study on hand kinematics [6], we found that AE with 2 latent dimensions was able to account for 95.43% of the input data variance, while PCA was able to account for 86.45 % (Fig. 4).

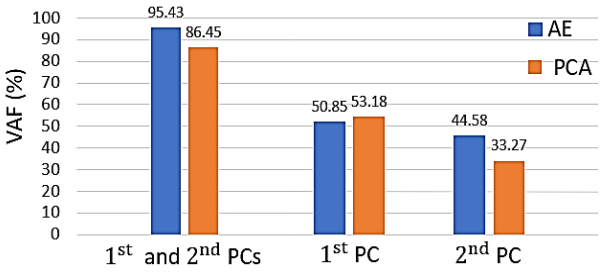

Figure 4: Comparison between Principal Component Analysis (PCA) and the Autoencoder network (AE) in terms of Variance Accounted for (VAF) explained by the latent space.

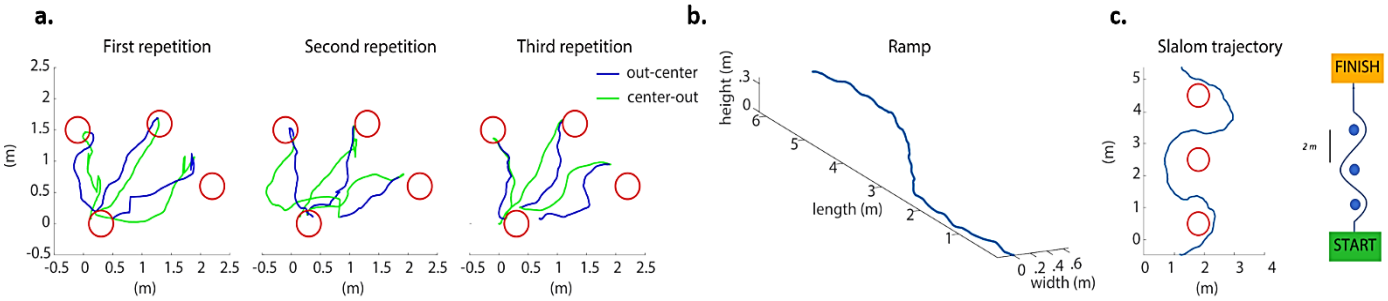

Figure 5: Wheelchair's trajectory during exercises. **a.** wheelchair trajectories while going from the starting point to the external target in green, and in blue the trajectories while going back to the starting target; **b.** wheelchair's trajectory while going up a ramp with a slight slope; **c.** wheelchair's trajectory while doing a slalom.

This result was partially expected due to the fact that AE networks are intrinsically designed to learn both linear and non-linear features from the input data. The more interesting result observed in this study relates to the comparison of the VAF explained by the single dimensions of the latent space obtained with PCA and AE. Fig. 4b, shows that the variance dropped significantly across the first and second PC, while the variance explained by the AE was comparable among the first two latent dimensions. This result demonstrates the limitations imposed by the orthogonality of PCA, and also highlights the benefits deriving from the application of an AE network, which is able to distribute the variance more evenly among its components (in our case we were interested in the first and second components).

B. Driving the wheelchair

The trajectory of the wheelchair extracted by the Intel Realsense sensor can be observed while performing the wheelchair maneuvers mentioned above (section *D*).

The wheelchair was fully tested on one subject. The first task of the real driving was the reaching of three different points in space and the coming back to the starting point. From a visual inspection of the trajectories it is possible to notice how the subject improved in driving a real powered wheelchair, with the trajectories becoming straighter and smoother. In the ramp exercise (Fig. 5b) the subject was able to safely ascend the ramp and stop at the end of it, although the trajectory of the wheelchair seen from above was not comparable to a straight line. More importantly the change of height did not affect the measures of the IMUs, indicating that the correction algorithm that was removing the effects of the wheelchair motion from the subjects body motion was properly working. Moreover, the subject was able to complete the slalom exercise (Fig. 5c) making quite smooth turns not too far from the obstacles and with no need for many corrections.

IV. CONCLUSIONS

The BoMI developed in this study is proof of concept of a powered wheelchair control interface which uses autoencoder networks to map the high dimensional shoulder kinematics into proportional powered wheelchair control commands.

There are two main limitations to this study. First, the powered wheelchair interface control developed was tested on only one subject. Second, we used a specific AE architecture, whereas there are an infinite number of possible AE structures that can be explored, some of which could also be more efficient in our specific application compared to the one used in this study.

Taking into account the limitations mentioned above, some possible future improvements include: the investigation of other AE architectures, the completion of experimental tests of the powered wheelchair control interface on healthy subjects, and if such tests reveal successful the extension of these experiments to subjects with SCI.

***Abstract*— The use of virtual reality in motor rehabilitation has gained significant interest in recent years. To track a subject's motion in a virtual reality environment, a real time estimation of his/her movement is necessary. Wearable inertial measurement units represent one of the most suitable technologies to do so. However, it is well known how their recorded signals, once integrated, are affected by unpredictable drift, introducing errors that are hard to cope with. A number of successful methods have been proposed in the recent literature for the reduction of such errors for offline analysis. Unfortunately, those methods may not be used for real-time estimates of the foot displacement.**

In this paper we propose a method to estimate the foot displacement in real-time using an inertial measurement unit attached to it while mitigating integration errors.

***Keywords*—MIMU, Virtual Reality, movement analysis**

I. INTRODUCTION

THE use of virtual-mixed reality (VR/MR) for gait analysis and motor rehabilitation has gained significant interest in recent years.

Studies have shown that VR/MR environments can both ease the motor rehabilitation activities making them part of a more appealing experience and provide an opportunity for monitoring and recording the patient's performance of a task [1]. One potential solution for tracking a subject's motion in a VR/MR environment is the use of Magnetic Inertial Measurement Units (MIMUs). MIMUs are commonly used in gait analysis to estimate temporal and spatial parameters [2].

However, the estimation of such parameters in Real Time (RT), which is necessary in VR/MR applications, hasn't been dealt with as much as the offline estimation, which was developed for evaluation and/or monitoring purposes. In both cases, one of the main challenges in estimating foot displacement from MIMU's measurements is the reduction of the errors introduced by the acceleration double integration.

An approach commonly used to mitigate these errors is the Zero Velocity Update algorithm (ZUPT) [3], which can be combined, in offline applications, with the Direct and Reverse Integration technique (DRI) as suggested in [4], in order to refine the estimate of foot's displacement.

In this paper we present a preliminary study proposing a RT solution for estimating foot displacement from the measurements of a MIMU attached to it and taking advantage of some features of the approach proposed in [4] to mitigate integration errors.

II. MATERIALS AND METHODS

The data used for this study were obtained from a single healthy subject wearing a MIMU (Shimmer, Dublin, Ireland) attached over each foot (Figure 1). The MIMUs acquired linear acceleration and angular velocity with respect to the axes of their Local Reference System (LRS) via Bluetooth, at 100 samples/s in packets of a nominal size of 0.2s (20 samples) using MATLAB R2021a (The MathWorks Inc., Natick, MA, USA). Data were synchronised by identifying the first common timestamp between the two MIMUs.

Fig. 1 Experimental set-up

The subject was asked to walk along a straight line at self-selected speed for about 11 metres.

To reduce the error introduced by the RT double integration of the linear acceleration signals the following was done:

A. a RT identification of Heel Strike (HS) and Toe Off (TO) timings [3];
B. the double integration of the acceleration signals for each gait cycle;
C. the foot displacement is obtained by applying the algorithm proposed in [4] for each gait cycle and used to correct the foot displacement estimation obtained in RT.

For comparison purposes, gait speed and spatio-temporal gait parameters were also determined offline using the method proposed by Trojaniello et al. [4].

For both RT and offline methods, linear acceleration and angular velocity signals were used to provide a reliable

estimate of LRS's orientation with respect to the Global Reference System (GRS) as described in [5]. All linear acceleration signals were first expressed in GRS to remove gravity and then expressed in the LRS instantiated at the first frame of the acquisition.

A detailed description of the RT method is reported below.

A. RT gait events estimation

For each packet of data received, medio-lateral (ML) angular velocity was used to identify a first estimate of gait events as follows:

- The time of the first minimum of amplitude detected (-30 deg/s threshold [6]), was associated with the timing of a TO candidate. If in the following data packet, a maximum was found (50 deg/s threshold [7]), the time between the two could be considered as part of a swing phase, confirming that the ML angular velocity minimum found was in fact a TO.
- The time of the second minimum of amplitude detected (-30 deg/s threshold), was associated with a HS candidate. If in the previous data packet, a maximum was found (50 deg/s threshold), the time between the two could be considered part of a swing phase, confirming that the ML angular velocity minimum found was indeed a HS.

Then, a refinement of the gait events detection based on the technique explained in [4] was made as follows:

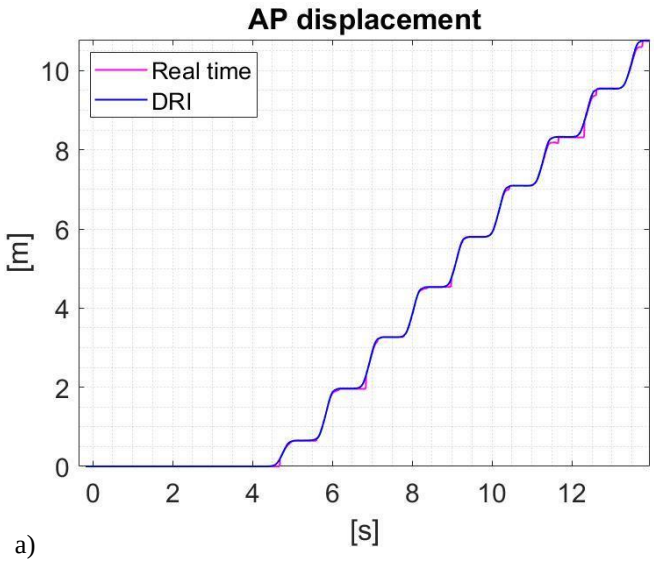
- Considering the interval between the first estimate of TO and the beginning of the following swing phase (first value of the ML angular velocity higher than 50 deg/s), the refined TO was identified as "the instant of minimum anterior-posterior (AP) acceleration [...] preceding the instant of the last maximum AP acceleration value" inside the interval.
- Considering the interval between the first estimate of HS and the end of the previous swing phase (first value of the ML angular velocity lower than 50 deg/s), the refined HS was identified as "the minimum value of the ML angular velocity occurring [...] before the instant of maximum AP acceleration" inside the interval.

Since a packet could end with one of the events, so that the latter was not identified as a minimum, an additional control was added:

- If no TO was found after a time interval exceeding the duration of a stance phase of a slow walk (0.7s), then the first value of angular velocity under the threshold (-30 deg/s) was considered as a TO candidate and the same procedure explained above was applied.
- If no HS was found after a time interval exceeding the duration of a swing phase of a slow walk (0.6s), then the first value of velocity under the threshold (-30 deg/s) was considered as a HS candidate and the same procedure explained above was applied.

B. RT foot displacement estimation

To limit the drift due to the double integration of acceleration, the latter was integrated only for a specific interval of time, including swing phase and a portion of the stance phase. Assuming that during the stance phase the displacement is limited, the acceleration signal outside the integration interval was not integrated. The integration interval was identified as the interval between the minimum value of acceleration norm preceding the TO and the first value of acceleration norm under the threshold of 0.2 m/s^2 following the HS. For this purpose, the acceleration norm was filtered (Butterworth filter with cut off frequency of 10 Hz).



Since at the ends of the interval the foot was considered still, the mean value of the acceleration was removed, a double integration of the acceleration was performed, and the ZUPT-DRI technique was applied ([4]) at the ends of the interval, to limit the drift due to the integration.

C. RT foot displacement correction

The method proposed in [4], which performs a DRI of the acceleration between two instants identified as HS + 40% of stance duration, was used to provide a more reliable estimation of the foot displacement at the end of each gait cycle to correct its RT estimation. For the aforementioned method, a minimum of two complete stance phases is required. For each gait cycle, the correction of the RT foot displacement estimation was made.

III. RESULTS

Only the foot displacement along AP direction is reported given its relevance in determining the stride length. The AP displacement estimates obtained using the proposed RT method and using the offline method are shown in Figure 2a, while the relevant absolute difference in estimating the stride length is shown in Figure 2b. Gait speed absolute difference between the two methods for each gait cycle is shown in Figure 2c.

a)

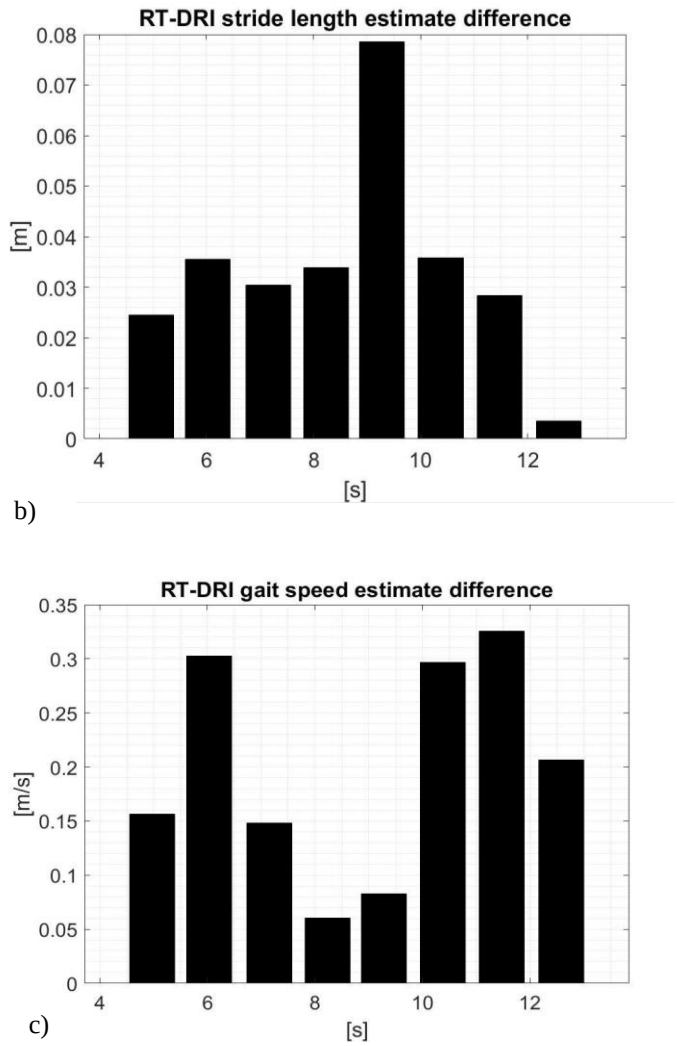


Fig. 2: a) AP foot displacement for both RT and offline methods; b) difference between offline and RT methods estimates of the stride length at each gait cycle; c) difference between offline and RT methods estimates of the gait speed for each gait cycle.

IV. Conclusion

Determining the stride length in RT and tracing foot displacement within the gait cycle is crucial for a suitable use of VR/MR in gait training applications. In this work we attempted to achieve this result uncovering a number of critical issues to be addressed. A validation on additional subjects and walking conditions is needed to validate the proposed method.

***Abstract*— Biorobotics assistance to rehabilitation has the potential to benefit patients and clinicians significantly, helping to improve outcomes and support clinician users in key task while promoting their sustainability. However significant barriers to a widespread adoption of robotics technologies in clinical practice still exist. For these reasons, as one of the kick-off activities of the Fit4MedRob project, we have performed a literature mapping study to inform the design and execution of a large national survey aimed at identifying unmet user needs, barriers of currently available solutions, and key requirements for biorobotics devices supporting physical and cognitive rehabilitation. The survey results will constitute the cornerstone of research, implementation and evaluation activities of the project and significantly contribute to foster the translation of biorobotics from the experimental setting to established practice in the Italian rehabilitation services landscape.**

***Keywords*— biorobotics, cognitive rehabilitation, physical rehabilitation, requirements.**

I. Introduction

BIOROBOTICS, i.e. a melting pot of technologies spanning from bioengineering to robotics, including artificial intelligence, controls, sensors, smart materials, has been proposed as an appealing option to improve the clinical outcome of physical rehabilitation and personal care treatments in a sustainable manner. This because of the unique combination of features offered by robots: they host sensors and computational reasoning to understand and decipher environmental or patient intentions, and they have physical bodies able to perform actions in response to such reasoning. However, significant clinical, organizational and socioeconomical issues still exist for a wide and successful employment of biorobotics in healthcare and rehabilitation. For example, current rehabilitation and assistive models offered by the Italian national healthcare system lack in personalization and adequate continuum of care throughout all the phases of the rehabilitation process. Hence, excluding few exceptions nationwide, rehabilitation outcomes are typically unsatisfactory for the patients albeit expensive to the system.

For these reasons, a large consortium of 11 academic 11 clinical research centres and 3 companies has been created in December 2022 in response to the Italian national initiative on biorobotics, rehabilitation and digital technologies.

A. Background

Fit for Medical Robots - A new generation of biorobotic and digital technologies for a sustainable welfare (F4MR) is the name of the large project consortium, comprising 25 partners, funded by the Italian Ministry of University and Research (MUR), to achieve the above-mentioned goals within a time-horizon of four years.

The project is organized in the Hub and Spokes fashion, with three spokes each corresponding to a project mission. Spoke 1, co-coordinated by the University of Pavia and the Don Gnocchi Foundation, focuses on the pivotal mission of clinical translation and innovation (see Fig.1). Spoke 1 aims to run extensive, in terms of number of patients and/or duration, multi-centric, clinical trials using healthcare or personal care robots that are currently available or developed by the F4MR consortium. Besides identifying their clinical efficacy and evidence (and limits), such treatments will also be assessed in terms of generated value from the perspectives of the involved stakeholders (final users and their families, workers and healthcare professionals, hospital facilities, payers, e.g., insurers, healthcare systems, etc.). In parallel, pivotal actions aimed at understanding and overcoming current legal barriers within the healthcare system will be implemented.

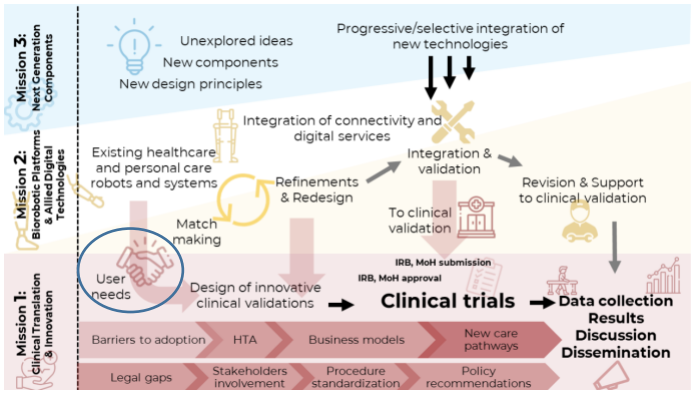

Fig. 1: Overall organization of the F4MR project, its three missions and their inter-relations. This article focuses on the first activity of Mission 1, dedicated to the elicitation of unmet user (both clinician and patient) needs to foster wider adoption.

B. Objective

One of the first objectives of the spoke 1 of Fit4MedRob is to carry out a thorough user (both patients and clinicians) needs elicitation and analysis, to inform development of new systems during the project, improve existing devices, perform sound impact, cost and sustainability evaluation of biorobotics applications, and foster their wider adoption in clinical practice. For this purpose, a literature review of questionnaires used to elicit requirements of robotics-assisted rehabilitation has been performed, in order to develop a F4MR-specific survey instrument to be distributed in the consortium. The overarching objective of the two activities is to collect requirements that can inform the remainder of the F4MR project phases.

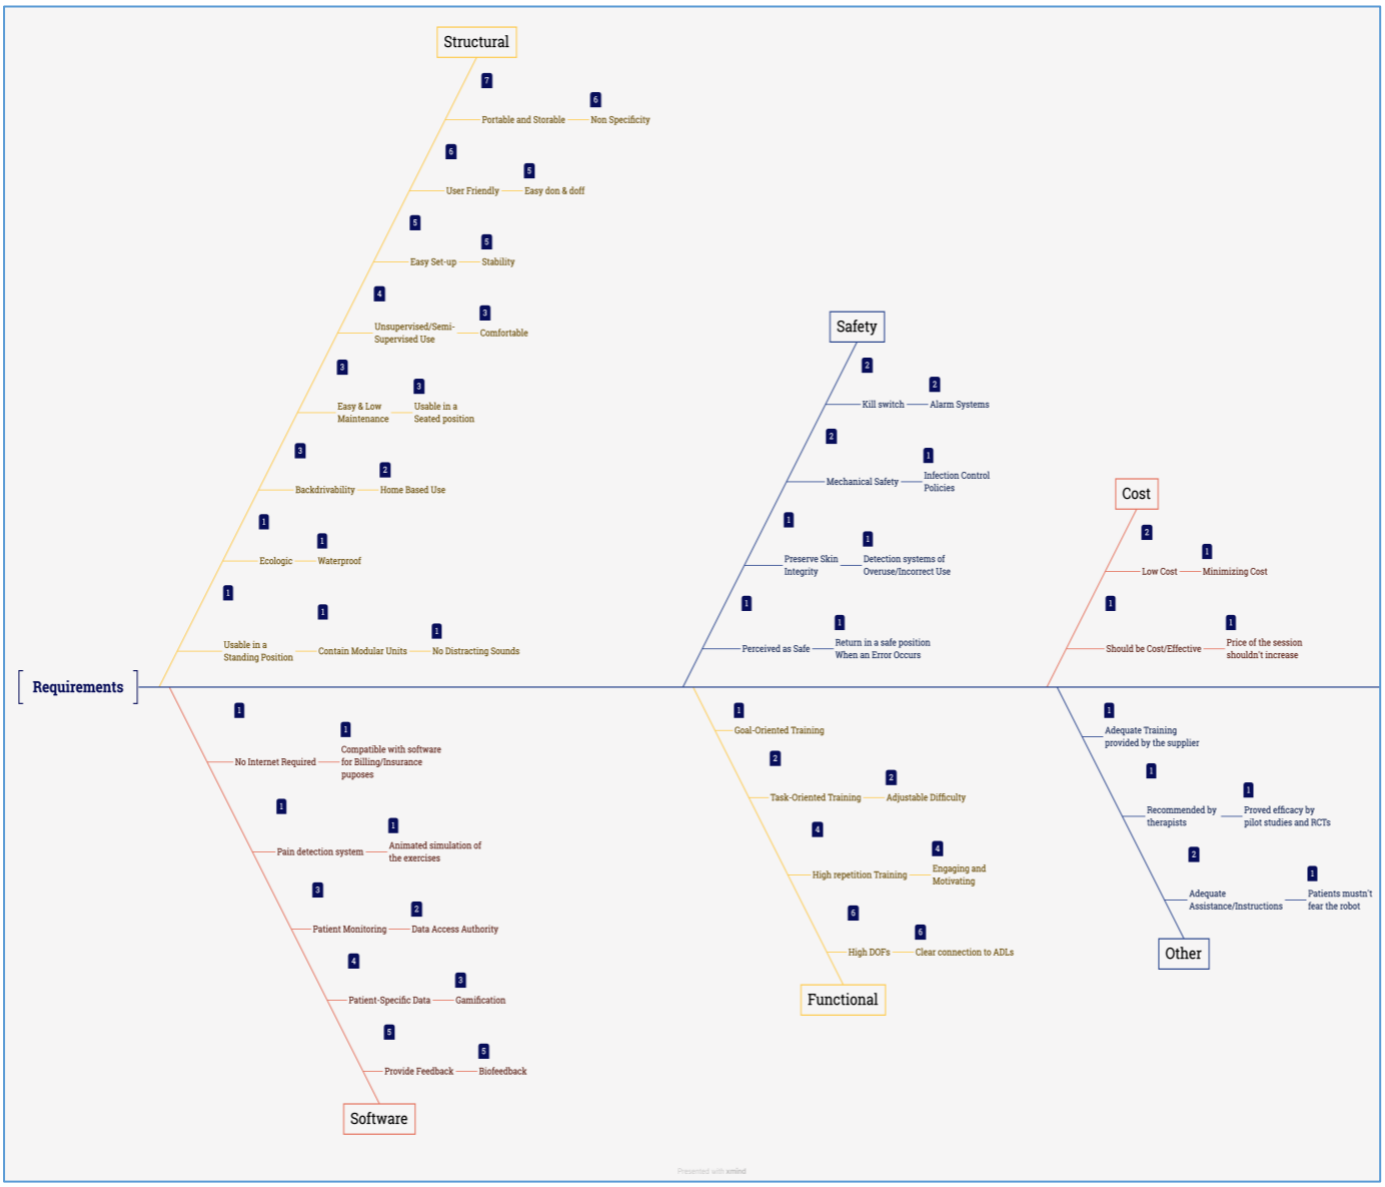

Fig. 2: A conceptual visualization of the user needs and requirements identified in the literature review, organized in 6 macro categories. The figure reports (in blue) the number of articles in our review mentioning/supporting the specific requirement.

In this paper we present the results achieved by the first 2 months of spoke 1 activities, and preview a preliminary version of the formal requirements collection instrument we plan to use for identification of unmet user needs and barriers preventing widespread adoption of currently available device.

METHODS

In order to cover both peer-reviewed as well as grey literature (e.g. industry whitepapers or informal surveys), Google Scholar was searched using the following query: *requirements AND robot AND rehabilitation AND (survey OR questionnaire)*.

Since the retrieved results were quite scarce, we did not apply further filtering based on time of publication.
Additional inclusion criteria consisted in:

- The paper included a requirements analysis aimed at therapists and patients (both or either one)
- The article is not a review of the effectiveness of the rehabilitation robot itself.

Roughly 50 papers were screened by title and abstract, and only 12 were actually selected for full-text analysis and further used to inform our research and F4MR instrument design.

II. RESULTS

A total of 53 requirements, summarized in Fig.2, have been identified from the selected articles. After reviewing the requirements 6 categories were created: Structural (n = 17), Software (n = 12), Functional (n = 6), Safety (n = 8), Cost (n = 4), Other (n = 6). It is worth mentioning that some requirements naturally belong to multiple categories. For

instance, “user friendliness” is meant as a general concept and should also be included in software requirements, on top of the reported categorization in structural requirements that we adopted for Fig.2. In the following we expand on a selection of requirements we identified for the different categories, and discuss the key findings of the review together with their relevance for F4MR.

A. Structural Requirements

A common theme among the interviews conducted in the reviewed articles, is the need for the therapeutic robot to fit the needs of as many patients as possible [1]–[6] (Non-Specificity), this included taking into account the physical characteristics of patients, such as age, weight, disabilities etc., but also to include the specific exercises needed for their therapy (High DOFs[1]–[3], [5], [7], [8],High repetition[2]–[4], [9], Usable in a seated[2], [3], [9] or standing position[3]).

One frequent complaint was about the difficulty of using the robot (User Friendly)[1], [2], [5], [7], [8], [10], but also the long and complex process of set-up[1]–[4], [10], donning and doffing[1], [2], [4], [6], [7]. Many therapists felt that they wouldn’t consider robot therapy if the initial steps required to use it were too time consuming[2], [4].

Other relevant requirements to take into consideration are comfort[1], [2], [6], stability[1]–[3], [7], [9] and focus (No distracting sounds)[6] of patients using the robot.

When it comes to Home-Based robots, there were some conflicting opinions, where some believed that a domicile robot could help with the amount of therapy performed by patients[1], others believed that and independent use wasn’t recommended due to incorrect use, overuse and over reliance[1].

Nonetheless a semi-supervised use was generally seen as positive[1], [3], [4], [10], with some suggesting the possibility of group therapy[4].

B. Functional Requirements

While using the therapeutic robot there should be a clear link to the Activities of Daily Living[2]–[4], [9]–[11] such as grooming, personal hygiene, feeding oneself etc. It is also important to allow for goal-oriented therapy[2] specific to each patient.

C. Software Requirements

Patient monitoring is seen as a critical need by therapists[2], [6], [8]. In order to do so it is mandatory to gather patient-specific data[1], [2], [4], [8] on therapy sessions and configurations for donning. It goes without saying that this data mustn’t be modified by users, therefore data access authority is required[1], [8].

Motivation is also quite important[1], [4], [7], [10], and many believe that robots can help by providing feedback to patients (and therapists alike) [1], [2], [4], [8], [10], gamification[1]–[3] (even though some are against using it[1]) and by making the exterior of the robot attractive[12].

Another somewhat important detail is being compatible with other software, such as notes, billing/insurance [8] etc.

D. Safety Requirements

Obviously, Safety regulations must be followed. The main concerns for safety requirements were about misuse of the device, especially if it allows unsupervised use by patients. In order to make it safer there must be a kill switch[1], [8], alarm systems with sounds and messages[1], [8], and it must slowly return in a safe position whenever an error occurs[8]. Mechanical safety should be guaranteed[1], [6] (no finger traps etc.) at all times.

E. Cost Requirements

Many complained that the devices were too expensive[2], not cost effective[10], and often weren’t even eligible for refund by the public healthcare system[1].

Some papers also investigated how much money the therapist/institutions were willing to spend[1], [3], [9] to acquire or use the device, but the prices were heavily dependent from the country where the study was conducted and the economic situation at the specific times of the survey/interviews.

F. Other Requirements

Providing adequate Assistance[1], [2] and Training[10] should be taken into consideration when developing a robotic device. Some patients weren’t too sure how to feel about the robotic device since they were afraid it might look too technical[6]. Therefore it is important to make sure the patients do not feel scared by the robot[5], and findings suggest that if the use is recommended by therapist[10] himself it helps with patient acceptance and feelings towards the device.

G. F4MR user needs elicitation study

In the immediate future we will implement our own survey instrument using a web-based questionnaire solution, inspired both by the findings of the present literature mapping study and by comparable (albeit more narrow-scoped) studies like ECAD’s RehaTech4Child Survey[13].

The requirements elicitation instrument that will be the basis of the user needs identification study of F4MR has the following structure, and investigates key constructs identified in this review:

- Questions about demographics and work experience. Other than therapists, we will also include engineers as part of our respondents.
- Did you already use robotic devices for therapy purposes?
    - If the answer is yes, questions about their experiences and opinions with robotic devices will follow.
      In particular, for each device listed, a set of questions extrapolated from the present literature mapping study will be asked.
      Although the primary subjects of the F4MR project are patients with certain illnesses, such as CNS and PNS injuries and disorders, people at risk of occupational diseases and the frail elderly are also included.
      Furthermore, it is of special interest the effects that robot therapy has had on paediatric patients.
      Therefore, knowing what kind of patient these machines were subjected to, what the objectives of robotic rehabilitation were and whether they were actually met, will be crucial.

- Otherwise, we will expand on their knowledge and beliefs on robotic devices and if they wish to use them.

III. Conclusions

The aim of this article was to present a list of requirements and unmet user needs for the development, improvement and evaluation of therapeutic robots for rehabilitation. We performed a literature mapping study to inform a project-specific instrument development, and inform subsequent phases of F4MR. Among the most important findings that emerged we highlight the need to fit the needs of as many people as possible while keeping rehabilitation robot devices user friendly. Furthermore, devices should be light weight and easily transportable and storable, especially if home-based use is considered. It is also key to make the robot engaging and motivating for the patients. Finally devices able to perform a wider range of well implemented exercises, instead of a single one, seem preferable.

Based on the results of the literature mapping study a F4MR requirements elicitation instrument is being developed, to be disseminated within the F4MR consortium to gather the largest sample of Italian national respondents to date. Results of such study will be pivotal to inform the following key phases of the project.

***Abstract*— Background: Balance disorder and vestibular dysfunction are related to an increase of the risk of fall related to the ageing of people and to specific pathologies. Mixed Reality is a new tool that could support the clinicians during the hospital activities. The aim of this work is to propose a first version of Mixed Reality application to support the clinicians in fall risk diagnosis. Material and Methods: The application is based on Unity Engine to present the Mixed Reality environment on HoloLens™ 2 used in combination with the Wii Balance Board, managed with Vestlab application, to evaluate the movement of pelvis. The subject must reach with pelvis 8 different target on a 2D plane. Nineteen healthy subjects performed the test. Results and Conclusion. The HoloLens 2 tracks the 3D movement and rotation of the eyes and of the head, meanwhile from the Vestlab application tracks the movement of the pelvis. The evaluation of the application shows the adaptability of Mixed Reality to offer to clinicians a new tool to diagnose the risk of fall by tracking the trajectory and the rotation of the head and of the pelvis.**

***Keywords*—Mixed Reality, Diagnostic, fall prevention, Balance.**

I. Introduction

Balance disorders and vestibular dysfunction are related to the progressive loss of function of sensory systems or the inability to control body movements due to the ageing or due to pathologies [1]. They could be positively treated through physiotherapy and rehabilitation to reduce dizziness and fall risk and improve the gaze stabilization or posture [2].

Mixed Reality (MR) is gaining popularity and academic interest in the medical sector [3] due to the capability to generate a controlled and user-specific environment, and perceptual stimuli that motivate the patient [4]. With MR, the user can freely interact with virtual objects (holograms) while having the possibility of interacting with the real environment, including also the specialist [5]. To use the MR, employment of a Head Mounted Device (HMD) is necessary, a wearable sensor that reproduces the holograms directly on its transparent display. One of the most popular devices is the HoloLens (™) (hereinafter referred as HoloLens), developed by Microsoft in 2016.

In recent studies [6], most of the application related to the use of MR in balance disorders are restricted to the rehabilitation field. MR rehabilitation programmes [7],[8] or similar technologies are shown to produce significant improvements in user outcomes and significantly more effects than alternative rehabilitation programmes with the same duration. In [9], Fung and Perez developed a system that combines visual representation with manipulation of physical environments and haptic feedback to improve balance and mobility after stroke. Pezzera [10] implemented a new software, MIRARTS (Mixed Reality Adaptive Rehabilitation Therapist Station), in HoloLens, which via MR allows the therapist to visualise quantitative values in real time, in form of text or graphs, related to a postural rehabilitation exercise. Qualitative experience supported by the quantitative data enables therapists to come at more appropriate decisions. Miller Koop [11],[12] developed an application aimed at determining the accuracy of HoloLens versus 3D Motion Capture in gait quantification. In [11], the first generation of HoloLens was used on ten healthy adults, while in [12] the second generation of HoloLens, the HoloLens 2 (HL2), was used on 66 healthy adults. In this study, subjects had to perform the continuous walking and the timed up-and-go (TUG) tasks, obtaining a statistically equivalence (error $\leq 5\%$, $p < 0.05$) between HL2 and motion capture system (MoCap).

Due to the totally absence of studies that involve the use of MR in balance diagnostics, the aim of this study is to prove the possibility of applying MR to develop an application for the assessment of balance disorders and to build an endpoints detection system that allows classifying and studying the subject's trajectory.

II. Material and methods

The device used to implement the Mixed Reality application was the HoloLens 2, the Microsoft Head Mounted Device. HoloLens 2 is a stand-alone holographic computer with transparent glasses that displays the holograms directly in front of the eyes of the subject [13] HL2 is equipped with an inertial measurement unit (IMU) sensor that includes a 3D accelerometer and a 3D gyroscope.

A high performing computer was used to manage the communication between HoloLens 2 and the MR application.

A PC equipped with Vestlab OS software (GN Otometrics, Taastrup, Denmark) (Hereinafter reported as Vestlab), a sotfware designed to perform diagnosis tests and procedures for the assessment of the balance disorders, was employed to guarantee the execution of the Limits of Stability (LoS) test in order to obtain the evaluation of pelvis movement. During this test, the user had to stand on a force plate and reach the target displayed on the PC by moving the pelvis. LoS provides an objective measure of displacement of the patient's center of gravity when he is asked to lean to eight different postural position using a force plate. Moreover, it allows the clinician to evaluate the subject risk of fall.

The force plate used was the WII Balance Board-powered by the Nintendo® and it was connected to the PC using the Bluetooth connection.
Nineteen healthy subjects (mean age: 27.21±3,08) performed the LoS test only once. Head trajectories were recorded by using HL2, meanwhile the Vestlab recorded the pelvis movement.

Before starting the test, the subject needed to place himself on the centre of the WII Balance Board and wore the HL2

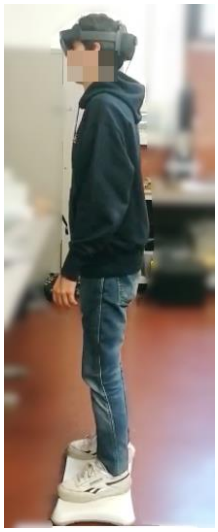

Fig. 1: A subject during the execution of the diagnostic test.

directly on his head. Figure 1 shows the subject during the tests.

After that, the user could start the MR application on HL2 in order to allow the device to record head and eyes' movements.

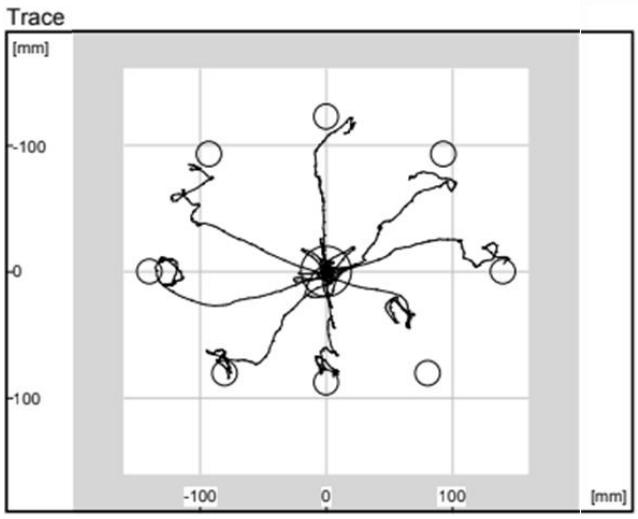

Fig. 2: Pelvis's subject 2D trajectory obtained directly from Vestlab

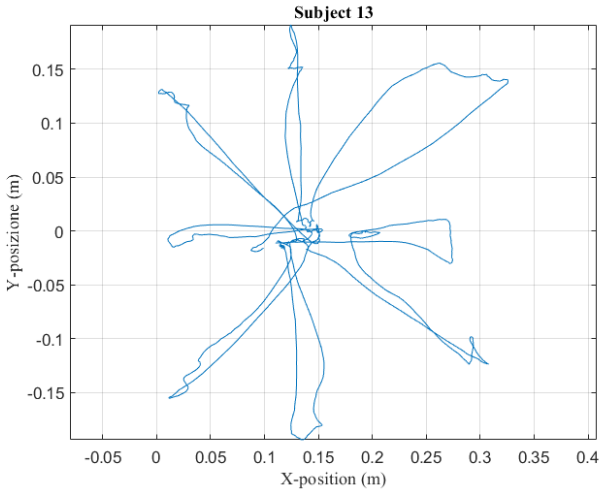
Lastly, the clinician started the Vestlab application to initialize the LoS test.

During the LoS test, the subject had to reach with the pelvis eight targets one at a time placed in the xy plane. In particular, figure 2 shows the subject's pelvis outward trajectory to reach the eight targets obtained directly from the Vestlab software.



The subject had 20 seconds to reach the target, after that the target disappear and the user had to return at the origin point. If a target is reached, the subject had to return at the origin point.

The HL2 IMU allow to acquire 3D coordinates and 3D angles of head with a sample frequency of 12 Hz. Through our algorithms, data were stored in a txt files and subsequentially download it for the data analyses. The proprietary Vestlab algorithms (not Open Source) compute the following data: reaction time (time in seconds it took the patient to realize they needed to lean toward the target), movement velocity (°/s, how quickly the patient moved toward the target), endpoint (where the target is), maximum excursion (if target was reached initially and whether or not target was reached during the test), and direction control (percentage of movement in direction to the target by the different ~~orientations~~ directions in the space (forward, backward, left and right).

III. Data Analyses

At the beginning, the data were converted from the HoloLens's System of Reference (SoR), a left-handed SoR, into a conventional right-handed SoR.

HoloLens records the test trajectory as a unique track (figure 3), therefore properly cutting the track with an endpoint

detection system is necessary.

Fig. 3: Subject's head 2D trajectory at the end of the test

Subsequently, the reaction time, movement velocity, endpoint, maximum excursion and direction control were evaluated for the head. The mean of x and y positions to obtain the centre of the distribution for each subject. In this final position, a circumference with radius equal to 30 cm was centred.

The circumference was used to virtually divide the overall continuous trajectory of the subject recorded by HL2 in segment based on distance from the centre. So, all the position were divided in inside and outside the circumference. Among all the positions outside the circumference, the algorithm searches for the maximum distance points interpreting them as the final points of the outward movement and consequently the reaching of one of the targets. The opposite process is carried out with the parts inside the circumference finding the final point of the subject's inward movement to reach the return target. Considering the minimum radius that should include not only all the return points, but also the instant in which the

subject starts the trajectory for the next target.
With this characteristic, the circumference can detect and highlight the eight endpoints referred to targets.

These indexes of the points found by the algorithm were exported for the analyses. Coefficient of correlation for the movement velocity (°/s) was computed to evaluate a possible correlation between head and pelvis to idenfity if it is present a potential compensation between the head and pelvis movements during the balance strategy used by the subject to reach each single target.

Wilcoxon-Mann-Whitney test (Mann–Whitney U test) non-parametrical statistical analysis was performed to evaluate the difference between the head and the pelvis.

IV. Results

Figure 4 highlights the results of the trajectory endpoints detection system.

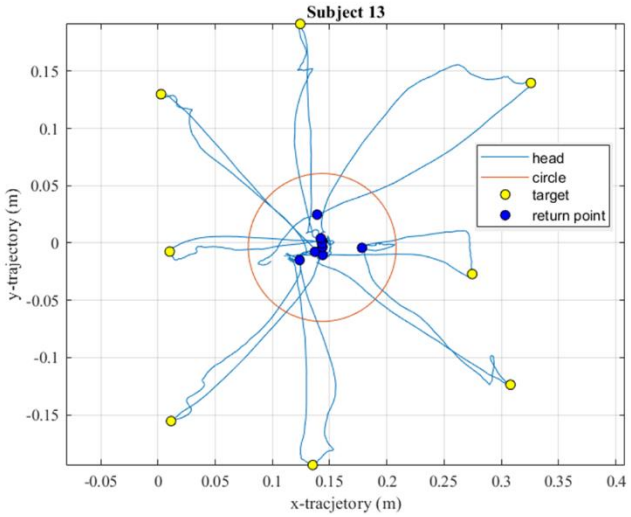


Fig. 4: Subject's Head trajectory with the endpoints of reaching targets

Figure 5 shows the eight endpoints distribution for all the subjects analysed in a polar plane. The coloured areas in the graphic represent the zones in which at least the 95% of subjects reached the targets.

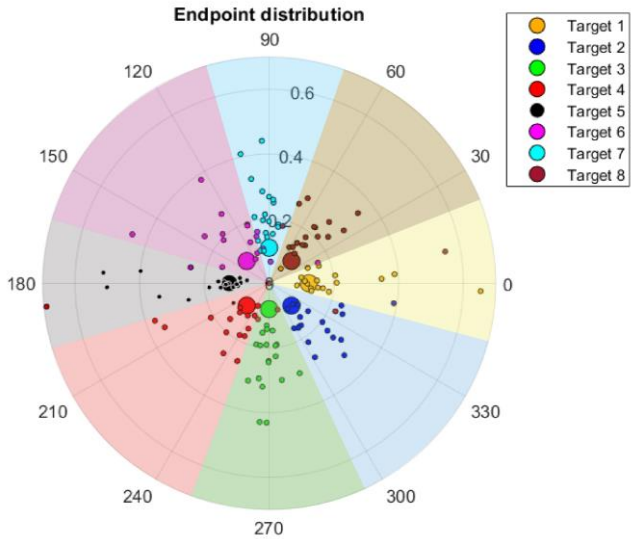

Fig. 5: Eight endpoints distribution for all the subjects in polar plane.

No correlation between the head movement velocity and the pelvis was found (Table I).

TABLE I
COEFFICIENT OF CORRELATION FOR THE MOVEMENT VELOCITY BETWEEN HEAD AND PELVIS

Target to reach	*Coefficient of correlation*
Target 1	0.29
Target 2	-0.13
Target 3	0.11
Target 4	0.25
Target 5	0.11
Target 6	-0.15
Target 7	0.32
Target 8	0.23

The statistical analysis performed is the Wilcoxon-Mann-Whitney test (Mann–Whitney U test) and for the trajectory of target 2, 3, 4 results are statistically significant.

V. Discussion

Even if it is shown no correlation between the head and the pelvis, the head movement reproduces a similar trajectory of the pelvis except for the order of magnitude. This is probably due to the bigger range movement of the head rather than the pelvis joint and also maybe to the instinct of the subjects to move the head together with the rest of the body.

Moreover, there is not a correlation between the head and the pelvis, so the similar movement is probably related to the necessity of the subjects to balance their own body to prevent their falling.

Using an endpoints detection system could be useful to better identify the trajectory the subject executes to reach the eight targets. In addition, this method helps to investigate the track of the head path and to compute specific parameters for each of the eight targets in order to enrich the analysis.

Consequently, an endpoints detection system could be a tool to characterize a healthy subject with important parameters.

Statistical analysis shows no significant results, probably because the movement of the healthy subject are similar, more expected and contained.

Despite the study presents just a first application of HL2, MR in combination with the software Vestlab can be adequate to evaluate the risk of falling.

The introduction of MR could present a benefit for the clinicians. MR is powerful and reliable tool, it is able of reproducing immersive environment and a more realistic space by merging the holographic object directly in the physical room. In this way, the patient is not affected by cybersickness, dizziness or other VR-diseases correlated [14].

The application of MR and innovative technology to decrease the risk of falling mostly in elderly people [15],[16] is particular interesting. However, most of the application use

proper exergames to prevent falls in the elderly, but not to diagnose the level of risk of falling [6].

Considering the results obtained, the MR application could be a resource in order to obtain more measurement that the clinicians could not obtain by only the routinary visit as the movement and rotation of the head and the correlation of their movements.

The system proposed is currently a prototype and it still could be improved. The code could be updated to get it more efficient and the additional software such as Vestlab might be removed in order to have a unity-based MR application for HL2. Moreover, the integration of the new Azure Kinect [17] should increase the useful information of the balance assessment due to the possibility of additionally tracking the lower limbs of the patient.

CONCLUSION

In this work a useful tool for the vestibular dysfunction diagnosis is given to the clinicians in order to allow them to distinguish pathological subject from the healthy ones and to quantify the gravity of their conditions.

***Abstract*—Motion intent detection (MID) through transient surface electromyographic (sEMG) is becoming central for the development of real-time assistive and rehabilitative technologies. However, the adaptation of such myoelectric interfaces in a user-independent framework represents a cutting-edge problem that hampers the practical usage of sEMG based human-machine interfaces. In this study least square canonical correlation analysis (LS-CCA) was employed together with SVM classifier in order to solve a shoulder joint MID problem. A publicly available dataset comprising eight healthy subjects was employed and four shoulder movements were considered. The LS-CCA was used for computing a subject-independent feature space using training data and then the trained SVM model was tested on an unseen subject, eventually implementing a leave-one-subject-out validation. Two window lengths for feature extraction (50 and 150 ms) and three feature sets were also compared. Overall, the best results were obtained using the 50 ms window length (multi-user classification accuracy about 70%), without any significant difference among the three feature sets.**

***Keywords*—Motion intent detection, Transient EMG, Myoelectric control, Cross-user classifier**

I. Introduction

In the last few years, the role of the surface electromyography (sEMG) for pattern-recognition purposes has become more and more important, due to its large range of possible applications regarding the human-machine interactions, in particular in rehabilitation system and prosthetic control [1]. Indeed, many studies presented different ways of using the sEMG to recognize human movements, mainly related to the upper limb and in particular for hand and wrist movements [2]–[4]. However, in more recent years, the recognition of the shoulder joint movements from sEMG data gained significant attention, since it is heavily involved in many upper limb movements and thus it plays a fundamental role in the design of wearable and assistive upper limb devices [5]–[7].

In this scenario, the early recognition of user's motion intent was investigated using transient epochs of sEMG signals [2]. However, the pattern recognition architectures developed using such transient data still maintained the user-specific approach, i.e., calibrated and used with signals recorded from the same user [2]. Nevertheless, it would be a great advantage being able to solve *inter-subject* problems, i.e. training a model through data related to one subject and then apply it to any other different subject, without any long adaptation sessions. Furthermore, the development of sEMG-based human machine interfaces for multi-users applications is important to facilitate the utilization of assistive device, e.g. to aid stroke patients in controlling a wearable lower extremity device [6]. There are some works focused on the motion intent detection (MID) problem using transient data [2], [5], [8], [9] but its extension toward a user-independent framework has not been yet investigated.

Hence, in the present study the identification of the motion intent of the shoulder joint has been investigated for providing a multi-user, calibration-free architectures. The theoretical framework employed was the canonical correlation analysis (CCA), selected for producing a generalized and unified feature space among users, suitable for delivering subject-independent pattern recognition models for shoulder MID problems. Further, a direct comparison between two window lengths for feature computation on transient sEMG data is proposed, together with the evaluation of three different feature sets for classification purposes.

II. Materials and methods

A. Dataset description and signal windowing

For this study, data belonging to a publicly available dataset were used [10]. Eight healthy subjects (four males and four females) aged 25.0 ± 1.8 years were involved. Each subject was instrumented with eight sEMG probes in correspondence of the following muscles: clavicular and sternal heads of pectoralis major, serratus anterior, trapezius descendent, trapezius transversalis, trapezius ascendent, infraspinatus, and latissimus dorsi [10]. Once equipped, they were asked to perform four shoulder movements: i) shoulder flexion by 90°; ii) shoulder hyperextention by -30°; iii) shoulder abduction by 90°; iv) shoulder elevation by 90° in a 45° rotated plane toward the external direction. Each subject repeated all the movements nine times. Bipolar disposable pregelled 26 mm diameter Ag/AgCl surface electrodes (Bielsan, Italy) connected to wireless and miniaturized probes (BTS-FREEEMG 300, Italy) were used. Atlas guideline of muscle innervation zones were considered for electrodes placement, with an inter-electrode distance of 26 mm. More details are reported in [10] and references therein.

Recorded sEMG signals were filtered between 30 and 450 Hz using a zero-phase, 4^{th} order, band-pass digital filter. Then, MID windows of 300 ms were computed on sEMG data, including 150 ms before and 150 ms after the beginning of the movement, thus centered on the movement onset, which

was identified taking into account the shoulder joint kinematics included in the dataset [10], as performed in [8]. At this stage, a total of 9 repetitions $\times$ 8 channels $\times$ 8 subjects sEMG trials for each movement were available for segmentation, feature extraction, and classification.

B. Signal segmentation and feature extraction

The selected MID windows were segmented into sliding windows with an overlap of 50%. In particular, two different window lengths were considered: one of the most used for pattern recognition purposes, 150 ms [11], and one of the shortest, 50 ms [2], [12], with an overlap of 75 ms and 25 ms, respectively. On each sliding window, 10 time-domain and 10 frequency-domain features were extracted and grouped into 3 features sets (Table I): *Hudgins feature set (HUD)*, composed by MAV, WL, SSC and ZC; *Time domain features combined with autoregressive model coefficients (TDAR)*, composed by MAV, SSC, WL, VAR, WAMP, ZC, AR1, AR2, AR3 and AR4; *Frequency feature set (FREQ)*, composed by MNF, MDF, PKF, TTP, SM1, SM2, SM3, FR, PSR and VCF.

C. Canonical correlation analysis

To maximize the correlation between features related to different subjects performing the same task, the canonical correlation analysis (CCA) was employed. Given two different feature matrices $X \in R_{d\times n}$ and $Y \in R_{k\times n}$, with n number of observations and d and k number of features (which could be same or different), the CCA finds two projection matrices, $W_x \in R_d$ and $W_y \in R_k$, able to maximize the following correlation coefficient:

$$\varrho = \frac{W_x^T X Y^T W_y}{\sqrt{((W_x^T X X^T W_x)(W_y^T Y Y^T W_y))}} \tag{1}$$

Since ϱ is invariant with respect to W_x and to W_y, the previous formulation is equivalent to:

$$\max\ W_x^T X Y^T W_y \tag{2}$$

$$\text{subjected to } W_x^T X X^T W_x = 1,$$
$$W_y^T Y Y^T W_y = 1.$$

Once W_x and W_y have been extracted, the new features matrices can be obtained simply by multiplying the original matrices by the projection matrices:

$$M = W_x^T X \tag{3}$$
$$N = W_y^T Y$$

The obtained features matrices M and N have dimension $n \times min(d, k)$ and they are highly correlated in the new space.

This CCA implementation can be simplified by solving a least square problem [13], minimizing the following function:

$$L_2(W, \lambda) = \sum_{j=1}^{k}(\sum_{i=1}^{n}((x_i^T w_j - T_{ij})^2 + \lambda||w_j||_2^2)) \tag{4}$$

TABLE I: LIST OF FEATURES

Domain	Feature name	Abbreviation
Time domain	Mean absolute value	MAV
	EMG Variance	VAR
	Waveform length	WL
	Zero crossing	ZC
	Slope sign change	SSC
	Willison amplitude	WAMP
	Auto-regressive coefficients (4^{th} order)	AR
Frequency domain	Mean frequency	MNF
	Median frequency	MDF
	Peak frequency	PKF
	Total power	TTP
	1^{st} spectral moment	SM1
	2^{nd} spectral moment	SM2
	3^{rd} spectral moment	SM3
	Frequency ratio	FR
	Power spectrum ratio	PSR
	Variance of central frequency	VCF

List of computed time-domain (top) and frequency-domain (bottom) features for the study. Full feature name (central column) and its abbreviation (third column) are reported.

with T defined as:

$$T = (YY^T)^{-\frac{1}{2}}Y \tag{5}$$

To obtain T, feature matrix related to one subject, i.e. *expert user*, constituted the Y matrix. Then, the remaining users, one by one, were made similar to T through (4) to create, at the end, a unified-style-space [14].

D. Experimental framework

Once extracted the feature matrices, projection matrices were computed from 3 repetitions of each movement (calibration subset, CLB-S) by using least-square CCA (LS-CCA). Then, the projection matrices were applied to a subset (training subset, TRN-S) including the remaining repetitions of each movement, i.e. 6 repetitions, and used to train SVM models.

One subject at a time was selected as the expert user [14] and the LS-CCA was applied between the CLB-S belonging to the expert user and that of another subject. The obtained projection matrix corresponding to the other user was then multiplied by the TRN-S of the same subject. Each user in turn was correlated with the expert one in the same way and the obtained projected TRN-S were concatenated to form a unique new feature matrix in the new, highly correlated feature space. One subject was retained from the procedure, since it is used for testing. The same process was applied to all the subjects and thus each subject, in turn, was used as the expert user and for testing. Finally, for dimensionality reduction, the spectral regression algorithm was applied to the new, highly correlated feature matrix, with dimension $n \times (c-1)$, where c represents the number of classes [7]. A graphical representation of the presented framework is reported in Fig.1.

For the classification stage, a support vector machine (SVM) classifier with a linear kernel was employed. The SVM was trained through the reduced matrix obtained after concatenation and dimensionality reduction. Then, it was tested on the

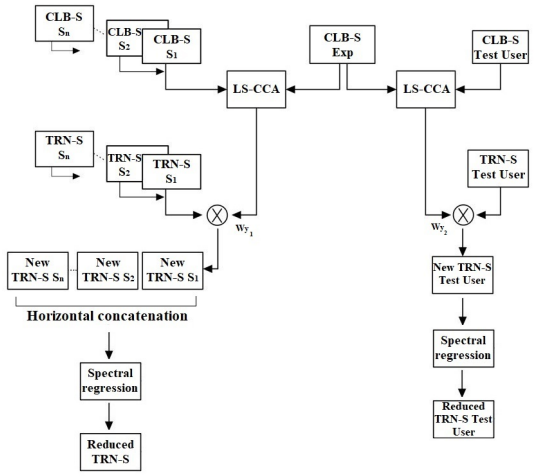

Fig. 1: Schematic representation of the presented framework. n is the maximum number of subject for the correlation (here 6, not considering expert and testing user). CLB-S indicates the calibration subsets of the subjects used to perform the LS-CCA to extract the projection matrix W_y. Reduced TRN-S is the subset used to perform the training of the SVM after the projection, concatenation and dimensionality reduction. Differently, reduced TRN-S test user is used for the testing phase of the classifier. The test user is left out from the concatenation for the training session.

new feature matrix belonging to the test user which was not included in the training session (unseen data). This analysis was repeated for all the three different feature sets and for the two window lengths. Finally, the performance of the framework was evaluated considering classification accuracy and statistically compared through a two-sample t-test with the accuracy obtained performing the same analysis but without applying the LS-CCA based framework. Significance level was set at $p < 0.05$.

III. Results

A. LS-CCA framework

Classification accuracy in all the tested conditions and with and without the application of LS-CCA framework, is reported in Fig. 2 as the average values among all the subjects, each one considered once as expert user and once as testing user. In particular, it can be noted that the accuracy with the LS-CCA ranges between 64% and 71%, except for the FREQ dataset with a 150 ms window (Fig. 2). Conversely, accuracy without the LS-CCA resulted always about 25%. Differences between the results with and without the application of the LS-CCA were statistically significant for each considered case.

B. Window length

In Fig. 3 is reported the comparison between the results obtained with the two window lengths used for feature extraction. In all the conditions, classification performances using a 150 ms window were equal or lower with respect to 50 ms window. However, only for the *FREQ_LSCCA* feature set, the difference between the use of 50 ms or 150 ms was statistically significant.

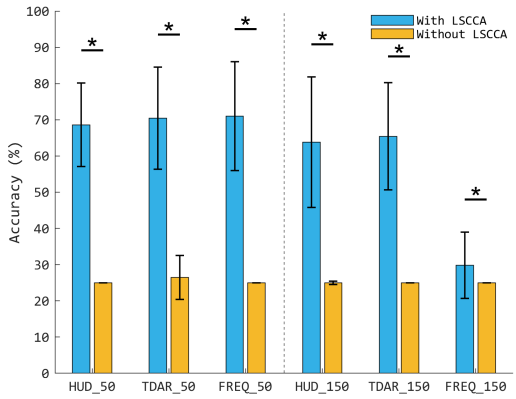

Fig. 2: Classification accuracy for the three feature sets (*HUD*, *TDAR* and *FREQ*) with window length of 50 ms (left side) and 150 ms (right side). Asterisk indicates a significant statistical difference.

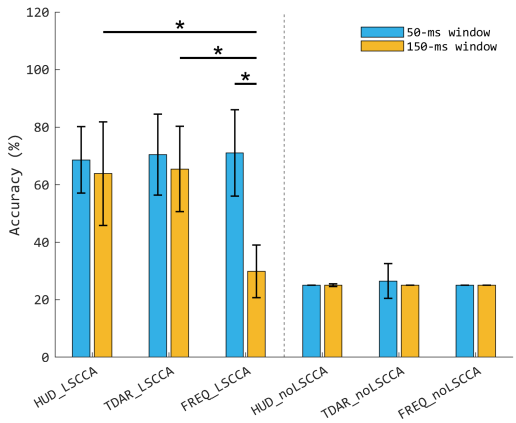

Fig. 3: Classification accuracy for the three feature sets (*HUD*, *TDAR* and *FREQ*) with LS-CCA (left side) and without LS-CCA (right side). Asterisk indicates a significant statistical difference.

C. Feature dataset

The *HUD* and *TDAR* feature sets are composed by time-domain features, while *FREQ* set contains frequency-domain features. Without the LS-CCA, no statistically significant differences were observed between the accuracy obtained with the different feature sets, nor using a 50 ms window, neither with a 150 ms window (Figs. 2 and 3). With the use of LS-CCA, the *FREQ* feature set showed the highest accuracy (71%) with the 50 ms window length, while in the 150 ms condition the *TDAR* feature set presented the highest value (65%). However, significant differences arose only between *HUD* and *FREQ*, and between *TDAR* and *FREQ*, using 150 ms window in both cases (Fig. 3).

IV. Discussion

In the present study, a framework based on the application of the LS-CCA to multi-user MID pattern recognition problems

has been investigated. Nowadays, the topic of motion pattern recognition is largely studied, with particular attention devoted to the multi-user scenario [14], [15]. The MID problem is relatively less studied with respect to the motion recognition, due to its higher intrinsic complexity [6], [9]. However, it represents a research area of interest mainly for medical technology, rehabilitation, and prosthetic, since decoding the intent of motion can aid the use of assistive devices [6]. Hence, in this study, an approach based on the LS-CCA has been applied to the MID problem for multi-user usability. The CCA has been yet employed to solve motion recognition problems [14], [15], i.e. to classify movements having available the entire gesture, with features extracted from a static epoch of the sEMG signal. On the other hand, the recognition of the motion intent deals with transient sEMG epochs: features are computed from a time window relative to the very initial part of the movement, much shorter than the common gesture recognition problem.

The LS-CCA framework proposed in this study proved to be a reliable way for addressing the multi-user problem within a MID context. A significant improvement in the classification accuracy can be appreciated, from 25% up to 71% in the best case (Fig. 2). These outcomes highlighted that the CCA succeeded in enhancing the correlation of the different users with an expert one, providing high classification performances also when a short time window (50 ms) was used for feature computation. Only in the case of the *FREQ* feature set computed with 150 ms window, the improvement of the accuracy was not observed (Fig. 3).

Regarding the use of different window lengths, 150 ms is one of the most used for motion recognition problems [8], [14]. However, the accuracy using 50 ms window are equal or even higher than with respect to those related to 150 ms window (Fig. 3), showing up also a significant difference with *FREQ* feature set together with LS-CCA. Although for motion recognition applications, optimal values for window length are between 150 ms and 200 ms [11], recent studies reported high classification performances also with shorted window lengths, equal or below 50 ms [2], [12].

Finally, in this study, *HUD*, *TDAR* and *FREQ* sets guaranteed similar performances and no significant differences have been observed, except between *HUD* and *FREQ* and between *TDAR* and *FREQ*: the *FREQ* feature set in LS-CCA with 150 ms showed the lowest accuracy (29%). Instead, the *FREQ* feature set reached the highest accuracy in LS-CCA with the 50 ms window, highlighting again the reliability of the 50 ms window for feature computation.

V. Conclusion

In this study, a framework based in LS-CCA is proposed for multi-user myoelectric pattern recognition. The novelty lies in the application of this methodology for motion intent detection, based on transient sEMG data. The LS-CCA allowed the generalization of the feature space among the subjects, with a domain adaptation that provides significant advantages in terms of computational demands with respect to recently introduced techniques such as deep domain adaptation and transfer learning. Moreover, it was observed that features computed from 50 ms window gave similar results, or even better, than those computed from 150 ms window. This, together with the efficient computational methodologies employed, i.e. LS-CCA and SVM, allow possible transfer of such methodology for rehabilitative and assistive technologies.

Performance Evaluation of the Gloreha Sinfonia Device in Bimanual Modality

M. Lapresa[1], E.M. Romano[1], L. Zollo[1] and F. Cordella[1]
[1] *Research Unit of Advanced Robotics and Human-Centred Technologies, Department of Engineering, Università Campus Bio-Medico di Roma, Via Alvaro del Portillo 21, 00128 Roma, Italy*

***Abstract*—Hand exoskeleton based devices are widely used to deliver bilateral therapy, and it is worth assessing their performance to evaluate their accuracy in reproducing on the injured hand the configuration recorded on the healthy hand. The aim of this work it to assess the performance of the *Gloreha Sinfonia* device in terms of the accuracy in reproducing the kinematic configuration in bimanual modality and responsiveness, during two types of tasks: a grasping task and a free flexion/extension task. To this purpose, an optoelectronic motion capture system was used to record the position of retroreflective markers positioned on both the sensorized and motorized glove, and the metacarpophalangeal joint angle was estimated. The responsiveness of the system was evaluated through the computation of the activation delay of the motorized glove, and was in the order of 1.5 s. The accuracy was evaluated through the computation of the Mean Absolute Error of the aligned angular trajectories of the two hands. Errors were in the order of 12 deg and 9 deg respectively for the grasping and flexion/extension trials. Nevertheless the magnitude of the errors, the benefits of the use of *Gloreha Sinfonia* in improving the hand function remain undisputable as demonstrated in many clinical studies.**

I. INTRODUCTION

Neurological disorders, such as stroke, represent the first cause of long term disability worldwide [1]. More than 12.2 million stroke cases are reported globally each year [2]. Around 60% of people who survive stroke suffers from sensory-motor deficits on the contralateral limb of the affected cerebral area. Main limitations include paresis, spasticity, loss of sensitivity and reduction of Range of Motion (RoM). The administration of a prompt rehabilitative treatment is crucial to allow reeducating the patient to autonomously perform Activities of Daily Living [3]. Robot-mediated therapy allows delivering task-oriented and intensive exercises and quantitatively assessing the patients' improvements [4], therefore representing a valuable support to the traditional therapy.

Numerous examples of robot-mediated rehabilitation applied to the hand can be found in the literature. These applications often involve the use of exoskeletons, devices whose mechanical structure mirrors the skeletal conformation of the limb. Such systems are tipically used to move the paretic hand according to predefined gestures, to deliver task-oriented therapy as well as mirror therapy, which consists in replicating on the injured hand, through a bilateral approach, the movements generated by the healthy hand [5, 6]. The *Gloreha Sinfonia* device [3], the BRAVO exoskeleton [7], the hand exoskeleton developed in [8], the Motion Actuator Glove [9] and the soft gloves-based hand rehabilitation system proposed in [6] are examples of exoskeleton-based devices used to deliver bilateral therapy. All these systems allow reproducing on the affected hand, through a motorized exoskeleton, the movement of the healthy hand recorded through different types of sensors. The performance evaluation of these systems in reproducing the kinematic configuration of the healthy hand on the paretic one is paramount to assess the quality of the rehabilitation therapy. To the best of our knowledge, the performance of the *Gloreha Sinfonia* device was not evaluated yet.

Therefore, the objective of this work is to assess the responsiveness and accuracy of the *Gloreha Sinfonia* in reproducing the hand kinematic configuration in bimanual modality.

The paper is organized as follows: the materials and methods exploited to conduct the analysis are reported in Section II, results are shown and discussed in Section III and conclusions are provided in Section IV.

II. MATERIALS AND METHODS

A. Experimental Setup

The *Gloreha Sinfonia* (Idrogenet, Italy) is a device used to perform hand rehabilitation, which allows restoring the functional hand RoM [3]. It is an exoskeleton capable of independently moving and monitoring the five fingers of the hand. It consists of three modules:

- A glove equipped with five resistive flex sensors (Flexpoint Inc.), that allow evaluating finger flexion and extension range, connected to an electronic board that sends data to the computer via a USB protocol;
- A motorized glove driven by five electric motors (LA12 Actuator, TECHLINE). Each motor, which is placed into a dedicated unit far from the patient, controls the tension of flexible trasmissions that can be mounted on the back of the sensorized glove to assist the user in performing flexion and extension movements of the fingers;
- A software for the data acquisition and motor control, that integrates virtual reality environments to replicate task-oriented daily life activities.

The motorized glove can be used as an independent module for passive hand mobilization or in combination with the sensorized glove to deliver bimanual mirror therapy. In the bimanual modality, the patient wears the sensorized glove on the

healthy hand and the motorized glove on the paretic hand, and performs flexion/extension, grasping or reaching movements with the healthy hand. The angular information measured on the healthy hand is used to control the motorized glove placed on the paretic hand so that the active movement performed by the subject is replicated as efficiently and faithfully as possible on the paretic hand.

Given the architecture of the device, in the bimanual mode it is not possible to record angular information on both hands with the embedded sensors. In fact, the system allows this information to be recorded only on the healthy hand which actively performs the movements.

Therefore, in order to record the angular information from both hands, the BTS Smart-D optoelectronic motion capture system (BTS Bioengineering) was exploited to record the position of retroreflective markers placed on both gloves. The system consists of 8 infrared cameras with a resolution up to 1.4 Mp, an acquisition frequency of 60 Hz, and with an accuracy ≤ 0.2 mm in a volume of $3 \times 2 \times 2$ m^3.

The experimental setup is shown in Figure 1. It consisted of the *Gloreha Sinfonia* system and of the BTS Smart-D optoelectronic system. In particular, both the sensorized and motorized glove were used. Eighteen retroreflective markers were positioned on each glove, as shown in Figure 2 [10, 11]. Markers B1, B2 and B3 allowed defining the hand base reference frame as follows: the x axis was defined as the unit vector pointing from B1 to B2, the y axis as the unit vector obtained by the cross product between $\overrightarrow{B1B3}$ and $\overrightarrow{B1B2}$ and the z axis which completed the frame. For the long fingers, three markers were placed in correspondence of the metacarpophalangeal (MCP) joints, distal interphalangeal (DIP) joints and tip of the fingers (TIP), respectively. For the thumb, three markers (i.e., MCP, IP and TIP) were placed respectively on the metacarpophalangeal joint, interphalangeal joint and tip of the finger. Markers positions were expressed with respect to the hand base reference frame according to Eq. 1

$$M_{hand} = -R^{hand}_{camera} \cdot B1^{camera} + R^{hand}_{camera} \cdot M^{camera} \quad (1)$$

where M^{camera} and M^{hand} were the coordinates of the generic marker expressed with respect to (w.r.t.) the cameras global reference frame and hand base reference frame, respectively, R^{hand}_{camera} was the rotation matrix which expressed the orientation of the cameras global reference frame w.r.t. the hand base reference frame and $B1^{camera}$ was the origin of the hand base reference frame expressed in the camera global reference frame. Then, local reference frames were defined at each joint starting from marker positions. The flexion axis (i.e., the z axis) of each finger was defined as the unit vector normal to the plane defined by markers MCP, DIP and TIP, the x axis was defined as the unit vector pointing from the proximal to the distal marker (i.e., from B2 to MCP for the MCP frame, from MCP to DIP for the DIP frame and from DIP to TIP for the TIP frame), and the y axis as the unit vector which completed the frame.

Fig. 1: Experimental setup: (1) monitor with the virtual reality environment which replicates the hand movements; (2) motor unit; (3) sensorized (left hand) and motorized (right hand) gloves with retrorefletive markers; (4) BTS Smart-D optoelectronic motion capture system.

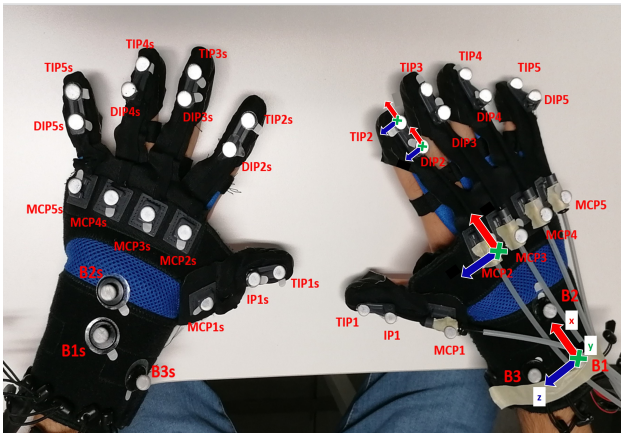

Fig. 2: Retroreflective markers positioned on the gloves.

The underactuated mechanical structure of the motorized glove implies that when the MCP joint flexes, also the other joints flex. Therefore, only the flexion/extension angles of the MCP joints were computed in this work. Angles were extracted as sequences of Euler angles obtained from the rotation of the local reference frame at the DIP w.r.t. the MCP local reference frame. The computed angles were positive for finger flexion and negative for finger hyperextension.

B. Experimental Protocol

One healthy male volunteer aged 21 years was enrolled to perform the experimental acquisitions. He wore the sensorized glove on his left, dominant hand, and the motorized glove on the right hand. He was asked to comfortably sit in front of the table on which the monitor showing the virtual hands was placed (Figure 1). In this experimental protocol, the virtual reality which shows the virtual hands replicating the executed movement is only employed as a built-in functionality of the system, but its therapeutic effects were not taken into account

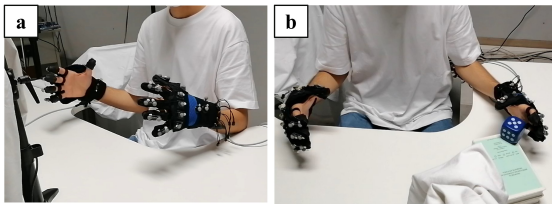

Fig. 3: (a) Initial reference configuration, (b) grasping task of the cube.

as the executed trials were not part of a therapy but they were only technical trials to evaluate the system performance. The volunteer started all the trials from the same reference position, i.e. shoulder adducted, elbow flexed at 90°, wrist in its neutral position and hands completely open, as shown in Figure 3a.

The volunteer performed two types of trials: a free flexion/extension movement of the hand (i.e., flexion of the hand from full extension and return to full extension) and a grasping and release task of a cubic object ($5.5 \times 5 \times 5.5$ cm^3), shown in Figure 3b. For each type of trial, he was asked to perform the movement with the left hand, on which the sensorized glove was placed. The motorized glove placed on the right hand replicated the movement according to the bimanual operation modality. In particular, five repetitions were recorded for each type of movement. We chose to enroll only one volunteer because the aim of this work was to evaluate the accuracy and responsiveness of the system that is independent of the analyzed subject. However, the volunteer performed five repetitions of each type of trial to guarantee a sufficient amount of data to perform the analysis.

C. Data Analysis and Performance Indicators

Angles were extracted through the previously described protocol using the BTS Smart Analyzer software, and then exported as text files to MATLAB R2021b to be post-processed. The MCP flexion/extension angles were filtered with a low-pass Butterworth filter with cutoff frequency of 1 Hz.

The performance of the *Gloreha Sinfonia* device was evaluated by extracting the following performance indicators:

1) Activation delay of the motorized glove (*Delay* [s]), to evaluate the responsiveness of the system, defined as the time from the movement onset of the healthy hand wearing the sensorized glove and the activation of the motorized glove;
2) Mean Absolute Error (*MAE* [deg]) between the angles calculated for the left hand (i.e., the hand with the sensorized glove) and the right hand (i.e., the hand with the motorized glove), to evaluate the accuracy of the system in reproducing angular configurations;
3) Standard Deviation (*SD* [deg]) of the error between the angles of the right and left hand.

The onset of the finger flexion movement, for each hand, was chosen by identifying the first frame for which the movement speed (i.e., the first time derivative of the angular trajectory) exceeded the 10% of the peak movement velocity for each finger. The errors were calculated after aligning the angle tracks by subtracting the activation delay to the right, motorized, hand.

The Kruskal-Wallis test was conducted to evaluate the effect of the finger and of the type of trial (grasping or free flexion/extension) on the computed MAEs. The level of significance was set to 0.05.

III. Results and Discussions

Figure 4 shows the angles computed for a representative grasping trial: the *Delay* is highlighted. The behaviour was similar for all the grasping and flexion/extension trials.

The average delay computed on the five repetitions of each type of movement was 1.48 ± 0.28 s for the grasping trials and 1.51 ± 0.63 s for the free flexion/extension trials. Therefore, the system exhibits a delay in the bimanual modality, due to the activation time of the motors.

The average MAEs are shown in Figure 5 for each finger. As evident, for the grasping trials, the errors ranged between 8.23 ± 3.07 deg for the thumb and 18.5 ± 5.51 deg for the little finger. For the free flexion/extension trials, average errors ranged between 8.26 ± 2.45 deg for the thumb and 10.5 ± 4.06 deg for the little finger.

The Kruskal-Wallis test did not evidence a statistically significant difference between the MAEs computed for the five fingers, for both type of trials ($p - value = 0.06$ and $p - value = 0.84$ for the grasping and flexion/extension trials respectively). The type of trial, instead, influenced the magnitude of the computed MAEs ($p - value = 0.0022$). In fact, errors were in general higher in grasping trials (median error 12.46 deg) w.r.t flexion/extension trials (median error 9.12 deg). This suggests that the interaction with an object could significantly modify the accuracy of the system in reproducing angular configurations, as the movement generated by the motors could be limited by the interaction of the fingers with the object.

Qualitatively, the pattern of the joint angles was slightly different between the two hands (Figure 4). In fact, a smooth trend can be noted for the sensorized glove and a jerky trend for the motorized glove. This behavior is related to the fact that the motors move by discrete steps corresponding to a percentage of the full scale of the motor itself [12]. In addition, the values from which the joint angles replicated by the motorized glove start and at which, in the final phase of motion, stabilize, are greater than those that characterize the joint angles of the sensorized glove. This aspect highlights that, in the bimanual mode, the motorized glove of the *Gloreha Sinfonia* does not allow the paretic hand to assume a configuration of full and maximum finger extension, given the presence of the transmission cables.

The magnitude of the MAEs calculated in this work could be related to the fact that the *Gloreha Sinfonia* motorized glove is an underactuated cable-driven device, therefore it does not allow to precisely control the angular configuration of each joint. Nevertheless, the system allows reproducing the qualitative configuration of the healthy hand on the paretic hand with sufficient accuracy for the considered application,

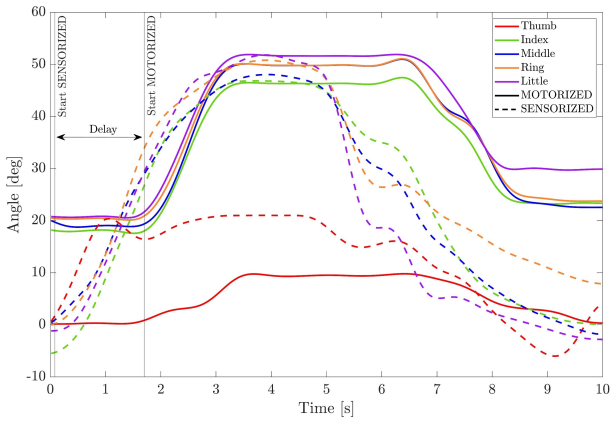

Fig. 4: Grasping trial. The angles calculated on the sensorized and motorized glove are shown with dotted and full lines respectively. The delay between the activation of the sensorized and motorized glove is highlighted.

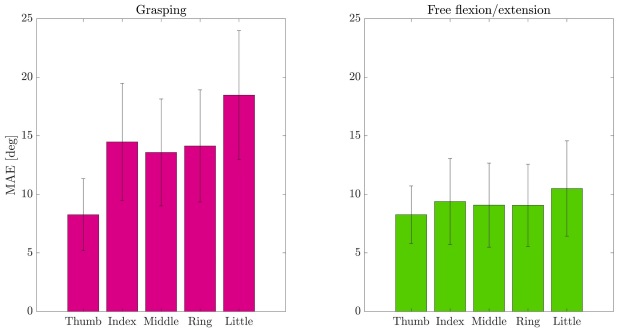

Fig. 5: MAE and SD computed on the five repetitions of each type of movement. For the grasping trials MAE±SD were 8 ± 3, 14 ± 5, 13 ± 4, 14 ± 5, and 18 ± 5 deg for the thumb to little finger, respectively. For the free flexion/extension trials MAE±SD were 8 ± 5, 9 ± 3, 9 ± 3, 9 ± 3, and 10 ± 4 deg for the thumb to little finger, respectively.

which is comparable to the accuracy of other existing systems [8, 9].

IV. Conclusion

In this work, the responsiveness and the accuracy of the *Gloreha Sinfonia* system in reproducing the kinematic configuration in bimanual modality was evaluated. The delay related to the activation of the motors was in the order of 1.5 s. The use of a marker-based motion capture system allowed evaluating the accuracy in reproducing the angular configuration on the contralateral hand through the motors activation. The MAE was in the order of 12.46 and 9.12 deg for the grasping and flexion/extension trials, respectively.

An improvement in motor response time would avoid the initial delay and, thus, make the execution of the exercise in bimanual mode synchronous.

Nevertheless, since the device is developed to administer a rehabilitative therapy to post-stroke patients, these aspects (i.e., motor response time delay of 1.5 s and MAEs in the order of 10 deg) do not negatively affect the effectiveness of the system, as demonstrated by clinical studies [13, 14].

A Safe Reinforcement Learning platform for Autonomous Robotic Tissue Approaching

Ke Fan[1], Giancarlo Ferrigno [1], Elena De Momi[1]
[1] *Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan*

***Abstract*—Surgical subtask automation in robotics can improve patient throughput, reduce quality-of-care variance among surgeries and relieves surgeons' fatigue. Reinforcement learning (RL) has shown considerable performance in autonomous control in complex environments, which can benefit autonomous surgical subtasks. However, existing RL platforms for surgical robots do not consider any safety requirements since they only allow robots to learn behavior through maximizing rewards based on unsafe trial-and-error interactions with the environment, which is unacceptable in automating surgical subtasks. In this work, we designed a safe RL platform that integrates safety criteria with an RL library and the da Vinci Research Kit (dVRK) for surgical robotic learning. A tissue approaching task under safety constraints is built on this platform, which is common in real-world surgical execution. We evaluate the designed platform using RL algorithms in simulation, provide analysis and show that the robot can learn safe behavior with our platform. Results show the safe RL platform can comply with safe constraints well during the task.**

***Keywords*—Safe RL, autonomous surgical subtasks, dVRK**

I. INTRODUCTION

Robot-Assisted Minimally Invasive Surgery (RAMIS) has obtained considerable achievements in the last two decades e.g. the development of the da Vinci surgical system (Intuitive Surgical, CA, USA). RAMIS allows performing complex surgical operations with high accuracy and flexibility while minimizing the post-operatory impact on the patient [1]. Surgical task automation has become a growing research field, aiming at improving patient throughput, reducing the difference in nursing quality between operations, and possibly providing automated surgery in the future. Nonetheless, substantial specific expertise of individual skills and a complicated development process are required to design the manually-tuned control policies [2], [3].

Learning-based methods, especially RL-based methods, provide a promising alternative to automating surgical tasks. These approaches are able to develop controllers for complex skills and generalize to a broader range of tasks and environments [4]. However, normal RL can not guarantee safe criteria. Agents will sometimes try dangerous or harmful behaviors in the course of learning [5], which is unacceptable, especially in the surgical robotics field. Methods to address the safety in RL have been proposed including Constrained Policy Optimization (CPO) [6] and Primal-Dual Optimization [7]. The latter is based on Lagrangian relaxation and updates parameters in primal and dual spaces in turn, which is proven to have better performance than CPO [8].

To develop safe RL algorithms, an effective learning platform is necessary. Currently, the most popular learning platform is "gym" from openAI [9]. The "satfy-gym" is then proposed based on the concept of safe RL, which is also the only learning platform to validate safe RL algorithms through a set of simple scenarios. There are also many learning platforms that are compatible with the dVRK such as dVRL [10] and UnityFlexML [11]. These learning platforms built the RL simulation environments for dVRK robots on top of Unity3D, integrating mainstream RL algorithms, and trying to endow the robot with standardized surgical skills.

However, The agents trained with these platforms do not consider safe constraints. Moreover, these platforms can not process safety-constrained RL problems which we will introduce in the next section.

In this work, we build a novel simulation platform for da Vinci surgical robot, which is used to accomplish a tissue approaching task. Most importantly, the platform is designed especially for processing safety-constrained RL problems. The platform can collect constraint information during the interaction from the simulation environment and send it to the python RL trainer. Then the safe RL algorithm can exploit this constraint information to endow the agent with safe behaviors. The code is publicly available at https://github.com/fanke1213812138/safe-RL-platform.

II. METHODS

The objective of this work is to approach the tissue under safe constraints, i.e. approaching the target tissue without collision with the nearby tissues or organs. For that, we designed a learning platform for the da Vinci surgical robot. The platform is composed of three parts: 1) a safe RL library for robots to learn behavior considering safe constraints during interaction with the environment; 2) the dVRK robots and surgical contents constructed on top of the physics engine; 3) a side channel is established as the bridge between the simulation and the RL lib to collect and send the constraint information. The system architecture is shown in Fig. 1.

A. Safe RL Lib

The safe RL Lib deals with the problem of training an agent with safe constraints based on constrained Markov Decision Processes (CMDPs)[12]. CMDPs are equipped with a set of cost functions $c_i, \dots c_k$, separate from the reward function. The feasible set in a CMDP is given by

$$\Psi_C = \{\pi : J_{C_i}(\pi) \leq d_i, i = 1, \dots, k\} \tag{1}$$

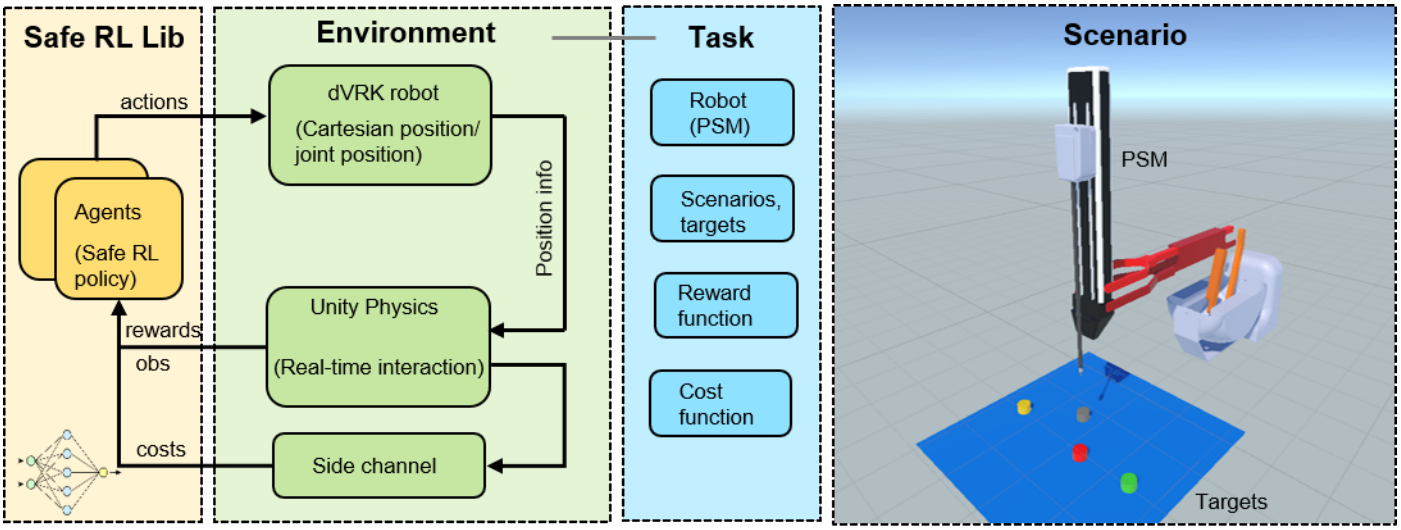

Fig. 1: Platform provides dVRK compatible simulation environments for surgical robot learning, safe RL algorithm and a learning task with a scenario and considering safe constraints in the meantime

where J_{C_i} is a cost function defined in the same way as the reward function, which shows how much the agent violates the constraints. The cost return should be less than a value d_i. Therefore, the constrained RL is to find a set of policies Ψ_C that satisfy the safe constraints. An optimal policy in constrained RL is given by:

$$\pi^* = \arg \max_{\pi \in \Psi_C} J_r(\pi) \tag{2}$$

where $J_r(\pi)$ is the reward function.

The safe RL algorithm aims at solving the above constrained RL problem. We use the PPO-Lagange algorithm [3]. Lagrangian methods use adaptive penalty coefficients to enforce constraints and solve equations (1) and (2) by solving the equivalent max-min optimization problem.

$$\max_{\theta} \min_{\lambda \geq 0} \doteq f(\theta) - \lambda g(\theta) \tag{3}$$

where $f(\theta)$ is the reward objective, $g(\theta)$ is the constraint, λ is the Lagrangian penalty coefficient and θ is the policy parameters.

B. Environment

The simulation environment supporting the patient side manipulator (PSM) of dVRK was built to manipulate various surgical objects. We use Unity3D as the physics engine for interaction. The trajectories (S, A, R, C, P, p_0) for RL training are collected during the interaction between the agent and the unity3d environment. S is the set of state, A is the set of agent actions, R is the reward function, C is the cost function, P is the transition probability function ($P(\acute{s} \mid s, a)$ means the probability of transition from$s$ to $\acute{s}$ by taking action a) and p_0 is the initial state distribution.

The observation space is the low dimensional information such as the object Cartesian positions poses and relative distance. The action space is the six joint positions of PSM or the Cartesian position of the end tip of PSM. In the latter case, the inverse kinematics of PSM is used. We built a side channel to send cost information to Rl trainer in addition to reward information.

C. Task and scenario

The agent which is the PSM in this context accomplishes the tissue approaching task. The task is built as an unity3D scenario. In the tissue approaching task, a dense reward function is designed, which gives a reward making the agent track the target. The cost function is sparse, which means the cost is obtained only when the agent touches constraints.

III. EXPERIMENT

In this section, we validate our safe RL platform by implementing the PPO-Lagange algorithm on a learning task with safe constraints.

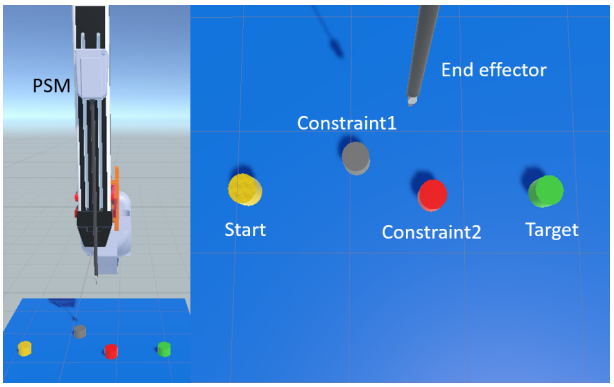

Fig. 2: Experimental setup. PSM is the agent which aims to reach the target without collision.

A. Experimental setup

In our simulation environment, a manipulation workspace was built for PSM and objects to work with as shown in fig.

2. In this task, the aim of the agent (PSM) is to move the end effector from the start position to the target position and avoid collision with constraint objects meanwhile. The end effector should bypass the gray and red objects.

In this context, the state is the Cartesian position of the end effector and the target; the action space is $a \in [-1, 0, 1]^2$ which means the end effector of PSM moves backward/stop/forward along x and y axis. The reward is dense: getting 30 points when reaching the target and $\left(1 - \frac{d}{max(d)}\right)$ points before reaching the target. d is the distance between the end effector and the target and $max(d)$ is the distance between the start position and the target position. The cost is sparse. When the end effector collides with the constraint objects, the agent gets 5 cost points. We also trained a policy based on the normal RL. We make the agent bypass the constraints by implementing punishment on the reward function. The reward function is:

$$\left(1 - \frac{d}{max(d)}\right) - \left(1 - \frac{d(cons)}{max(d)}\right) \tag{4}$$

where $d(cons)$ is the between the end effector and constraints. The training results are shown below.

B. Results

After training the PSM to achieve the goal, we observed two different behavior between the safe RL and the normal RL as shown in Fig. 3. The normal RL policy will act more conservatively trying to avoid collision from start. While the safe RL will learn to bypass the constraint until the action going to be unsafe, which is beneficial in a narrow space. In the approaching process, the distance between the end effector and the target of the safe RL-based agent is always smaller than that of the normal RL-based agent as shown in Fig. 4.

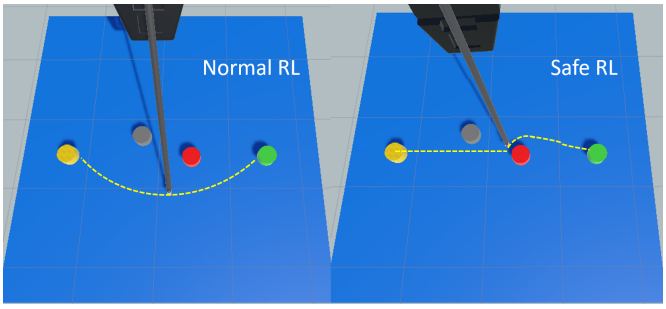

Fig. 3: Trajectory of the normal RL-based agent and the safe RL-based agent after training.

IV. Conclusion

In this work, we took three main steps toward building a safe RL platform for surgical robot learning to accomplish the tissue approaching task. Results show that our platform can confer the agent with safe behavior. We proposed to integrate a constrained RL algorithm into our safe RL library, building a simulation environment for the dVRK robot. We introduced a side channel to send cost information in addition to the normal RL information such as rewards, observation, and termination.

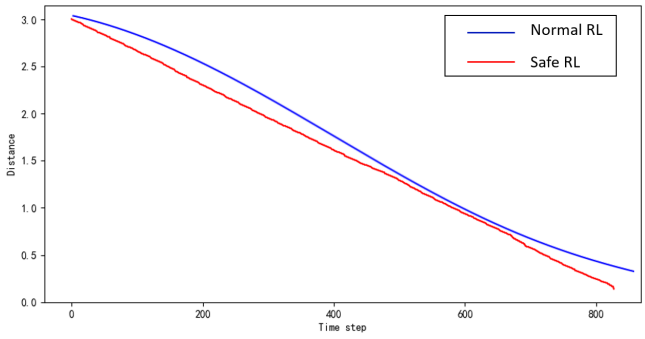

Fig. 4: Distance between the end effector and the target of the normal RL-based agent and the safe RL-based agent.

A task with safe constraints was built to validate the learning platform. We believe safe criteria are very important to surgical robotics. We will develop more effective safe RL algorithms based on the platform to enable the application of RL in surgical robotics in the future.

***Abstract*— The present study aims to quantitatively assess gross and fine motor development in school children and investigate the influence of possible intrinsic factors. One hundred and fifty children from an Italian primary school participated in the study, which included assessments of anthropometric characteristics and characterization of gross and fine motor performance using wearable inertial sensors. When analysing gross motor development, the results showed that stance and double support duration increased with age, and that overweight was associated with a reduction in the development of automaticity. Quantitative assessment of fine motor skills showed that older children had shorter and less variable cycle durations and less regular and more complex movement patterns. The study highlights the advantages of using sensor-based assessments for monitoring gross and fine motor development in children.**

***Keywords*—motor development, inertial sensor, gross motor control, fine motor control**

I. Introduction

TIMELY motor development in childhood is crucial for a healthy adult life and aging, as it affects not only physical but also mental health and social participation [1]. Assessment of both gross and fine motor development as a part of the overall neuropsychological, and developmental examinations is fundamental to predict possible developmental problems such as developmental delays and disorders [2]. However, the ways in which intrinsic and extrinsic factors influence this development are still not clear.

Several tests have been proposed for the characterization gross and fine motor control, although their evaluation is mainly based on qualitative observation, limiting quantitative assessment to the measure of test durations [2]. Recently, wearable inertial sensors have allowed for the development of a quantitative longitudinal assessment approach for the monitoring of gross and fine motor development that can be used in ambulatory conditions [3].

The present study, which is part of the I-MOVE study [1], a school-based intervention trial, aims at characterizing gross and fine motor performance by exploiting parameters describing temporal performance and its variability, associated to peripheral realization of movement patterns, and nonlinear metrics, characterizing the underlying motor control [3], [4]. In order to investigate the influence of intrinsic factors on motor development, results will be analysed with respect to age, sex, anthropometric characteristics (for gross motor) and handedness (fine motor control).

II. Methods

A. Participants

One hundred and fifty children from an Italian primary school participated in the study, 72 first- (38M, 34F; age 75±5 months) and 78 third grade (48M, 34F; age 108±6 months). The study was approved by the University of Bologna Bioethics Committee, on the 18th of March 2019 (Prot. n. 0054382 of 18/03/2019). The study was conducted following the Declaration of Helsinki and approved by the school board.

B. Experimental protocol

Anthropometric characteristics (height, weight, triceps and subscapular skinfold thicknesses) were collected according to standardized procedures.

Gross motor development: children walked along a 20m straight path 3 times back and forth at self-selected speed (NW) and once in tandem (TW) wearing three synchronized inertial sensors (OPAL, APDM, Usa, sf =128Hz) on the lower back and on the shanks [3], [4].

Fig. 1: Normal walking (NW) and tandem walking (TW)

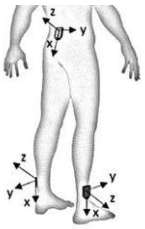

Fig. 2: Sensor positioning during locomotor tasks (NW and TW)

Fine motor development: children performed the Placing Bricks test (PB) [2] while wearing 2 synchronized tri-axial inertial sensors (OPAL, APDM, USA, sampling frequency, 128Hz), one per wrist; both hands were tested.

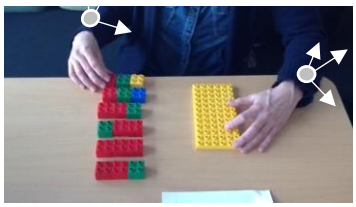

Fig. 3: Placing Bricks (PB) test and sensor positioning (white circles)

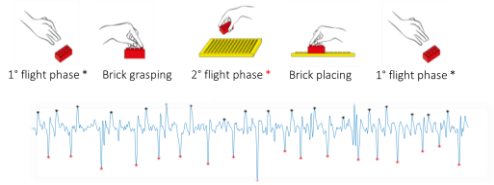

Fig. 4: Placing Bricks (PB) phases. Exemplificative phase segmentation on the measured signal.

C. *Data analysis*

Gross motor development: The following temporal parameters were estimated: stride-, stance-, double support-time. Variability of temporal parameters was calculated using Poicaré plots (short-term and long-term variability). Nonlinear metrics (recurrence quantification analysis and multiscale entropy) were calculated on 3D trunk acceleration to estimate regularity and complexity of movement pattern, respectively [3].

Estimated parameters were statistically analyzed (Kruskal-Wallis test 5%) with respect to age, sex, and anthropometric characteristics (i.e. weight, height, BMI, and triceps and subscapular skinfold thicknesses).

Fine motor development: The following temporal parameters were estimated: cycle duration, brick to board flight time, board to brick flight time [5]. Variability of temporal parameters was calculated using Poicaré plots (short-term and long-term variability). Nonlinear metrics (recurrence quantification analysis and multiscale entropy) were calculated on 3D wrist acceleration to estimate regularity and complexity of movement pattern, respectively.

Estimated parameters were statistically analyzed (Kruskal-Wallis test 5%) with respect to age, sex, and handedness.

III. Results

Gross motor development: Stance and double support duration increased during NW and decreased during TW with age independently from sex, while their variability decreased in both NW and TW. Automaticity (i.e. recurrence indexes) increased with age during NW more in female than in males, while it decreased during TW independently from sex. Complexity (i.e. entropy) increased with age during TW, but not in NW. No dependency on height or weight alone was identified independently from age, while overweight (i.e. BMI and skinfold thicknesses) was associated to a reduction in the development of automaticity during NW independently from age and sex.

Fine motor development: No difference between male and female participants was highlighted and motor performance with the dominant hand was more rapid and less variable, as expected. Older children showed shorter and less variable cycle duration than younger children. With respect to nonlinear measures, older children showed less regular (i.e. recurrence) and more complex (i.e. entropy) movement patterns.

IV. Discussion

Both sex and anthropometry resulted to influence gross motor development in the target population, in particular overweight appears to delay the maturation of automaticity.

When analyzing fine motor skills, older children showed shorter and less variable cycle duration than younger children: these results can be related to the expected maturation and the fine motor skills training during school years. On the other hand, older children showed less regular and more complex movement patterns, showing that their motor control allow the exploration of more flexible movements [4].

The present work highlighted the advantages of sensor-based quantitative assessment and the relevance of nonlinear metrics for assessing motor control development in school-children.

Personality Traits Influence the Perception of a Robotic Arm endowed with Social Cues

C. La Viola[1], L. Fiorini[1], G. Mancioppi[1] and F. Cavallo[1]
[1] *Department of Industrial Engineering (DIEF), University of Florence, Via Santa Marta 3, Firenze, Italy*

***Abstract*— When interacting with robots, humans follow similar behavioral patterns as when they interact with other humans. In fact, the personality traits of people have a role in modifying how users perceive a robot that is interacting with them. Similarly, different combinations of social cues on a robot could modify its perception in terms of social aspects. In this context, this paper aims to explore the role of personality in the interaction with a robotic arm and it will investigate how different social cues can affect its perception. The social cues considered in this work are the face, the sound, and 2 different movements (i.e., direct and indirect). Thirty healthy people were included in this experiment. They were requested to perform a robot-to-human handover with different "social" properties. Quantitative feedbacks were collected through a questionnaire to evaluate the perceived emotion, fluidity, likeability, safety, and animacy of the interaction. Participants were divided into 2 clusters based on their Openness personality trait. Results show that when increasing the number of social cues on the robotic arm, the human perception tends to have a similar score for the 2 types of movements, while the differences were higher when comparing the scores of the interaction without social cues.**

***Keywords*—Robotic arm, Social robotics, Laban Movement Analysis, Robots and personality**

I. Introduction

Personality traits explain how people interact with each other [1]; also, when a person interacts with a robot, the human's personality traits play a key role in the perception of the interaction [2]. Researchers have started investigating how the role of personality influences Human-Robot Interaction (HRI) [3], [4], and the role of social interaction is of paramount importance when applied in the field of robotics rehabilitation, where robots are expected to interact with humans [5]. Such HRI in rehabilitation scenarios can be achieved through various social cues, namely robotic sound [6], [7] robotic face [8], [9], and robotic movement [10], [11]. Robotic movement is tackled in literature in different ways, and this work will face it using a theory of movement coming from the classical dance world: Laban Movement Analysis (LMA) [12], [13]. LMA explains movement according to various parameters and the different combinations of such parameters generate movements that carry emotional information. LMA is already used in rehabilitation robotics to make the robots move and interact with children affected by autism spectrum disorders [14], [15]. What was evinced from the literature is the use of LMA especially in humanoid robots (i.e. Nao, Softbank Robotics, Japan), for the execution of cognitive tasks. However, one limitation emerged from the works of rehabilitation and LMA: the social robots used in literature entangle limited capabilities for the execution of physical and manipulation exercises. Therefore, this work aims at establishing a new paradigm, where the manipulation capability of a robotic arm is used to perform cognitive exercises. Particularly, this work explores the interconnection among human perception based on personalities, LMA, and a robotic arm that offers manipulation capabilities. In this way, it would be possible to obtain a rehabilitation session managed by a robot that stimulates the patients in both the physical and the cognitive realms. For this reason, this work focuses on two research questions. The first aims to evaluate how people perceive a robotic arm endowed with different Laban movements in combination with different social cues. The second investigates how the difference in personality traits influences the perception of robotic movements. To evaluate human perception in a cognitive and physical stimulation scenario, the authors designed an experiment involving a robot-human handover. Such exercise can be extended to other kinds of rehabilitation exercises, such as the Tower of London test [16]. The next section will describe the overall procedure to create the experiment.

II. Materials and Methods

A. Robotic Arm and System Architecture

The entire system uses ROS [19] for robotic control. To manage the data collection and the user feedback, a specific web server was implemented and deployed on a Docker container. The networking among the component is done using a local router over the HTTP protocol. The ROS architecture is composed of a controller node, in charge of managing each HRI, 3 nodes, one for each social cue, and 3 utility nodes for the random generation of interaction sequences, for the dispatching of data to the web server, and for the persistence of relevant data. A schema of the proposed architecture is found in Figure 1. The robotic arm used in this experiment is the Panda robot (Franka Emika, Germany). All the user interactions were recorded using a RealSense camera (Intel, USA). Each interaction was triggered by e dedicated ROS service manually called by the experimenter. This allowed control over the duration of the session and management of any unexpected behavior.

B. HRI Design: Movement, Face, Sound

The handover task designed in this work is performed by the robot following two different types of Laban Movement, which will be addressed as Direct and Indirect movements. The first one is based on the LMA definition of angry behavior, while the latter was designed in LMA to trigger happiness. Such movements are generated starting from the authors' previous work [17] and are composed of parameters from the Laban Effort Graph (LEG), which describe the inner attitude towards the use of energy [18], and the Laban Space (LS), or how the person moves in the surrounding space, on the 3 axes [14]. The selected Laban parameters for these movements are explained in Table I. As for the face, it was entirely replicated from a previous work [9] where such a face

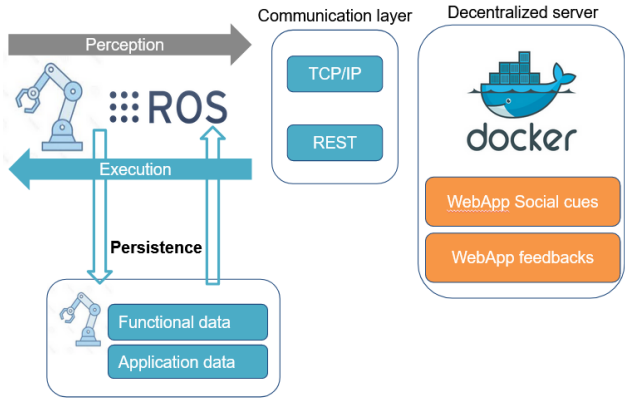

Fig. 1: Architectural schema of robotic components

TABLE I PARAMETERS FOR THE IMPLEMENTATION OF LABAN MOVEMENTS

Movement ID		**Direct (D)**	**Indirect (I)**
Laban Effort Graph (LEG) parameters	*Space*	Direct	Indirect
	Time	Sudden	Sudden
	Weight	Strong	Light
	Flow	Bound	Free
Laban Space (LS) parameters	*Horizontal*	Spreading	Spreading
	Vertical	Ascending	Ascending
	Wheel	Advancing	Advancing

was used on a non-humanoid robot for HRI with older adults. The face is displayed on a tablet at the robotic arm's base. Finally, the sound was designed starting from Zhang et al. [7], reproducing a similar sound pattern. The sound was created using the pygame library (https://www.pygame.org/docs/) and synchronized with the movement of the robotic arm. Each change in the movement triggered a change in the chord played by the sound system.

C. Participants

A total of 31 healthy young people were enrolled in the study. The people enrolled were researchers, medical doctors, psychologists, and nurses that volunteered in the experiment. All volunteers were accepted into the study, with no eligibility criteria. The data of one participant were excluded, for a failure in the technological setup. The group of thirty participants included in the study is composed of 61% female and 39% male; their education level is composed of 3 groups (38.7% Bachelor's Degree, 41.9% Master's Degree, and 19.4% Ph.D.). The mean age of participants is 30.4 years (standard deviation = 3.7). Before starting, all the participants received information on the test and a formal description of the experiment on paper; all of them signed the informed consent.

D. Experimental Procedure

The HRI task consists of the handover of a colored ball from the robot to the user. As the user receives the ball, then should put it in a box of the same ball color.
A single interaction can be divided into 3 main phases, namely Robotic Action, Human Action, and Questionnaires (Figure 2). Before starting with the first phase, the user is asked to fill in demographic and personality information. Then, the *Robotic action phase* takes place, which is composed of 5 sub-phases: i) The robotic arm turns toward the colored balls, ii) The robotic arm gets closer to the balls and picks one of them, iii) The robotic arm turns toward the user, iv) The robotic arm performs a Laban movement and gets closer to the user to handover the ball, v) The robot goes back to the idle position. The choice of the movement and which ball to pick is random. For the *User action phase*, there are 2 sub-phases: i) The user receives the ball from the robot, ii) The user puts the ball in the related box. After each interaction, the user was requested to complete the *Questionnaires phase*. This phase consists of filling the Self-Assessment Manikin [19] questionnaire (i.e. valence, arousal), a subset of the Godspeed questionnaire [20] (i.e. the fields of Animacy and Safety), and two Custom questions related to the Likeability and the Fluidity of the movement. The handover is performed 8 times for each participant, to allow all the combinations of movement and social cues. In the specific, there are 2 possible movements (Direct and Indirect) and 4 possible combinations of social cues (only movement, movement and sound, movement and face, movement, sound, and face); for this reason, the total interactions done per user are 8. At the end of the experiment, the experimenter asks 5 open questions to the participants. In this work only the last question will be evaluated, namely "Imagine bringing the robot home to use for your purpose, which configuration (sound, face, movement) would you like to have?". This experiment is relevant for a rehabilitation scenario because the different colors of the boxes or the balls can be combined to complicate the exercise based on the cognitive load that the therapist wants to reach in the phase of therapy (e.g. place the red ball in the blue box).

Fig. 2: Schema of Interaction Phases

E. Data Analysis

The participants in the experiment were clustered into two groups using a K-mean algorithm based on the results of the personality assessment. Such assessment is based on the BFI10 analysis [21] that classifies personality according to 5 components: Openness, Extraversion, Neuroticism, Conscientiousness, and Agreeableness. Then all the parameters coming from the questionnaire were grouped by personality cluster. For the questionnaire scores, the SAM values were extracted on a scale of 1 to 9; the Godspeed questions, each one evaluated from 1 to 5, were summed up together to obtain an aggregated index with all the scores for the Godspeed elements where the maximum value is 25 for Animacy and 15 for Safety and the minimum values are respectively 5 and 3. The Custom scores of Likeability and Fluidity were evaluated on a scale of 1 to 5. The authors

TABLE II DIVISION OF GROUPS IN CLUSTERS: DISTRIBUTION OF PERSONALITY TRAITS

	O	*E*	*A*	*C*	*N*
LOW-O	5.36	6.00	7.07	7.00	5.21
HIGH-O	8.82	5.88	6.41	7.12	6.35

Legend: O = Openness, E = Extraversion, A = Agreeableness, C = Conscientiousness, N = Neuroticism

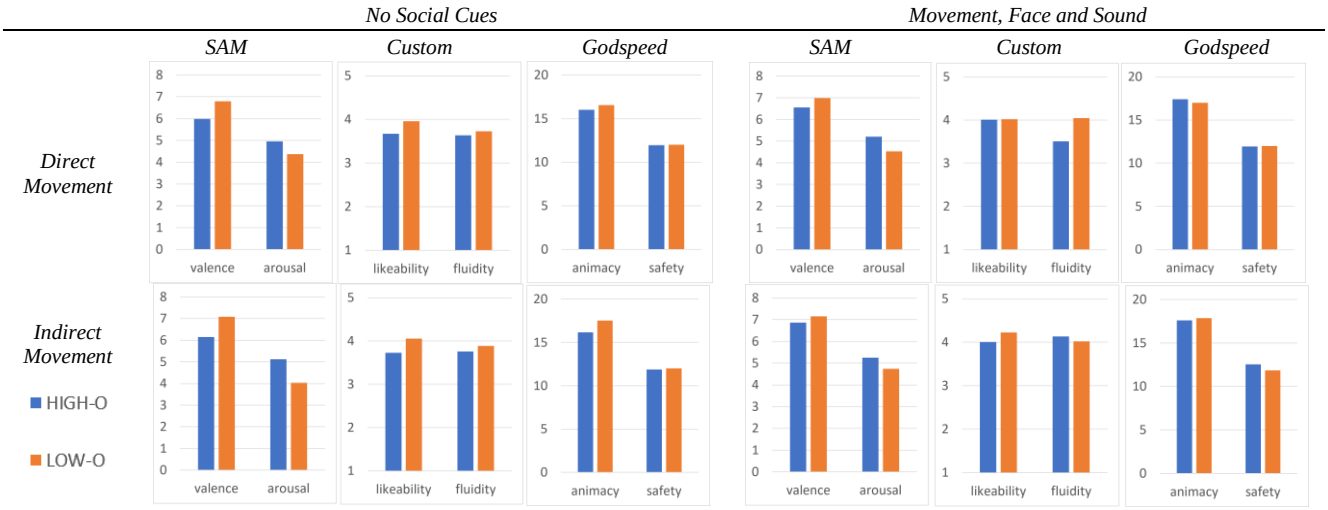

Fig. 3: Different Scoring grouped by Movement and Personality for the two clusters

analyzed the open answers using content analysis [22], and the preferred configuration of social cues and the preferred movement were extracted. This paper reports and compares the questionnaire data of the two cases where users interacted with the robot in presence of all the social cues and without any social cues.

III. Results

The clustering technique of K-mean allowed the authors to identify 2 clusters based on their BFI scores, as depicted in Table II. We can observe that the main difference between the two groups is in the Openness component, so the clusters will be addressed as HIGH-O and LOW-O. Such groups are composed of 13 and 17 people respectively, and their Openness values are 8.82 and 5.36. All the questionnaire scores were aggregated for each cluster and interaction, and the results are plotted in Figure 3. At first glance, the scores obtained by the cluster LOW-O are generally higher than the other one. This difference in scores fades out when compared to the interaction with all the social cues. As for the percentage of the preferred configuration, the one where both face and sound are present was the most voted, with 76.47% of preferences by the HIGH-O group and 53.85% by LOW-O. Related to the preferred movement, both groups preferred the Indirect one, with 52.94% in HIGH-O and 46.15% in LOW-O. It's noticeable that both HIGH-O and LOW-O groups expressed no preference for one specific movement (41.18% and 30.77% respectively). More details are in Table III.

IV. Discussion

The purpose of this study was to find whether personality affects the perception of robotic movements, and the trait of Openness was found suitable to influence human perception. The trait of Openness is defined as the capability of being creative and open to new ideas.

Table III Preferences of Movements By Cluster

	No Preference	*Indirect*	*Direct*
HIGH-O	*41.18%*	*52.94%*	*5.88%*
LOW-O	*30.77%*	*46.15%*	*23.08%*

The two personality clusters of this study show a general trend in all their answers but present a counterintuitive result. For the LOW-O group, the scores are always higher (i.e. more positive perception), while the expectancy was that the higher scores were related to the HIGH-O group. This counterintuitive result should be further investigated, and the correlation between the participant's past experiences with robots and the level of confidence they have in using a robot should be looked into. Only for the Arousal domain of the SAM, the HIGH-O group always has a higher score. As arousal is how strongly the participant perceived the feeling, this could be related to the personality, as more Openness could trigger the increasing emotional perception of a movement.

The results are aligned with findings from other authors that explored the role of Openness in the perception of robots. In [23], [24], Openness was proven to be effective in increasing the positive feeling toward the robot, and in [25] the role of Openness helped the participants in perceiving a robotic voice as positive.

For the Safety dimension, it is possible to notice that there is no fluctuation in its values among the interactions. This is encouraging, as the perceived safety is not changing depending on the movement, social cues, or considering personality. This result suggests for future experiments neglect this component when designing other Laban movements. Another element of contrast among the graphs in Figure 3 is the Fluidity evaluation with all social cues. The variation between the Direct movement and the Indirect is in contrast with the variation in the interaction with no social cues, which is close to 0. These findings suggest two possible implications: i) The interaction with all social cues impacts the perception of fluidity for the HIGH-O cluster, ii) When all the social cues are present, different movements are perceived differently in terms of fluidity.

At last, a general consideration can be extrapolated from the overall graphs. The use of multiple social cues decreases the perception of differences for all the considered parameters (but fluidity); therefore, the personality influences the perception of movement, but when movement is coupled with other social cues the difference gets flattened and the perception is more similar among different movements. The robotic arm employing all the social cues was the preferred configuration

for both groups, suggesting the fact that more social cues imply a higher quality of social communication.

The preference on which movement was the best is not unanimous in the two groups though. While the HIGH-O group has the most scores divided by Indirect and No Preference, such division is less uniform for LOW-O, having a distribution on the 3 possible answers much more balanced without a real polarization (Table II). This is probably due to the intrinsic effect of the Openness personality trait, which influences how people live new experiences. People belonging to LOW-O in fact, show a distribution that does not define a clear preference, enhancing the idea that the LOW-O group has more issues in categorizing robotic arm movements that which are seen for the first time.

V. Conclusion

The designed experiment confirmed the two research questions. The results obtained show how personality, specifically the Openness component, can affect the perception of movement for some parameters. The inclusion of social cues suggests that they have a real impact on the perception; indeed the use of multiple social cues also seems to decrease the difference in movement perception derived from personality traits. In future works, the sample size should be enlarged, and statistical analysis should be computed to verify the trends observed in this study. This work marked a key point in the definition of the best configuration of social cues for a robotic arm that performs exercises with humans and the parameters used in this study (e.g., animacy, fluidity, etc..) are relevant for future implementations because they can be markers for an effective and engaging HRI.

These results can be a starting point in the design of cognitive rehabilitative scenarios with a social robotic arm. For this reason, collaboration with clinicians is necessary, and the design of social cues should be further discussed with psychologists and adapted to HRI rehabilitation scenarios.

***Abstract*—Cycling is a widely used rehabilitative method since it is a safe and intensive exercise that shares several similarities with walking. When practiced outdoors, cycling becomes a model of Sport-Therapy, favoring social inclusion and promoting the psychological well-being of the subjects. The aim of this study is to design a motor-assisted recumbent trike in order to allow even severely impaired people to pedal outdoors. The main novelty of the designed system is in the control strategy which implements an assist-as-needed cooperative approach in order to maximize the residual volitional contribution of the pilot. A commercial recumbent trike (CATRIKE 700) was equipped with a DC brushed motor mounted on a custom-made aluminum support and coupled with a free wheel to transmit torque to the main chain without applying any additional resistance. A Proportional Integral Derivative (PID) controller was implemented in order to modulate the PWM duty cycle to keep a constant target cadence. A feasibility study involving three healthy volunteers and three stroke survivors was conducted. The designed setup proved to be suitable for assisting a fully-active exercise as well as for handling completely passive legs movements. Moreover, it proved to be a good solution in assisting the user in compensating for muscle weakness or fatigue. Future works will combine the voluntary effort of the pilot and the assistance of the motor with the action of Functional Electrical Stimulation (FES) and will verify the feasibility of the hybrid motor-FES approach.**

***Keywords*—Cycling, motor, Hybrid, Stroke, muscular activity, Sport-therapy.**

I. INTRODUCTION

Neurological disorders such as Spinal Cord Injury, stroke, or Multiple Sclerosis are among the main causes of disability and have a significant impact on the quality of life of affected people. A number of studies supported the role of goal-oriented, active and repetitive movement in enhancing motor re-learning, taking advantage of neural plasticity mechanisms.

Cycling represents a pseudo-walking aerobic and periodic exercise, which can improve functional mobility and bring peripheral benefits, such as improvement of muscle strength, bone density, and cardiovascular fitness [1]. Moreover, it provides a safe platform for exercising even at the early stages of the disease and can be maintained for reasonably long periods, maximizing activity-dependent neuroplasticity [2]. Cycling also represents an example of Sport-Therapy, being an accessible form of exercise also for people with disabilities, favoring social inclusion and overall the physiological well-being. Despite the aforementioned benefits, the tendency of severely impaired muscles to early fatiguing and the presence of death areas within the pedaling cycle make difficult to perform a prolonged training in daily life condition, e.g. outdoors. In the last few years, some solutions have been investigated to overcome these issues. Most of these proposed the development of instrumented recumbent trikes instead of stationary cyclo-ergometers, to facilitate cycling exercises outdoors also in highly impaired people and to measure training performances in order to optimize the mechanics of pedaling [3]. Some Authors proposed a motor-assisted cycling system as a solution to prolong the exercise and offer the possibility to train outdoors [4] - [5]. The combination of motor assistance with the residual voluntary contribution of the user may increase the training intensity and duration. Furthermore, to exploit even more the therapeutic benefits of pedaling, such devices should include the possibility to be combined with Functional Electrical Stimulation (FES) [6]. Thus, the aim of this work is to present a novel motor-assisted cycling device to allow even severely impaired people to pedal outdoors, exploiting an assistance-as-needed cooperative approach. The proposed system has been designed to be integrated in the near future with FES to exploit the efficacy of the hybrid FES-motor approach.

II. APPARATUS

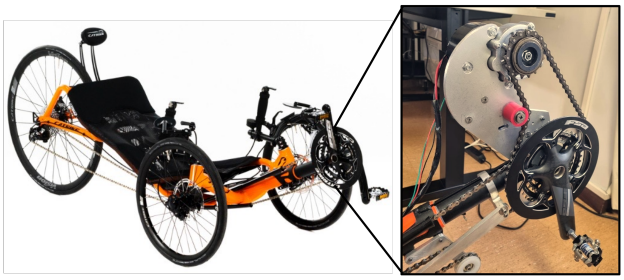

Fig. 1: The commercial recumbent trike with the detail of the structure developed to couple the DC motor

The designed system is shown in Fig.1. A commercial recumbent trike (CATRIKE 700) was chosen for the light but solid vertebrae space frame. Commercial pedals were replaced with sensorized pedals (X-Power, SRM GmbH), in order to measure the tangential and radial forces exerted by the patient's legs, with a sampling frequency of 30Hz. Pedals can be used with cycling shoes equipped with pedals-compatible cleats or with custom-made ankle foot orthoses (AFO), in the

case of disabled users, to keep the ankle angle at 90° and to constrain the leg's movement in the sagittal plane. A brushed motor (24V DC supply, LFaster) was mounted on the trike frame with a custom-made aluminum support which allows for a mid-drive configuration. When the motor is active, it moves the transmission line and the cranks simultaneously, through a second transmission chain mounted on the external chainring, assisting the pedaling action by directly moving the legs. In this way, the motor applies torque at the crank which in turn transmits the rotation to the rear wheel through the main chain. Furthermore, the motor shaft is coupled with a freewheel sprocket that gives the possibility to apply no additional resistance to pedaling when the motor does not support the movement. The motor is controlled via Pulse Width Modulation (PWM), managed through a high current H bridge module (HiLetgo, BTS7960b) by the central control Unit (Raspberry Pi 4 model B). The trike was instrumented with a custom-made tachometer, developed with a Hall sensor (ARCELI, 44e402) mounted on the fixed frame, and a set of 20 50mmx50mm magnets on the internal side of the crankset, used to acquire the pedaling cadence. The control software application was developed in C++ in a Linux-based environment. The motor is controlled in a closed loop to keep a target pedaling cadence. A Proportional Integral Derivative (PID) computes the difference between the measured and the target cadence, given as a set point, and modulates the duty cycle PWM signal accordingly. A trial and error procedure was applied to tune the controller parameters. The following parameters were identified: $K_p = 0.2$, $K_i = 0.001$, $K_d = 0.6$. An intuitive user interface allows one to adjust the target velocity while training.

III. Validation

A feasibility study was conducted in order to verify the performance of the motor-assisted trike in supporting the pedaling exercise under different conditions. The trike was used indoors, placed over a roller and the sixth trike gear was set for all the trials. Three healthy volunteers (2 female, and 1 male, 29 ± 7 y-o, right dominant leg) and three stroke survivors participated in the study. Table I shows the clinical and demographic characteristics of the stroke survivors. The study was approved by the Ethical Committee of Politecnico di Milano (number 31/2021; date: 21/07/2021) and each subject signed the informed consent before participating in the study.

A. Experimental protocol

Each subject performed three consecutive trials, each lasting about 2 minutes. The first trial consisted in a voluntary pedaling trial (VOL), during which the subject was asked to pedal completely voluntarily trying to maintain a constant cadence of 40 rpm, without any motor assistance. The second trial consisted in a partially assisted pedaling trial (VOL+MOT), in which the volitional contribution of the subject was assisted cooperatively by the motor action, i.e. the total power at the crank was exerted by the combination of muscle contractions and motor power. Also during this trial, the subject was asked to maintain a constant cadence of 40rpm. The third trial (MOT) consisted in a passive pedaling trial, in which the legs were moved only by the motor action, controlled to maintain a constant cadence of 40 rpm, and the subject was asked not to voluntarily participate in the exercise. Tangential forces exerted at the pedals were acquired with two commercial MTB/quick release pedals (X-Power, SRM GmbH) with a sampling frequency of 30Hz via a tablet application. Furthermore, the motor output, quantified in terms of duty cycle set by the control algorithm, was acquired with a sampling frequency of 1000Hz.

B. Analysis

Sixty pedaling cycles during each trial were selected for the analysis. Each pedaling cycle were defined as a complete revolution of the left crank and the zero angle corresponded to the left crank up in the vertical axis. All the analyses were performed in Matlab (R2021b version).

IV. Results and discussion

Table II reports the results of the three trials for all subjects who participated in the experimental protocol. All the participants were able to pedal for the entire duration of the voluntary trial maintaining the desired velocity and developed higher forces in the voluntary trial with respect to the cooperative and passive conditions, as expected. During the three trials, an asymmetric pedaling pattern in stroke survivors is suggested by the comparison between the mean values of tangential force exerted by the two legs separately during the voluntary trial. Such high differences were not found in healthy subjects which developed a more symmetrical pedaling pattern. Comparing the two groups of subjects, the healthy subjects developed more similar forces at the pedals in VOL and VOL+MOT trials, while the stroke survivors showed a significant decrease in forces between the VOL and the other two trials. In particular, the two groups show different behavior in the cooperative trial, which reflects the tendency of stroke survivors to let the motor primarily drive the movement. Consequently, the motor output needed to execute the same movement (same target speed of 40 rpm and same gear) for the stroke patients in the VOL+MOT trial was higher with respect to the healthy subject. In this case, the reduced patients' voluntary contribution (indicated by the decrease in mean tangential forces for the same cadence) may be attributed to the onset of muscle fatigue (please consider that the voluntary trial was also performed at first), or due to the slacking effect (i.e. a phenomenon in which the patients remain mainly passive and not engaged in the exercise). Overall, the tangential forces of the three trials were significantly different for all subjects, with a p-value< 0.001 (one-way ANOVA).

Fig.2 shows the data acquired for two stroke survivors (S2, S3), over 60 revolutions, during the three trials (VOL, VOL+MOT, MOT). Comparing the two subjects in terms of symmetry of pedaling it can be appreciated that S3 shows the tendency to compensate for the weakness of the affected side, by developing higher forces with the non-affected leg,

Subj	Gender	Age	Days post-stroke	Type of stroke	Paretic side	6min walking test	Motricity index
1	M	37	273	Hemorrhagic	Left	290	54
2	M	54	216	Ischemic	Left	320	92
3	M	47	287	Hemorrhagic	Right	395	76

Age is expressed in years, 6min walking test in meters

TABLE I: Demographic and clinical characteristics of the stroke survivors

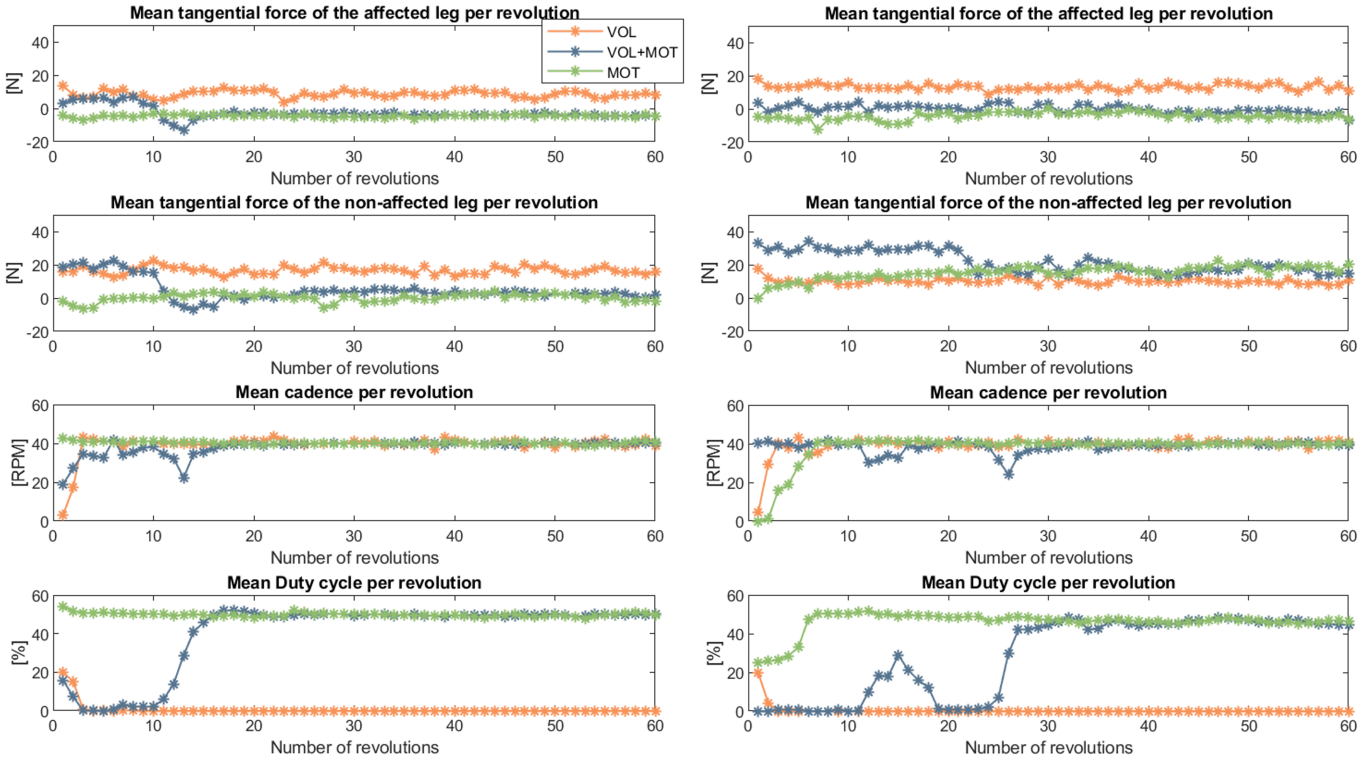

Fig. 2: Mean values of tangential forces, cadence, and duty cycle for two stroke survivors (S2 on the left, S3 on the right) displayed over 60 revolutions, during the three trials (VOL: voluntary, VOL+MOT: cooperative, MOT: passive)

resulting in a highly asymmetric cycling pattern. During the hybrid trial (VOL+MOT) the slacking effect is demonstrated by the behavior of the mean forces and duty cycle over time. During the first part of the hybrid trial, both subjects behave actively developing forces similar to the ones of the voluntary trial, needing no assistance from the motor. After a while, they started decreasing their voluntary contribution, reaching a completely passive state. Overall, the behavior of the control system showed the ability to rapidly compensate for the changes in voluntary contribution to fulfill the desired exercise (i.e. to keep the cadence fixed) in a cooperative way.

V. Conclusions

A motor-assisted cycling system can be considered a good solution to prolong cycling training and allow the practice also in outdoor environments, enhancing the sport-related psychological benefits, even in severily impaired subjects. This study presents the first stages of development of a motor-assisted recumbent cycling system and the results of a series of tests performed by three stroke survivors and three healthy volunteers to verify the feasibility of the approach. Our system is characterized by a motor directly coupled with the crank. This allows both fully-active exercises, meaning that the user is able to pedal also without motor assistance and the mechanical actuation does not introduce any additional friction, and fully passive exercises, even in absence of any voluntary contribution, in case of muscle fatigue or severe impairment. Furthermore, this solution introduces the possibility to perform the exercise in a cooperative way where the motor is in charge of supporting the user to maintain a constant pedaling cadence when she/he is not able to do it autonomously. So far, only feasibility tests were performed to assess the motorized system functioning at different levels of assistance. The designed setup proved to be suitable for the assistance of an active exercise as well as for the handling of completely passive movements. The

TABLE II: Mean values of tangential force of the non-dominant/affected (Tg F ND/A) and of the dominant/non-affected leg (Tg F D/NA) and mean values of cadence and duty-cycle calculated over 60 revolutions for each subject (S: stroke, H:healthy) under the three modalities..

control software showed stability and precision during cadence tracking and unwanted and potentially dangerous accelerations were avoided. In conclusion, it can be asserted that the motor action can represent a valid assistance, reducing the workload for the subject in active training, and also a valid system for passive training giving the possibility to passively move the patient's legs in the early stages of the rehabilitation program. Based on the results obtained during the validation phase, what is not missing is the ability of the system to enhance users' participation, avoiding patient accommodation. To guarantee a fully cooperative behavior of the system, future insights would consider the development of a torque-based control, given the indirect measure of the power exerted by the motor and the direct assessment of the legs' power developed at the pedals. Future works will also focus on the combination of the motorized system with FES in stroke rehabilitation. The idea behind a hybrid FES-motor approach would be to add to the cycling training the well-known therapeutic benefits of FES, so as to further enhance motor re-learning. The possibility to combine FES with the residual voluntary contribution of the subject maximizes the neuro-plasticity mechanisms, while the motor guarantees a safe and prolonged exercise [7].

ACKNOWLEDGEMENT

***Abstract*— Cerebral palsy is often diagnosed through general movements assessment in infancy. However, this tool requires extensive training and is thus difficult to implement on a large scale. Early identification of motor disorders makes possible to leverage the neuroplasticity of infancy for intervening as soon as possible. Computer vision techniques based on a single RGB-D sensor system integrating an RGB camera with a depth sensor in the same device allows to carry out assessments at home or in the clinic. Recently, we published a markerless protocol for studying upper limb movements on infants by using a single RGB-D camera, an open-source markerless motion tracking method (Deep Lab Cut) for estimating estimation of the 2D trajectories of the selected Point of Interest and a purposely developed method for reconstructing their 3D trajectories and extracting nine general movements related metrics. This study aims at proposing a video processing method for improving the robustness of that previously published by limiting the effects of accidental movements of the camera or the infant's seat that could easily occur especially in a non-controlled environment such as the home.**

The above mentioned nine metrics were evaluated with both the original and the improved methods and their values compared. The results demonstrated the improved method limits the detrimental influence of unintentional and unexpected movements.

***Keywords*—Markerless, RGB-D, General movements, Infant movement analysis, Movement disorders.**

I. Introduction

Cerebral palsy (CP) is the clinical description given to a constellation of neuromotor impairments stemming from perinatal brain injuries such as periventricular leukomalacia, intracerebral haemorrhage, infection, and infant stroke [1]. Arguably, the greatest boon to early identification of infants with CP has been the validation and dissemination of the general movements assessment, GMA. This instrument came into being as understanding of the significance of infants' spontaneous movements increased during the latter decades of the 20th century ([2] [3]). Two patterns in particular, predominantly cramped-synchronized movements and the absence of fidgety movements at three to five months of age reliably predict a later finding of CP [4]. Despite the power of the GMA in early identification, its key mechanism of gestalt pattern recognition (from video) requires a significant investment in assessor training and validation [5], making the GMA challenging to implement broadly across clinical practices. Early intervention depends on early identification, which suggests the need for a widely disseminated screening process, which is not found in the current approach to delivering CP care [6]. Families have been identified as the cornerstone of early intervention [7].

Marker-based, multi-camera, 3D analysis of infant movement has been used to detect both upper [8] and lower extremity movements [9] correlated with GMA assessment of CP. Given that marker-based systems typically require multiple cameras and a laboratory setting, an accurate and reliable, markerless, computer vision approach that can be operationalized in either the home or clinic setting may make screening more widely accessible. Markerless, computer vision technology further preserves the non-intrusive character of the GMA, leveraging, as does the GMA itself, video to assess an infant's movements unhampered by markers or other sensing devices [5].

Avoiding markers may be particularly appropriate in the case of infants where they may be poorly tolerated and, as a result, introduce movement patterns that are not part of the infant's typical GM repertoire [5].

Use of a commercial RGB-D sensor system that integrates an RGB camera with a depth sensor in the same hardware is a promising approach which enhances portability and makes it possible to carry out assessment in more confined spaces [10] such as the home or clinic.

Such an integrated system promises to help fill the current gap in infant movement assessment by providing a low-cost, compact platform that can be implemented repeatedly and longitudinally in the infant's naturalistic environment, where movement repertoires are most likely to characterize the actual behaviours of the infant ([11]).

Recently, we published a study proposing a method for assessing infants' GM that features a simplified instrumental setup, suitable for home (or clinic) by recording infants' upper body movements with a single, commercial RGB-D sensor [12].

This study proposes a video processing method aiming at improving the robustness of the previously published method, by limiting the effects of accidental motions of the camera or the seat of the infant.

The improved method was applied to the recordings of a single infant characterized by accidental motion of the camera.

II. MATERIALS AND METHODS

The infant selected for this study was sitting in a baby seat covered with a green cloth to facilitate background exclusion during identification of infant, was positioned on the floor in front of an RGB camera with an integrated depth sensor (Figure 1). The child natural movements were recorded for a target duration of three minutes at 8 months from birth.

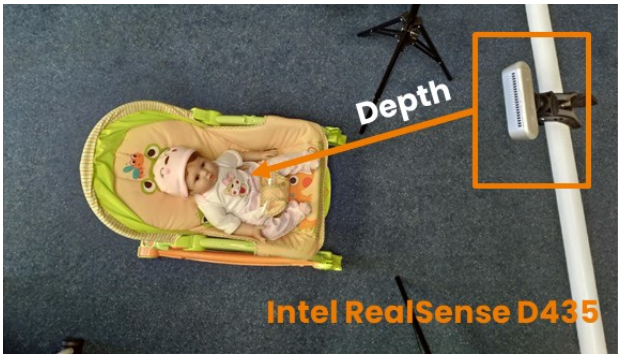

Fig 1. Experimental set-up.

The camera used for the recordings was a commercial RGB-D sensor (Intel RealSense D435 combining a pre-calibrated RGB camera with 1280x720 native resolution and frame rate of ~30fps with a depth sensor generating depth-coded images with 640x480 native resolution and frame rate of ~30fps).

Each pixel of the depth image had an intensity proportional to the distance of the surfaces in the image from the camera. Depth images were generated by the stereo vision of two infrared sensors mounted on the device with the left sensor used as point of view. If a region is seen only by the left sensor, the resulting depth image in that region remains black ("black area"). RGB and depth images were pre-calibrated, however a residual misalignment between the two remained.

The markerless motion tracking software used in this study was DeepLabCut [13], an open-source toolkit for pose estimation in which a training set of images is manually labeled and returns the x,y coordinates of the tracked points along with a confidence level, varying from 0 (lowest confidence) to 1 (maximum confidence). DeepLabCut provides a framework for supervised, deep learning to tune an existing, high-performance convolutional neural network (ResNet) to the features of a specialized dataset to produce a high level of recognition accuracy.

A sequence of steps was implemented to reconstruct the time series of the 3D coordinates of the selected points from the recorded RGB-D videos and to extract the associated GM metrics (Figure 2).

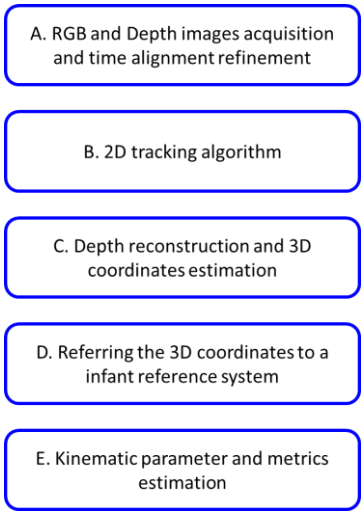

Fig 2. Block diagram of the proposed markerless -based method.

All blocks are explained in the following sections (a more detailed description can be found in [12]).

A. RGB and depth images acquisition and time alignment refinement

The images acquired with the RGB camera and the depth sensor required refinement of the time alignment obtained from the manufacturer's proprietary software, since neither frame rate is exactly constant. The timestamps provided by the acquisition software were used for this purpose [12].

B. 2D Tracking algorithm

RGB images were converted into video files using ImageJ [30] and fed to the DeepLabCut image processing tool. The tracking software was trained to identify seven points on interest (PoIs) on the infant's upper body: left and right shoulders (LS and RS), elbows (LE and RE), and wrists (LW and RW) and belly button (B). All PoIs were manually labeled on 10% of the video frames (540 frames), identified by DeepLabCut using a k-means algorithm that selected frames based on pixel characteristic variability, to create a training set.

After the network was trained and validated, DeepLabCut provided the PoI positions in all RGB frames referred to the image coordinate system(CS_I) , together with their confidence levels. When a PoI was occluded, its position was provided with a low confidence level. A recognition network was trained individually for each infant video to achieve the greatest possible accuracy prior to the association of RGB and depth coordinates of PoI.

C. Depth reconstruction and 3D coordinates estimation

The 3D position of PoIs tracked in the RGB images was obtained by implementing the method which exploits the depth sensor recordings by taking into account PoIs occlusions, lacking of depth information due to the presence of "black areas" and residual spatial misalignment between RGB and depth images [12].

Resulting depth coordinate gaps shorter than 0.2 s were then filled by applying a cubic spline interpolation.

D. Referring the 3D coordinates to an infant reference system

In order to limit the effects of accidental motions of the camera, a new local reference system (infant reference system, CS_{Infant}) was identified as the system having the origin in the centroid (C) of the 3D coordinates of LS, RS and B, with the medio-lateral-axis joining LS and RS, the antero-posterior-axis perpendicular to the plane defined by LS, RS and B and the vertical axis resulting from the cross-product between antero-posterior and medio-lateral axes.

The 3D position of PoIs was referred to the new infant refence system and then their coordinates were low-pass filtered (Figure 3).

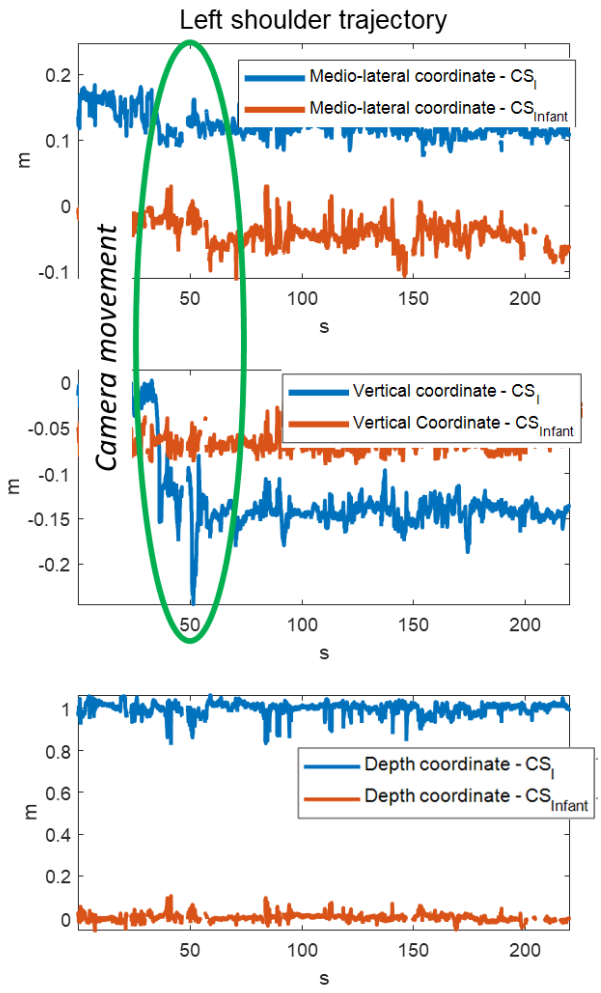

Fig 3. 3D coordinates of left shoulder in both reference systems. The blue line represents the image reference system while the red one represents the new infant reference system. The effects on the shoulder trajectory of the accidental camera movement occurring between frames 40 and 50 are circled in green.

E. Kinematic parameter and metrics estimation

From PoI 3D trajectories the following metrics for quantifying GMs were estimated [9]:

- area in which the trajectories of the wrists differed from the moving average for the same trajectories, normalized with respect to the length of the moving average window (two seconds) (A1_t);
- area in which the trajectories of the wrists were outside of the standard deviation of the moving average for the same trajectories, normalized with respect to the samples in which the trajectories were outside the standard deviation (no information regarding the normalization was provided in the reference work) (A2_t);
- periodicity in the wrist trajectories (PI_t);
- area in which the speed profiles of the wrists differed from the moving average for the velocity profiles, normalized with respect to the length of the moving average window (2 seconds) (A1_v);
- area in which the speed profiles of the wrists were outside of the standard deviation of the moving average for the velocity profiles, normalized with respect to by the length of the moving average window (2 seconds) (A2_v);
- periodicity in the wrist velocities (PI_v);
- the skewness of the velocities of the wrists (SK);
- the cross-correlation of accelerations between left and right wrists (CC).

In addition, we estimated the range of motion (ROM) of the elbow angle (EA).

III. RESULTS

Table 1 shows the values of the nine GM metrics (for left and right sides, both separately and together) estimated from the upper body 3D PoIs obtained by applying the proposed method compared to the estimates obtained applying the original method presented in [12].

For sake of comparison, also the trajectories from the original method were low-pass filtered and only gaps longer than 0.2 s were filled.

IV. Conclusion

This work has confirmed that GM metrics can be effectively estimated with a single low cost RGB-D sensor without using markers on the infant's body. The proposed experimental setup allows its use as a screening tool at home, therefore avoiding inconvenient hospital visits therefore facilitating the assessment of true neurodevelopmental performance. This focus could be very beneficial for enhancing screening of neurodevelopmental disorders particularly for infants and families in rural and remote areas, a population with reduced health services.

On the one hand, this method allowed to limit the effects of accidental motions of the camera or the seat of the infant, resulting in a reduced range of the variability of the 3D PoIs coordinates (Figure 3). On the other hand, by introducing B, the 3D coordinates of each PoI referred to CS_{Infant} are noisier than those referred to CS_I.

The above considerations were reflected on A1_t and A1_v obtained from the improved method showing larger values with respect to those obtained from the original method as shown in Table I.

For the same reasons, PI_t and PI_v showed larger values since these are calculated as the number of intersections between the trajectory/velocity and the arithmetic mean.

For what concerns A2_t, on one hand the removal of the artifacts due to the accidental movement of the camera would reduce the standard deviation of the coordinates, on the other hand the noisier signal would increase it resulting in a non-significant change in this metric.

The same reasoning could be applied on A2_v that seems to be more affected by the increase of noise in velocities.

As expected by limiting camera movements, the ROM EA with the improved method shows lower values.

SK shows similar results probably because the improved method has not altered the velocity distribution.

CC estimated with the improved method shows larger values probably because without camera artifacts, the correlation between the limbs could be better estimated.

Although most of the metrics are calculated on the wrist, tracking seven upper-body PoIs allows to limit the detrimental effects on the selected metrics estimation of unintentional and unexpected movements of either the camera or the infant's seat and makes the proposed method suitable also for the calculation of additional metrics based on the movement of the entire upper-body.

Future studies will be devoted to validating the proposed protocol on a higher number of infants for testing its use in clinical practice.

***Abstract*— We recently demonstrated the feasibility of the application of an electrical impedance measurement (IntraValvular Impedance, IVI) to biological heart valves (BHVs) for the monitoring of the valve condition after implant. In this study, we investigate the IVI sensing applied to a BHV when it is surrounded by biological tissue, similar to what happens in vivo. A commercial model of BHV was sensorized with three miniaturized electrodes embedded in the commissures of the valve leaflets and connected to an external impedance measurement unit. The sensorized BHV was implanted in the aortic position of an explanted porcine heart, which was connected to the LifeTec Group's Cardiac BioSimulator to perform *ex vivo* tests. For each pair of electrodes, the maximum percent variation of the IVI signal was evaluated and compared. The results demonstrate a detectable variation of the IVI signal when the sensorized BHV is surrounded by biological tissue, which is comparable to that we previously obtained in *in vitro* tests using a polymeric housing for the sensorized BHV.**

***Keywords*—Biological heart valve prosthesis, valve thrombosis, electric impedance, implantable sensor.**

I. Introduction

PROSTHESIS Valve Thrombosis (PVT) clinically manifests with the formation of obstructive thrombus on the valve leaflets, resulting in an increase in the transvalvular gradient and sometimes symptoms of heart failure, with consequent dysfunction of the prosthesis itself [1]. Subclinical Leaflet Thrombosis (SLT) is the precursor of PVT and is mainly characterized by hypoattenuating leaflets thickening (HALT) and reduced leaflet motion (RLM) [2]. SLT mainly affects transcatheter Biological Heart Valves (BHVs) rather than surgical BHVs and can be addressed by the assumption of appropriate anticoagulant therapy [3], [4]. The natural history of SLT is not yet fully known; HALT and RLM can develop not only in the first few months following the implantation but also over an extended period (up to one year). Therefore, serial imaging follow-up and proper evaluation of risks and benefits of long-term anticoagulation are extremely important [5]. Given the recent widespread use of heart valve prostheses (HVPs), it is important to identify the risk of SLT in order to be able to tailor an adequate anticoagulant therapeutic strategy for the patient , to ensure an optimal valve hemodynamic [4]

The functionality of HVPs can be evaluated with appropriate imaging following their implantation [6]. The postoperative follow-up includes periodic monitoring by echocardiographic examinations which, however, do not allow to identify the presence of SLT, mainly due to the transvalvular pressure gradients which remain within the physio-logical range [6]. 4D Multi-Detector Computed Tomography (4D-MDCT) is currently the gold standard diagnostic tool for the accurate evaluation of both the thickness and the mobility of the valve leaflets after implantation, therefore for the diagnosis of SLT [7]. Nevertheless, its routine adoption into clinical practice would expose the patient to a high amount of radiation and would introduce logistical constraints for health facilities.

We conceived an innovative sensorized HVP [8] that may open up important perspectives for a system capable of monitoring the functionality of HVPs after implantation. The novelty of the system deals with the application of impedance measurement techniques, currently used in implantable cardiac devices, to HVPs in order to early detect the possible presence of subclinical thrombotic formations that can alter the valve functioning and monitor its progressive deterioration. This would allow for the timely selection of an appropriate anticoagulant therapy prior to compromised cardiac function, resulting in a potential reduction of mortality and improvement in patient quality of life. We have defined this impedance-based technique IntraValvular Impedance (IVI) sensing and we have already designed and tested proof-of-concept prototypes of IVI sensing applied to mechanical HVPs [8].
We also recently presented the conceptual design of IVI sensing applied to BHVs [9]. Different solutions for the sensorization of a commercial BHV model were described and tested on a circulatory mock loop system reproducing both normal and reduced dynamics of the valve leaflets. In that study we found that IVI measurement is sensitive to experimentally-induced changes in valve leaflet motions, specifically for the prototype having small parallelepiped-shaped electrodes embedded in the commissures of the BHV leaflets. Hence, that electrodes configuration has been selected as the optimal one for the IVI measurement.
Furthermore, it is of interest to investigate whether any IVI signal variation is detectable during the opening/closing dynamics of the BHV also when it is surrounded by biological tissue, similar to what happens in vivo. Indeed, this configuration was not reproduced in our previous study since the sensorized valve was inserted inside a circulatory mock loop system by using a customized polymeric housing [9].
The present study aims to *ex vivo* evaluate the IVI measurement applied to BHVs, i.e. with the sensorized BHV implanted inside an explanted porcine heart connected to a cardiac biosimulator platform.

II. Materials and Methods

The IVI measurement is based on embedding miniaturized electrodes in the structure of the BHV, which are used for the

local electric field generation, by injecting sub-threshold currents (I) between each pair of electrodes, and for the recording of potential difference (ΔV) between the same electrodes. Following the Ohm's first law, the impedance measurement (IVI) is obtained as the ratio between the recorded ΔV over the injected I. Since the valve leaflets interfere with the local electric field lines during the valve opening and closing dynamics, IVI variations within the cardiac cycle (ΔIVI) reflect the cyclic movements of the valve leaflets. Thus, it is possible to correlate the alterations of IVI signal with the alteration of the mobility of the valve leaflets which may occur in presence of an obstacle, such as thrombus formations, as shown in Figure 1 [9].

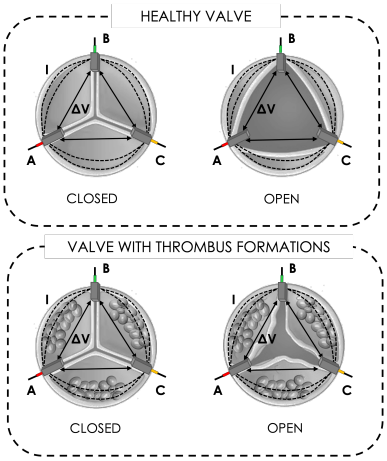

Figure 1. The principle of IntraValvular Impedance (IVI) measurement for a healthy valve (left) and for a valve with a thrombus formation (right): current pulses (I) are injected between each electrodes pair to generate local electric field interfering with leaflets movement and potential difference (ΔV) is recorded.

The *ex vivo* animal evaluation of IVI measurement was performed on a BHV which was sensorized following the optimal electrodes configuration we had previously identified [9]. The prototype was made up of a commercial BHV currently used for surgical aortic valve replacement (Soprano Armonia, LivaNova PCL, London, UK) and was equipped with three electrodes, conventionally called "A", "B" and "C". The three electrodes are visually distinguishable from one another based on the color of the heat shrink which covers the electrode–wire interface: red for electrode "A", green for electrode "B" and yellow for electrode "C" (Figure 2).

The electrodes were manufactured in Pt/Ir which is a biocompatible alloy typically used for implantable electrodes thanks to its biocompatibility and corrosion resistance [10].

The electrodes are small parallelepipeds with the following dimensions: height H=5mm, width W=1mm, thickness T=0.5mm.

Those electrodes, that we called "mini-platelet" electrodes, were positioned in the commissures of the BHV leaflets (Figure 2).

The positions of the electrodes near the valve leaflets were maintained by sewing them to the BHV structure using a suture thread (Figure 2). In addition, a conductor wire was welded in the longitudinal direction of each electrode's structure.

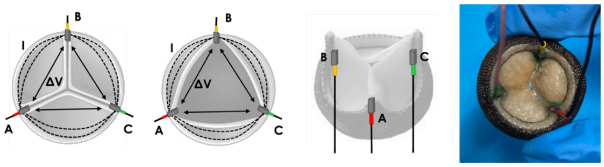

Figure 2. The assembled prototype which includes "mini-platelet" electrodes A (red), B (green) and C (yellow). Local electric field lines (I) and the corresponding potential difference measurement (ΔV) are represented for each pair of electrodes.

For each pair of electrodes ("AB", "BC" and "CA"), an IVI measurement was performed according to the bipolar measurement configuration, which consists of using the same pair of electrodes for both the local electric field generation (source electrodes) and the ΔV recording (receiver electrodes).

The conductor wires welded to the electrodes for signal transmission were connected to a dedicated external impedance measurement unit ("impedance-meter") [9]. The impedance-meter delivers sub-threshold current pulses within the ranges compatible with implantable cardiac devices (biphasic square waveform, 18μA amplitude, 4kHz frequency) to each of the three electrodes embedded in the BHV, thus generating a local electric field near the valve leaflets. Then, the impedance-meter records the potential difference between each pair of electrodes (ΔV_{AB}, ΔV_{BC} and ΔV_{CA}) from which the corresponding IVI measurement is calculated. Hence three IVI signals are obtained (IVI_{AB}, IVI_{BC} and IVI_{CA}), one for each pair of electrodes.

The sensorized BHV was implanted in the aortic position of an explanted porcine heart by a specialized cardiac surgeon. The sensorized prototype was then experimentally evaluated on the Cardiac BioSimulator platform (LifeTec Group™, Eindhoven, Netherlands) [11], shown in Figure 3.

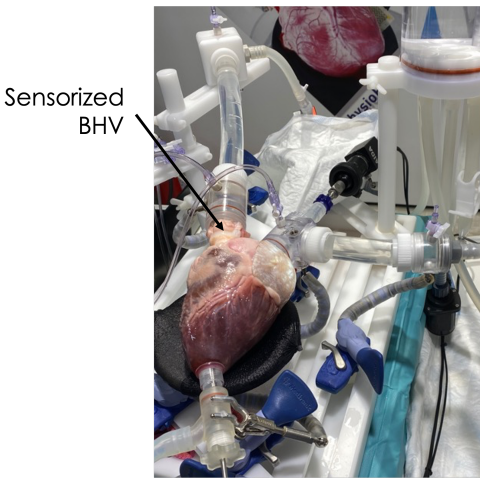

Figure 3. Cardiac BioSimulator platform used for the *ex vivo* animal testing of the sensorized BHV inserted in the aortic position of the porcine heart (indicated by the black arrow).

Two pressure sensors (P10-EX, Becton Dickinson, New Jersey, US) allowed to measure the left atrial and aortic pressure during the tests. IVI measurement was performed connecting the wires, welded to the electrodes, to the impedance-meter. The analog signals (left atrial pressure, aortic pressure, and IVI) were acquired with the MP100 Acquisition System (Biopac System, Galeta, CA, USA) and displayed in real-time using the Acq3.9.1 Software (Biopac

System, Galeta, CA, USA).

We evaluated the IVI measurement by setting the following parameters of the Cardiac BioSimulator platform: cardiac cycle rate of 50 bpm and stroke volume of 80 mL. The IVI signal was recorded between the three pairs of electrodes and IVI variations during the fully opening/closing dynamics of the valve were recorded.

We evaluated the maximum percent variation of the impedance module ($\Delta IVI_{max}\%$), calculated as shown in Equation (1), i.e. as the difference between the maximum and minimum value reached during the opening/closing dynamics, normalized with respect to the minimum value reached during the opening/closing dynamics. For each pair of electrodes, $\Delta IVI_{max}\%$ was reported as $Mean\ Value \pm SD$ calculated over multiple cardiac cycles.

$$\Delta IVI_{max}\% = \frac{=|IVI_{max} - IVI_{min}|}{IVI_{min}} * 100 \quad (1)$$

III. Results

For each pair of electrodes, the recorded atrial and aortic pressures, as well as the IVI signals, are reported in Figure 4, Figure 5 and Figure 6. In the figures, also the calculated $\Delta IVI_{max}\%$ for each pair of electrodes has been identified.

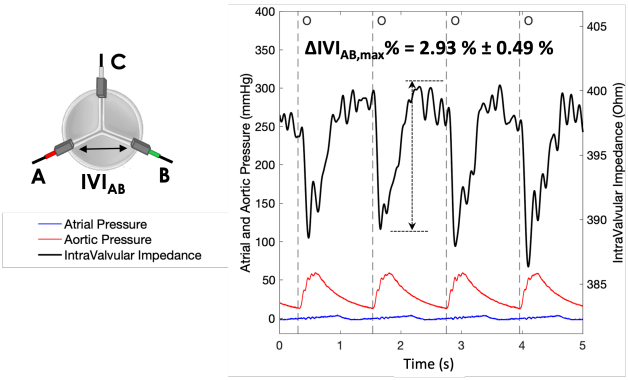

Figure 4. Atrial and aortic pressures and IVI signal recorded inside the porcine heart for the pair of electrodes AB.

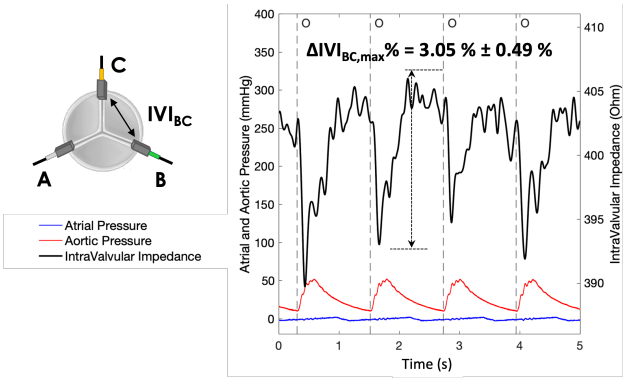

Figure 5. Atrial and aortic pressures and IVI signal recorded inside the porcine heart for the pair of electrodes BC.

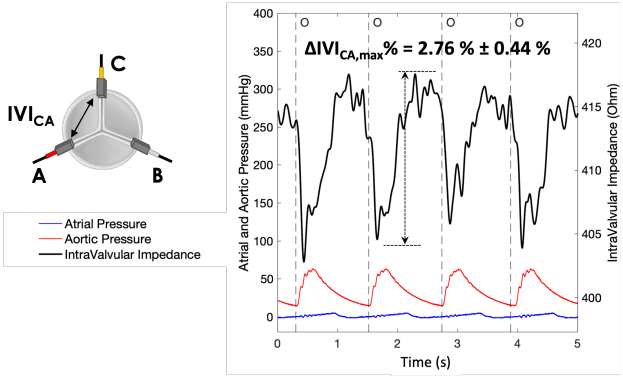

Figure 6. Atrial and aortic pressures and IVI signal recorded inside the porcine heart for the pair of electrodes CA.

The maximum percent variation of the IVI module was obtained in the electrode pair BC ($IVI_{BC,max}\% = 3.05\ \%$), followed by AB ($IVI_{AB,max}\% = 2.93\ \%$) and CA ($IVI_{CA,max}\% = 2.76\ \%$).

IV. Discussion

This study aims to investigate the IVI measurement applied to a sensorized BHV when positioned in a biological environment similar to the real *in vivo* one. This condition has been reproduced by surgically implanting the prototype in the aortic position of an explanted porcine heart. The porcine heart was then connected to the Cardiac BioSimulator platform, which ensures a realistic pulsatile flow through the valve and the pressurization of the cardiac chambers, allowing the evaluation of IVI signal during the valve opening/closing dynamics.

The results confirm the presence of a detectable variation of the IVI signal module within the cardiac cycle following the dynamics of the valve, also when it is surrounded by biological tissue. Moreover, the entity of that excursion is in line to what we previously obtained using a polymeric housing for the valve positioning; indeed, in that case the $\Delta IVI_{max}\%$ obtained for the complete opening/closing dynamics of the valve were in the range $2{,}29\% - 3{,}20\%$for the three pairs of electrodes [9].

The chosen electrodes configuration explains the wave pattern for the IVI signal: there is the maximum IVI signal when the valve is closed, as the valve leaflets close around the electrodes, maximally interfering with the local electric field lines. On the contrary, the IVI signal reaches minimum values when the valve is open, as the valve leaflets stretch outward minimally interfering with the electric field (Figures 4-6).

The intra-prototype variability of the IVI measurement, represented by the differences between IVI_{AB}, IVI_{BC} and IVI_{CA}, may be related to different aspects. First, since it is not possible to carry out simultaneous IVI measurements with the different pairs of electrodes, the signal recorded with each pair refers to a different heartbeat, which has an intrinsic variability. Second, the valve prosthesis does not have perfectly symmetrical leaflets; this determines different opening and closing dynamics for each leaflet, thus introducing a variability in the measured IVI signal between each pair of electrodes. Third, the measuring electrodes positioned inside the valve structure may have variable spatial

orientations and/or inclinations due to the difficulties in their positioning which have been manually executed by sewing. Fourth, even starting from electrodes of the same shape and size, the effective working electrode surface depends on the portion of electrode covered by the heat shrink (applied manually) at the electrode-wire interface; so different electrode surfaces achieved with slightly different portion of applied heat shrink, result in different IVI measurements, as described by Ohm's second law.

The main limitations of the study are related to the use of a working fluid which allows to simulate the electrical conductivity of the blood [8] but not its viscosity, and the absence of a flow sensor inside the Cardiac BioSimulator platform to also detect the transvalvular flow. Another limitation is represented by the missing of the left ventricle pressure sensing, useful for the determination of the closing time of the valve within the cardiac cycle.

Future research should aim to replicate these results in a wider range of working conditions, such as performing a hemodynamically altered situation in which the valve leaflets do not fully open and close due to their reduced mobility induced for example by a simulated "hypotensive" pressure condition.

V. Conclusions

The present study relates the *ex-vivo* evaluation of the IVI measurement applied to a BHV which was inserted in an explanted porcine heart connected to a Cardiac BioSimulator platform which reproduces the complete opening/closing dynamics of the valve. Overall, our results demonstrate the presence of a detectable IVI signal variation following the cardiac cycle phases, also when the valve is surrounded by biological tissue.

These are promising results to further pursue the development of a fully implantable solution of the proposed sensorized BHV.

Wearable sensor for in-vivo skin hydration monitoring

A. Cataldo[1], R. Schiavoni[1], A. Masciullo[1] and C. Demitri[1].
[1] *Department of Engineering for Innovation, University of Salento, 73100 Lecce, Italy,*

***Abstract*—Skin hydration is the water content within skin tissues and its monitoring is of crucial importance in many contexts. However, at the current state-of-the-art, there is a lack of objective, non-invasive and wearable monitoring systems for the correct evaluation of skin moisture. To this purpose, in this paper, a new wearable punctual sensing element (SE) was designed and validated to sense variation of skin hydration of the body, even in the case of area as small as a few millimetres. In particular, a truncated customized open-ended coaxial probe was designed. As a matter of fact, the dielectric properties of the skin can be related to the frequency domain (FD) response of the monitoring system. In this regard, full-wave simulations on human phantoms were carried out to demonstrate the feasibility of the system. This strategy, in combination with low-cost miniaturized instrumentation, has potential for achieving a fully wearable system for real-time monitoring of skin hydration.**

***Keywords*—skin hydration, wearable, dielectric permittivity, microwave reflectometry.**

I. INTRODUCTION

Water is a vital element for the skin and the entire body [1]. In particular, maintaining the right level of skin hydration ensures optimal skin health, and improves the skin's appearance. The natural aging process and exposure to factors such as ultraviolet radiation, tobacco smoke [2] and pollution can reduce the amounts of water in the skin, altering its natural function as a protective barrier. The first sign of a compromised skin barrier is properly the dehydration. This can result in symptoms such as redness, itching and peeling. Some of the causes of skin dehydration are related to severe dermatological diseases such as atopic dermatitis [3,4] (very common in children), ichthyosis, psoriasis [5] and eczema. As a matter of fact, skin hydration is an important parameter that is necessary to monitor, especially in the case of dermatological diseases, hormonal alterations [6,7] and for workers in hostile environments [8]. In the literature, most works relate to different methodologies for skin hydration monitoring [9-11]. However, some of these techniques are expensive (e.g., Confocal Raman spectroscopy [12], Near-IR spectroscopy [13], terahertz spectroscopy [14]) or are based on skin impedance [15] or capacitance methods, having a low measurement accuracy. It is worth noting that these types of systems are not wearable, aspect that could improve the patient's experience and the efficiency of the diagnostic process, for example, through real-time remote monitoring with the possibility to send data to the doctor. In addition, such a system needs to implement fully in vivo measurements so it is necessary to make a device that is comfortable for the patient and can provide good adherence to the skin.

For these reasons, this work addresses the design of an innovative wearable device that monitors skin hydration through microwave reflectometry. More in detail, in this paper, which is an extension and continuation of a previous work [16], a new configuration of SE was designed in order to obtain a sensing volume in the subsurface skin region only and to improve the ability to detect the hydration status of small areas, some just a few millimeters. In this regard, it is worth mentioning how some diseases cause punctual excoriations of the skin that need to be monitored over time. For this reason, a system that can detect changes in the moisture status of the skin with good spatial resolution can provide adequate information on the proper functioning of medical therapy.

This paper is organized as follows. Section II describes the theoretical background at the basis of the proposed system. Section III describes the design and the optimization of the new SE and the advancement with respect to the previous work. Section IV addresses the simulation results on human phantom demonstrating the feasibility of the proposed system. Finally, in Section V, conclusions are drawn and the future work is outlined.

II. THEORETICAL BACKGROUND

Microwave reflectometry is a very versatile technique used in several fields [17-22]. More in detail, an electromagnetic test signal is propagated through a sensing element to the target tissue, and useful information can be extracted from the analysis of the reflected signal, in terms of dielectric permittivity. As a matter of fact, the dielectric properties of human tissues can be described in terms of frequency-dependent complex dielectric permittivity $\varepsilon^*(f)$ according to the following equation:

$$\varepsilon^*(f) = \varepsilon'(f) - \varepsilon''(f) \qquad (1)$$

where $\varepsilon'(f)$ is the relative dielectric constant, $\varepsilon''(f)$ is the relative dielectric loss factor and f is the frequency. In particular, in the simulation results described in Section IV, the Cole&Cole model has been adopted. As is well known, Cole&Cole equation is a relaxation model that is often used to extrapolate the measured complex dielectric permittivity of biological tissues. It is given by the equation:

$$\varepsilon^*(f) = \varepsilon_\infty + \frac{\varepsilon_S - \varepsilon_\infty}{1+(j\omega\tau)^{1-\alpha}} \qquad (2)$$

Where ε_s and ε_∞ are the "static" and "infinite frequency" dielectric constants, ω is the angular frequency and τ is a time constant. The exponent parameter α varies between 0 and 1. The adopted Cole&Cole model is that of the reference Gabriel's database [23]. This is one of the most exhaustive and

well-established works in the field of the dielectric properties of biological tissues. As an additional note, it also worth noting that, the adopted model describes accurately the dielectric behaviour of biological tissues through a multiple contribution of a four-terms Cole&Cole expression. The operational strategy of the present work is based precisely on the difference in the dielectric properties of the tissues that can be detected by microwave-based systems and related to different skin hydration level.

III. DESIGN OF THE SENSING ELEMENT

The SE employed in [16] was a planar three-wire transmission line fabricated on a flexible rubber substrate with a layer of Kapton, capable of providing fit, comfort, and high measurement accuracy; however, the SE cannot be used on small areas due to its dimensions (50 mm × 90 mm).
In this work, an enhanced version of the system is presented. More in detail, the basic configuration chosen for the SE is the truncated open-ended coaxial probe, which has been optimized for the purposes of the application. In particular, the objectives to be pursued in the SE design phase were: i) non-invasiveness; ii) a good spatial resolution and capability of detection in the most superficial layer of the skin; iii) ability to analyze even small areas; and v) compatibility for the possible use with low-cost miniaturized FD instrument for in vivo analysis. These requirements have been met through a preliminary feasibility study and a subsequent in-depth simulation analysis which allowed to optimize the geometrical parameters and the configuration of the SE. In the simulation phase, the human tissue has been simulated through a three-layer structure composed by skin, fat and muscle with the frequency-dependent dielectric parameters reported in the "Gabriel&Gabriel" database [23].

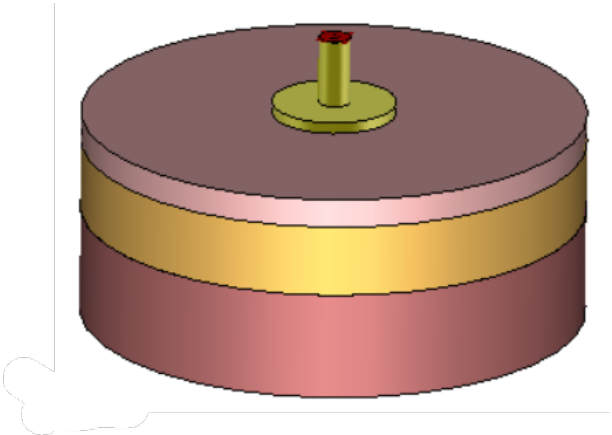

Figure 1: Scheme of the simulated new version of the SE in contact with the three-layer model.

A schematic representation of the proposed SE is shown in Figure 1. As can be seen from the figure, a termination flange was added in order to enhance the sensitivity in terms of the fringing field effect. More in detail, the radiate fringing effects at the probe aperture allow the electric field lines adequately penetrate into the skin portion under test. The fringing fields between outer and inner conductors of the sensor interact with tissues, causing changes in the reflection coefficient measured by the VNA. In addition, in order to optimize the sensitivity in the surface portion, an extremely low input power value of -15 dBm (approximately 32 μW) was chosen. In this way, the EM field is completely confined within the skin layer and decays very quickly, and the variation in the thickness of the skin layer does not affect significantly the response of the system. In addition, the chosen power input level corresponds to a Specific Absorption Rate (SAR) value below the limit imposed by safety regulations. [24, 25]

IV. FULL-WAVE SIMULATIONS WITH DIFFERENT HYDRATION LEVELS

A set of full-wave simulations was carried out through CST Microwave Studio considering the SE in contact with a human phantom with different skin moisture levels, in order to analyse the sensitivity of the system. As explained above, human tissues exhibit a significantly dispersive dielectric behavior in frequency. For this reason, the Cole&Cole model reported in the Gabriel database [23] was used for the implementation of tissue dielectric properties in the simulation software. On such basis, this model has been adopted in describing the dielectric properties of tissues and, consequently, to optimize the full-wave simulation results. More in detail, the database contains dielectric frequency parameters for both dry and wet skin.

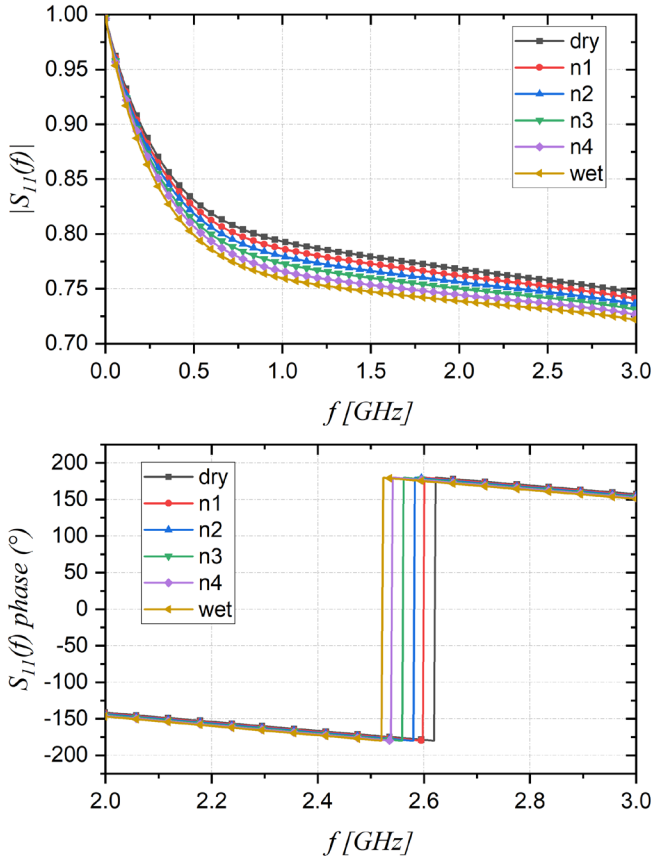

Figure 2: Simulation results for the S11(f)| of the SE in terms of magnitude and phase for 6 skin hydration states (different permittivity).

Accordingly, skin hydration intermediate conditions (from

n1 to n4) were also considered, starting from the dry skin condition and incrementing the dielectric parameters values by 2% for each simulation, until reaching the wet condition. Figure 2 shows the magnitude and the phase of the reflection scattering parameter $S_{11}(f)$. It can be seen that, over the whole considered frequency range, an increase in water in the skin leads to a lower response in terms of magnitude of the reflection parameter. A similar trend is also recognizable in terms of phase of $S_{11}(f)$. This phenomenon is due to changes in the dielectric permittivity of the skin at different hydration states. These results suggest that it could be of interest to relate the values of ε_r to the trend of $S_{11}(f)$.

V. CONCLUSIONS AND FUTURE WORKS

In this paper, the feasibility study of a microwave reflectometry -based portable and low-cost system for in-vivo skin hydration monitoring level is proposed. More in detail, the chosen probe configuration is that of a truncated open-ended coaxial probe equipped with a flange which when in contact with the tissue under test can be sensible to any dielectric variations. As a matter of fact, novelties were introduced compared to previous work [16] since this type of system is more sensitive to local changes in skin hydration compared to a trifilar SE and, consequently, allows more accurate monitoring of the evolution or healing process of dermatologic diseases. Furthermore, this type of system ensures in-vivo and non-invasive measurements and could be used in combination with a miniaturized vector network analyzer in order to ensure full-wearability, portability and low costs. In this regard, further work will be dedicated to validate and test the proposed system on a large-scale measurement campaign on volunteer subjects. Finally, a specific procedure will be implemented in order to extrapolate the dielectric properties of the tissues and its moisture levels from the FD measurements.

***Abstract*—Transcatheter aortic valve implantation (TAVI) is an established treatment for patients with severe aortic valve stenosis ineligible for surgery. Assessing computational modelling credibility is relevant for developing safe and reliable in-silico clinical trials for testing medical devices. The main goal of this work is to present a structural model of TAVI and follow the verification and validation activities suggested by ASME V&V40 standard.**

***Keywords*— TAVI, Finite-Element Analysis, Verification and Validation, ASME V&V40.**

I. Introduction

Transcatheter aortic valve implantation (TAVI) is an established treatment option for patients with aortic valve stenosis at high surgical risk [1, 2]. In the last few years, the success of TAVI is continuously increasing as this procedure is applied to young patients and the bicuspid aortic valve [3].

In this context, several computational models with different aims and model definitions have been proposed to investigate TAVI [4-11]. There is however an implicit risk in computational models for pre-TAVI planning, unless systematic verification and validation activities are performed according to regulatory bodies. The predictive value of computational models is a major concern for the assessment of cardiovascular dysfunction and treatment [12]. Assessing the credibility of computational tools is pivotal towards the development of accurate and realistic personalized approaches. This may also enhance the design process of novel devices, thereby accelerating their development and translation into the clinical practice [13].

This study aims to provide a computational framework for the verification and validation (VV) of TAVI-related patient-specific computer models according to ASME VV40.

II. Materials and Methods

The VV activities were performed on patient-specific computational models of TAVI according to a verification, and validation master plan based on ASME VV40. As the intended use, computer models aim to predict the acute outcome of patients underwent TAVI with the SAPIEN 3 Ultra device (Edwards Lifesciences, USA).

The context of use (COU) and the model risk assessment (relevant parameter changes <1%) were defined. The model form, the model input, the comparator, testing conditions and assessment output comparison were defined. Simulations were carried out for a group of n.20 patients, after signature of informed consent. Clinical workup included ECG-gated CT scans including the systolic and diastolic phases at in-hospital admission, transoesophageal echocardiography during the procedure, and post-TAVI ECG-gated CT done after one month from the procedure. Demographic data and cuff pressure measurement were also collected.

A. FEM Model Development

The workflow for the development of patient-specific modelling of TAVI involves the patient-specific segmentation, including the aortic wall, calcification and native aortic valve leaflets [14]. The aorta and calcification were segmented using the commercial software Mimics (v21, Materialise, BE) using diastolic images. Specifically, semiautomatic thresholding of different levels of grey intensity (Hounsfield units, HU) followed by manual editing was performed. Post processing of anatomic masks was accomplished using smoothing algorithms with factor of 0.4 and 10 iterations in all cases. The resulting masks were then imported as STL (Stereo Lithography Interface) format in Rhino CAD software (v.5.5, McNeel & associates, SP) [15]. Since aortic valve leaflets were not visible at CT scan, a parametric approach using anatomical landmarks was adopted (see Figure 1) [16, 17]. Using standard imaging protocol, 3rd-order NURBS curves lying on the three aortic cusps were developed to model the native valve leaflet attachment to the aortic root. Leaflet free-edges were defined by 3rd-order curves interpolating three points (i.e., anatomic landmarks) describing the commissures in the orthogonal valve plane. The belly of each leaflet was driven by a control point defined at the mid-level in the sagittal view.

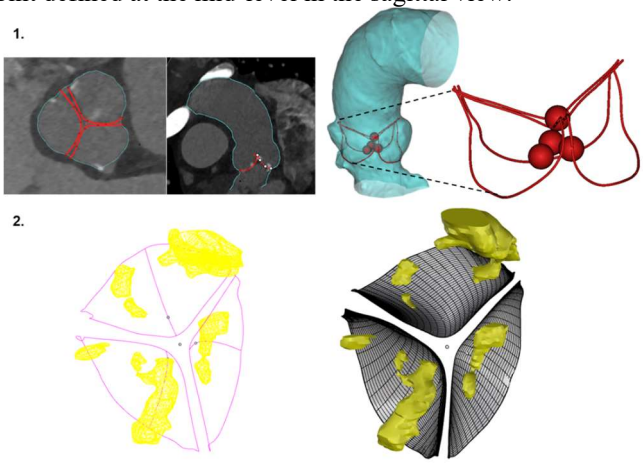

Fig. 1: Patient-specific model for the TAVI simulation.

An aortic wall tissue thickness of 2 mm was assumed while the aortic valve leaflets were 0.5 mm thick. For boundary conditions, a general blood pressure profile was adapted by

scaling the minimum and maximum pressure to those measured at in-hospital admission for each patient. The duration of the pressure profile was scaled to match the cardiac beat. Thus, the pressure profile was then applied to the aortic wall, thereby considering difference from patient-to-patient [18, 19]. Similarly, the transvalvular pressure gradient seen at echocardiography was applied to aortic valve leaflets. The distal and proximal ends of the aortic wall were fixed in all directions. Tie contact condition were used to link the calcification to aortic valve leaflets while different types of contact properties were explored. All simulations were performed with Abaqus\Explicit solver (v.2021hf7, Dassault Systèmes, FR).

B. Verification and Validation Activities

Verification activities were performed to assess the impact of solver parameter and setting while validation against an analytical solution was done to identify any errors of the computer code. Model verification was accomplished according to ASME V&V40 for each structural level accounting for the discretization error (DE), numerical code verification (NCV) and numerical solver errors (NSE). Specifically, the DE is the error associated with the chosen mesh, element type, and the level of mesh refinement. NCV quantifies the code's capability to well solve problems with known solutions while the NSE is the error associated with the type of solver and solver settings.

The relative error (RE) is used for rigor evaluation while the optimal element size was calculated using the convergence index, with errors kept <1% in all cases. The impact of solver parameters on computational time was also evaluated. Simulations were carried out using the same number of CPUs for all simulations (n=60). The investigated solver parameters were i) penalty factor, ii) mass damping (alpha), iii) viscous pressure, iv) bulk viscosity, and v) contact parameter. Comparison with respect to a baseline model is done using the relative error (RE) that was kept <1% in all cases. Output parameters for comparisons were the maximum stress, peak systolic strain, and wall-clock time.

Once the model was verified, a cardiac beat of the pre-TAVI condition of the patient was simulated and results were compared against CT data (i.e., the comparator). Specifically, the aortic wall strain measured as the changes in aortic diameter between systole and diastole divided by the diastolic diameter was considered as output parameter for the aortic wall. For the calcific valve leaflets, the orifice area measured from the CT scan at systole was used for comparison.

III. RESULTS

A. Discretization Error (DE)

1) Aortic Wall

The optimal element size was calculated using convergence analysis using the Mises stress as output parameter. The investigated element sizes and resulting relative errors were 0.5 mm (0.25%), 0.8 mm (0.87%), 1.2 mm (6.4%) and 1.5 mm. We concluded that an element size of 0.8 mm represents a good compromise between accuracy and computational costs. Similarly, the triangular element (S3) versus the quadrilateral element (S4) was tested, with the triangular shell elements resulting the optimal element type (RE=0.76% for S3 vs RE=1.25% for S4). Triangular elements have also better capability to capture the geometric discontinuity of the complex aortic wall shape than the quadrilateral element.

2) Valve leaflets

Meshes were obtained from the extrusion of shell elements with 4 layers through-the-thickness in all cases. For element size analysis, the investigated element sizes (and relative errors) are 0.5 mm (0.29%), 0.6 mm (0.38%), 0.8 mm (5.1%) and 1.0 mm. The element size of 0.6 was therefore selected.

For element types, three types of solid elements were investigated: unstructured prismatic (C3D6), unstructured hex element and structured hex element (C3D8). Due to the complex leaflet morphology, there is a likelihood to observe pronounced element distortion due to geometric discontinuity and high-frequency oscillations for the structured hex mesh.

Simulations demonstrated that both unstructured- and structured hex elements were not appropriate to capture leaflet shapes without providing element with warnings and/or errors. For one representative case, the RE was 0.67% for the unstructured prismatic element, 24.1% for unstructured hex and 23.3% for structured hex element.

3) Calcification

Given the complex and irregular shape of calcifications, the tetrahedron solid element (C3D4) was investigated as this was the only element type that reasonably described the calcific plaques. The investigated element mesh sizes (and relative errors) were 1 mm, 0.8 mm (61.25%), 0.6 mm (20.74%) and 0.5 mm (0.92%), using the principal stress as the output parameters. The element size of 0.5 mm was selected.

B. Numerical Code Verification (NCV)

1) Aortic Wall

On the basis of aortic physiology, the analytical solution of a thin vessel under pressure was considered as the representative problem. The analytical solution is valid for thin structure with isotropic behaviour and under small deformation. Under equilibrium of internal force and pressure condition, the circumferential stress is given from Laplace's law. For the NCV study, a hollow shell vessel was created and meshed with elements size and type defined in the DE section. The neo-Hookean material model was tested as many studies suggested a stiff behaviour for the aortic wall [REF]. After solution, we found a RE of 0.6% between predicted (31.82 kPa) and analytical (31.66 kPa) solutions.

2) Valve Leaflets

For aortic valve leaflets, the choice of an analytical solution was complicated by the multi-axial stress condition of the human aortic valve including tension, compression, bending and shear force. The analytical solution of cantilever beam was proposed assuming the bending as the main loading condition. The plate was modelled with dimensions of 25 mm as length, 0.25 mm as height and 0.5 mm as width, with element type and

size as described in section DE. As for the valve leaflets, the plate was realized starting from a shell mesh model then extruded with 4 layers. One edge of the beam was constrained in all directions, while a concentrated force was applied to the free end. From the simulation, the maximum deflection resulted 7,944 mm. The analytical formula of the maximum deflection gave the value of 8.010 mm, therefore the RE between predicted and analytical solutions was 0.77%, enabling to state that the finite element model can effectively acquire the deformations under these conditions.

3) Calcification

Since calcifications were mainly compressed by the surrounding tissues, the analytical solution was that of a plate subjected to uniform displacement condition in the range of small deformations. The plate was modelled with tetrahedron elements with size of 0.5 mm. Elastic-plastic material properties using literature data were used [REF]. A uniform uniaxial displacement is applied on the surface so that to remain in the elastic field. After solution, the RE between predicted (0.0200) and analytical solutions (0.0198) of the nominal strain developed was 0.77%.

C. Numerical Solver Error (NSE)

1) Aortic Wall

The NSE investigates the influence of numerical solver parameters for the aortic wall with comparison to a baseline (BL) reference simulation. To account for transient effect, the model was initially loaded to systolic pressure (t=0.1s) and then unloaded upon diastolic pressure (t=0.1s) and then a cardiac beat was simulated.

Given the low loading rate for simulating a cardiac beat, the default value of 1 for time increment was selected. Mass scaling of 5.0e-6 and 1.0e-6 led to ratio of kinetic to internal energy lower than 1%, but the value of 1.0e-6 was selected. No remarkable changes (i.e., RE<1%) were observed with alpha damping of 250. The system response is considerable influenced by increasing values of viscous pressure (with deviations leading to RE>1%). In terms of wall-clock time, the model is not appreciably affected by viscous pressure. Changes in the bulk viscosity did not influence the model response, with wall-clock time impacted only for value of 0.6. The default value of bulk viscosity is therefore adopted.

2) Valve Leaflets and Calcification

For the aortic valve, the BL model for NSE considered the interaction of valve leaflets with the calcific plaques and the aortic wall. A mass scaling of 1.0e-6 did not alter the simulation response when using frequency of 10. Since RE was <1%, no effective changes were determined in the system response with material damping. An alpha damping of 250 had minimal effects on output parameters and wall-clock time. As for to the aortic wall, the system response is considerable influenced by increasing values of viscous pressure (with deviations leading to RE>1%) and by bulk viscosity of 0.6. The utilize of friction coefficient (RE < 1%) did not deviate the system responses from output parameters and wall-clock time.

D. Validation

For the comparator (i.e., CT imaging), the test samples consisted of n.20 patients (one-to-one correspondence) with the following range of characteristics: age of 78-89 years; degree of stenosis from mild to severe; calcification volume of 500-1700 mm^3; body surface area of 1.3 to 1.6. CT imaging was performed with the same scanner and an uniformed testing protocol. Blind measurements were taken from an expert radiologist while the simulation output was automatized thanks to element sets taken at mid-ascending aorta for the strain output and leaflet edges for the orifice area. For the pre-aortic wall, the RE in the systolic strain was in the range of 8.6% to 13.6 % for the n.20 patients, with more marked differences in the left ventricular outflow tract region. For the calcific aortic valve, the differences between predicted and measured magnitude of the orifice area were in the range of 0.08% to 11.86% (2.78% ± 4.50%). Figure 2 shows the comparison of the orifice area at systolic peak between the numerical prediction and CT imaging.

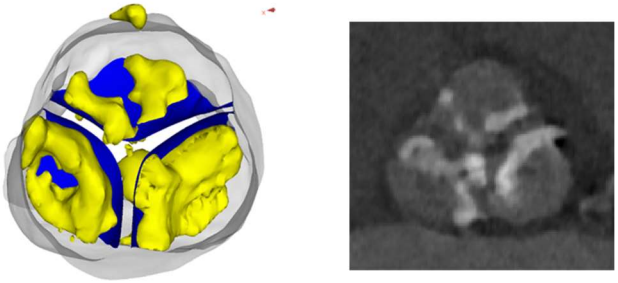

Fig. 2: Comparison between the numerical model (left) and the CT scan (right) at systole for a patient before TAVI.

IV. Discussion

In this study, a workflow for the verification and validation assessment for the TAVI model according to the ASME V&V40 standard was developed. VV activities allow to demonstrate that the credibility of the model is commensurate with the patient risk. In this perspective verified and validated predictive computational models offer the potential to reveal in a robust way the mechanisms of TAVI.

Regulatory agencies are currently evaluating the evidence achieved by simulations to reduce the time-to-market of biomedical devices and the cost related to the device design. There is therefore a growing interest in assessing model credibility [13] before this technique could be effectively implemented as a standard approach .

In this regard, the ASME has published the V&V 40-2018 technical standard “Assessing Credibility of Computational Modeling through Verification and Validation: Application to Medical Devices”, which introduced the model credibility evaluation process and gave the minimum requirements for the qualification with respect to regulatory agencies. Verification, validation, and uncertainty quantification (VVUQ) can be used to establish trust in the predictive capability of a given computational model. Verification assures that a computational model fits the mathematical description. Validation is performed to assess if the model accurately

represents the real-world system. Uncertainty quantification is implemented to determine the impact of numerical and physical parameters variations in the simulation outcome [61,62]. In future study, we propose to quantify the uncertainty of the proposed model of patient undergoing TAVI.

Few studies performed a systematic verification and validation as here proposed. Luraghi et al. [20] implemented a verification approach for the simulation of an idealized tri-leaflet heart valve model by inspecting the impact of element type, formulation, and damping factor. Similarly, Tango et al. [21] validated a FSI model of the aortic valve and root by comparing the predicted velocity field with in-vitro flow data. A similar work was recently proposed by Oks and collaborators [22]. Recently, Bosi et al. [23] validated the computational modeling of TAVI with both Sapien XT and CoreValve devices against post-procedural clinical fluoroscopy and echocardiography images. They found good agreement between predicted and image-based device diameters. However, the study from Bosi et al [23] has adopted the post-TAVI images to verify and validate the model. In this study, we performed the VV activities only using pre-TAVI imaging data with the goal to utilize post-TAVI data as an additional data source to further validate the present findings.

V. Conclusion

This study introduced a systematic verification and validation against CT data of patient-specific computational models replicated pre-TAVI scenario. Such an approach represents a step towards the utilize of accurate and realistic simulations of patients undergoing TAVI.

***Abstract*—The SAPIEN 3 Ultra transcatheter heart valve (THV) is implanted in the stenotic aortic valve using an expandable balloon. This study aims to characterize the mechanical behaviour of balloon-related polyamide 12 (PA12) under uniaxial tensile testing at controlled temperatures as well as the viscoplastic response. Three-dimensional (3D) digital image correlation (DIC) was also carried out to determine the strain distribution of the whole device. Data were used to develop a material constitutive model for finite-element analysis. Findings demonstrated the complex mechanical behaviour of PA12 used in balloon catheter, suggesting the need for accurate constitutive modelling.**

***Keywords*—polyamide 12, balloon catheter, transcatheter heart valve, mechanical testing, digital image correlation**

I. Introduction

POLIMERS are widely used in medical devices because of high compliance, low weight and good biocompatibility [1]. Polyamide 12 (PA12) is typically used for the manufacturing of single-use balloons adopted for the deployment of transcatheter heart valves (THV) [2]. PA 12 demonstrates both high strength and compliances as well as low coefficient of sliding friction [3]. However, the mechanical properties of PA12 depends on the surrounding temperature and media, the usage and the fabrication technology.

There is a general lack of knowledge in the mechanical properties for the PA12 balloon material. Some general studies on the material performances were published by several authors and manufacturers [4, 5]. Geith et al [6] stated that an anisotropic behaviour is used to describe the material response only above nominal pressure. However an elastic response is used (no visco, no plasticity) to describe the material. Amstutz at al. [7] demonstrated that the environmental conditions like temperature and humidity can influence the balloon mechanical performance. The viscoelastic and viscoplastic material response was also investigated [8]. However, not any simulation studies of THVs has considered the complex mechanical behaviour of balloon material. The mostly used material model is the linear-elastic model in all simulation studies [9-12].

The purpose of this study is to characterize the PA12 balloon response through extensive material testing, considering temperature and strain rate effects. The strain field of balloons was also quantified using digital image correlation. A constitutive material model suitable for computational analyses is also proposed.

II. Materials and Methods

A. Mechanical Testing

To characterize the mechanical behavior of balloon material, the following testing protocol was used: i) quasi-static uniaxial tensile stress-strain response upon failure at room temperature; ii) uniaxial tensile stress-strain response under steady cyclic conditions at room temperature; iii) uniaxial tensile stress-strain response under 37deg temperature. Both failure and cyclic testing were performed using an ElectroForce 3330 Series II (TA Instrument, Boston, MA), equipped with a 4kN load cell. In a different way, the testing at different temperature was carried out with an ElectroForce TestBench biaxial system (TA Instrument, Boston, MA) with 200N load cell in order to take advantage of the controlled-temperature bath. After cleaning the balloon with isopropyl alcohol, several specimens were cut from the balloon material using a surgical blade as done previously [13]. Rectangular specimens with length of 40 mm and width of 4 mm were obtained where with dimensions ensured by overlaying the transparent balloon material on a graph paper and then using solid line to guide the cut. A total of 15 samples (ie, n.8 for test at different temperature and n.7 for cycling testing) were tested. Balloon thickness was 0.12 mm as measured by a mechanical micrometer. Samples were extrapolated in both longitudinal and circumferential directions, although the PA12 is a isotropic material.

For stress-strain response upon failure, a constant cross-head speed of 0.005 mm/s was. For controlled-temperature testing, the specimen was submerged in water at controlled temperature of 25 C and 37 C for simulating human body temperature.

For cyclic testing, a constant cross-head speed of 0.01 mm/s was used for 10 cycles. The sample was loaded upon 10% deformation and then unloaded to a minimum load of 1 N. The displacement, force and time were recorded with frequency of 1 Hz during the material testing. The strain was calculated as $\varepsilon=\Delta L/Lo$ where ΔL is the change in the length and Lo is the initial specimen length. The stress was calculated as $\sigma=F/(w\cdot t)$ where F is the recorded force, w is the specimen width and t is the tissue thickness

B. 3D Digital Image Correlation

Two intact balloons used for the deployment of both 23 mm and 26 mm SAPIEN 3 Ultra THVs were tested to measure the displacement field under different fluid-filling volume steps. An holding chamber with two cannulas was used to keep the proximal and distal ends of the balloon while allowing free inflation. A random black-speckle pattern on a white uniform layer was used realized on the balloon surface. The 3D DIC system consists of two 50 mm focus cameras mounted on a tripod (VIC3D, Correlated Solution, USA). The balloon was initially inflated with the fluid upon the reference zero-pressure configuration as measured from the pressure gauge. Using a syringe, the fluid volume was gradually increased in steps of 1 ml upon the nominal fluid volume (ie, 17 ml for the 23 mm balloon and 21 ml for the 26mm balloon) and then images were recorded at each increment. During inflation, the fluid pressure was manually recorded. Prior acquisition, the DIC system was calibrated for stereo vision using a calibration table with grid spacing of 3 mm. For displacement analysis, the subset and step sizes were automatically chosen by the VIC3D analysis software. An initial guess of a point in the both the reference image and the deformed images was manually obtained. Rigid translation and rotation were eliminated. Data were transformed in longitudinal (LONG) and circumferential (CIRC) displacement and strain using a cylindrical coordinate system with the origin the middle of balloon axis.

C. Constitutive Modelling

The material response was fit using the Material Calibration App on the 3DEXPERIENCE (R2021 HotFix 8.13, Dassault Systems). Testing results were categorized in specimens obtained from the 23mm balloon versus specimens from the 26mm balloon. Constitutive parameters were assessed for the two specimen groups (ie, the 23 mm vs 26 mm). The material model used to fit the test data was a combination of Yeoh hyperelasticity, Johnson-Cook rate-independent plasticity, and non-linear PRF viscoelasticity (2 networks). This model can capture the “S” shape response typical of hyperelastic material behavior, offers good representation for large strains, and is typically a good choice when limited test data is available . The test data were imported, and the curves were edited (filtered and resamples) to ease the calibration. The curves were shifted so that the loading starts at t=0 seconds (and offset correction). Data sets with a large number of datapoints were reduced while preserving the characteristics of the curvature.

III. Results

Figure 1 shows the stress-strain response for balloon specimens tested at room temperature and controlled temperature. The higher the temperature is, the more compliant the stress-strain response is. No substantial differences were observed from samples extracted in the circumferential balloon direction versus the longitudinal direction. The stress-strain curves were characterized by a steep increase in the stress-strain response upon nearly 7% of strain, followed by a non-linear knee and a linear response uponfailure.

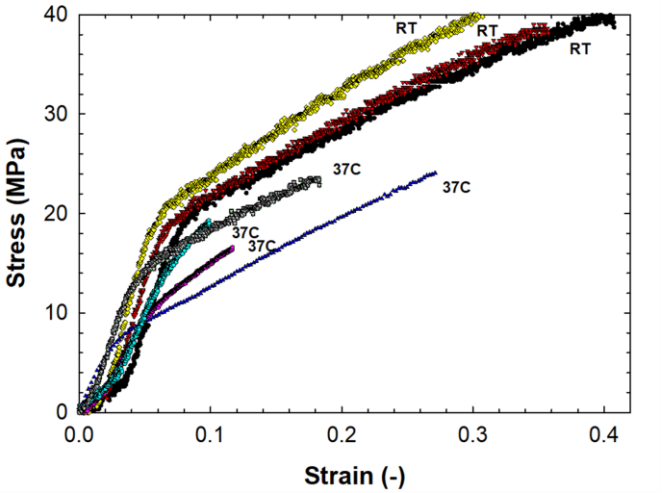

Figure 1. Stress-strain response for n.8 specimens tested at room temperature (RT) and controlled temperature (37C)

Figure 2 shows the stress-strain response for cyclic testing of different samples extrapolated from the 23mm and 26mm balloons. Specimens were loaded and unloaded multiple times during the test to gain insight into the residual deformation developed between different cycles. Cyclic testing was carried out up to ten cycles or specimen rupture during material testing. When all specimens from both the 23 mm and 26 mm balloon were put together, two different material families were observed (see Test1-4 versus Test 5-7).

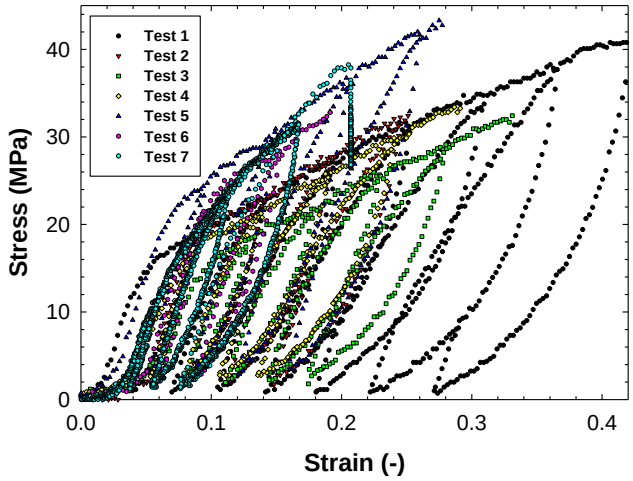

Figure 2. Cyclic stress-strain response for n.7 specimens cut from the 23 mm balloon (Test from 1 to 4) and the 26 mm balloon (Test from 5 to 7)

Figure 3 shows a representative fitting of one sample tested for seven cycles upon rupture. Specifically, the calibrated material model is a combination of Yeoh hyperelasticity with Johnson-Cook rate-independent plasticity and non-linear PRF viscoelasticity as characterized by 2 networks. Fitting was independently performed for the group of specimens from the 23 mm balloon versus those collected from the 26 mm balloon given the response characterized by two material families (see Figure 2).

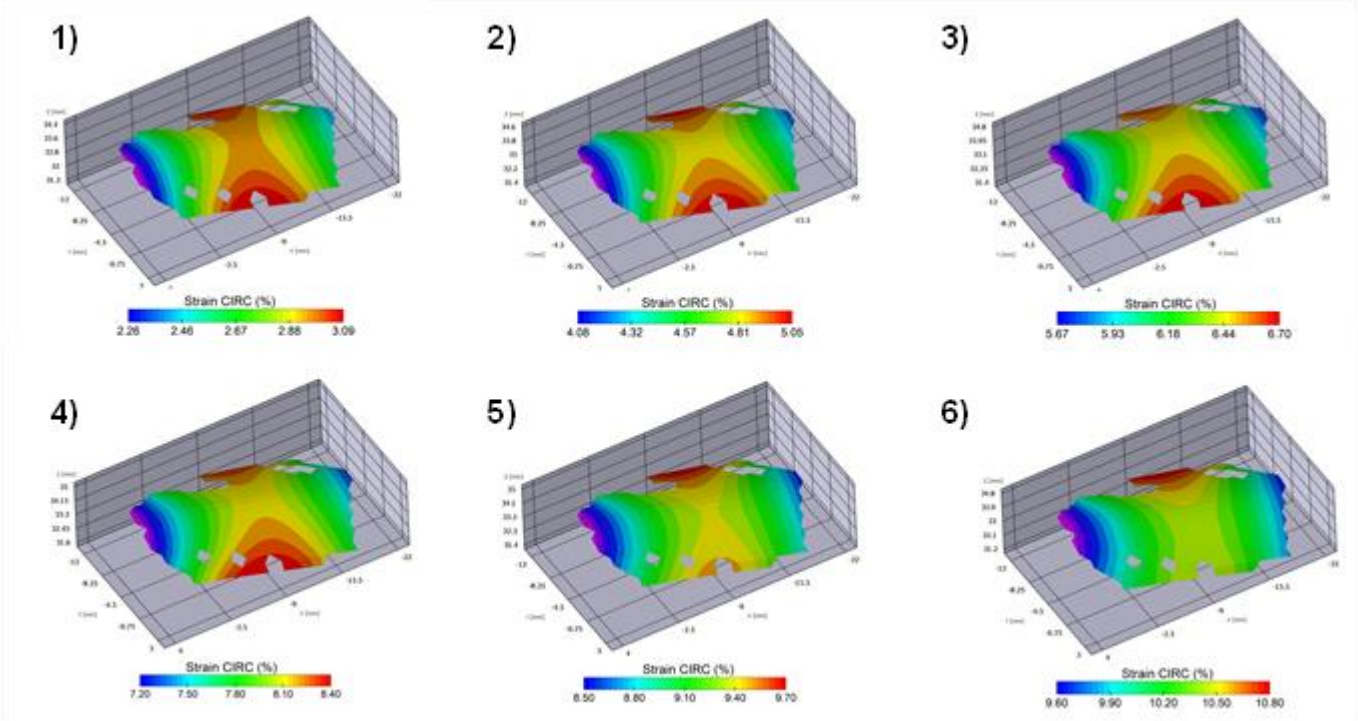

Figure 5. Strain map in CIRC direction at different level of expansion

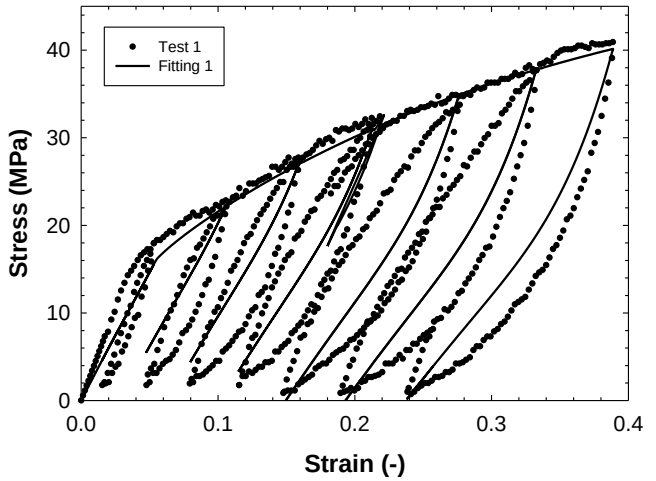

Figure 3. Cyclic stress-strain response for n.7 specimens cut from the 23 mm balloon (Test from 1 to 4) and the

The numerical stability of the constitutive model for the 23 mm balloon was good up to 20% strain which is well above the application strain (see Figure 4). For the 26 mm balloon, the numerical stability was good in all material directions between 0 and 5 strain values.

Figure 4. Range of stability of the constitutive model for the 23 mm balloon

strain increased upon 10% in the mid-section of the balloon.

IV. Discussion

A deep investigation of PA12 material used in balloon-expandable THV was performed to assess mechanical behavior and then develop precise constitutive model. Findings demonstrated that the PA12 mechanical behavior is best described by a combination of hyperelasticity, rate-independent plasticity, and non-linear PRF viscoelasticity. DIC analysis was also used to quantify the circumferential strain field during balloon inflation, and this data can be used to validate computational analysis in the future. Findings demonstrated that the need for accurate constitutive laws when computational models are used to simulate the deployment of balloon-expandable THVs in the human host.

Transcatheter heart valve implantation can be performed using a balloon to support the device deployment. Once the balloon and device assembly have reached the aortic root, the clinician fill the balloon upon a nominal fluid volume indicated by the manufacturer. The procedure is time-dependent and may vary between patient to patient. In borderline cases, the clinician may choose for the over-expansion of the balloon adding one or two milliliters of fluid with respect to the nominal fluid volume. It is however noted that our data demonstrated residual plastic deformation with cyclic inflation [14-17]. It is surprising that a normal clinical usage of the balloon is associated with permanent plastic deformation. Typically, the balloon material should be used (during inflation up to the nominal pressure) only within its linear elastic range.

Cyclic material testing on specimens extracted from 23 mm balloon were found consistent but different from samples obtained by the 26 mm balloon. One group showed a higher yield stress and stronger plastic hardening than the second group. Such differences are likely caused by the fact that we did not test fresh balloons but rather clinically-used devices. Indeed, not much insight was gained into the amount of plasticity developed by the material during the clinical procedure. All balloons had likely a different loading history during their clinical usage (& plastic deformation). It is assumed that fresh balloon device would exhibit a more consistent mechanical response as compared to current findings.

To assess the effect of temperature on the balloon material behavior, a third group of samples was tested. From the test, it can be concluded that temperature has a considerable effect on the balloon material properties leading to visible material softening. Furthermore, the specimens tested at room temperature confirmed the viscoelastic behavior of the balloon material, which was also observed in the second group of samples. As a matter of fact, the failure strain of this batch (~0.12 strain) is lower when compared to the first batch (~0.3 to 0.4 strain), due to the higher loading rate used during testing.

The actual use of a hyperelastic model in combination with Johnson-Cook plasticity and non-linear viscoelasticity for fitting the experimental data showed excellent results. The distinct initial elastic range, the plastic hardening, and the viscoelastic hysteresis were captured very well and appeared to provide a stable mechanical behavior over a wide strain range.

V. Conclusion

This experimental characterization of the material properties of PA12 used in balloon-expandable THVs revealed the importance of appropriate constitutive models. Material testing demonstrated that PA12 has an hyperplastic and viscoplastic response. While findings needs to be confirmed in fresh balloons, such material response needs to be considered in computational analysis and may impact the balloon performance when over-expansion is performed clinically.

[3] *Nephrology and dialysis, NOA Hospital, Massa, Italy*

***Abstract*—The aim of this work is to improve the management of haemodialysis by providing the tools to encourage home treatment. To this end, the design, implementation, and validation of a patient-specific phantom of an arm with arteriovenous fistula, used to train unqualified personnel in the cannulation procedure, is presented. This turns out to be the main obstacle to the transition to home treatment, given the difficulty of performing the dialysis treatment correctly. Through a collaboration with healthcare personnel, the phantom was fabricated using 3D printing technologies and then tested with the cannulation procedure. The test was repeated by expert and non-expert personnel, demonstrating its potential in learning the procedure.**

***Keywords*—home haemodialysis, patient-specific phantom, arteriovenous fistula, cannulation.**

I. Introduction

HAEMODIALYSIS is the most common treatment for renal failure, affecting about 9% of the world's population [1] and occurring with a gradual loss of kidney functions. It involves a blood filtration, which lasts a few hours and is repeated at least three times per week. This causes a clear deterioration in patient's quality of life and even a significant impact on the National Health System since it represents the 2% of the health budget in Europe [2]. By encouraging the transition to home treatment, this work has the aim to improve the patient's management of therapy and cut the costs of in-center haemodialysis. In fact, we propose a novel approach for caregivers' training with personalized phantoms for haemodialysis cannulation, ensuring better outcomes and consequently stimulating this passage. The cannulation procedure represents the main obstacle for home therapy, since the operator in most cases feels unable to act on dialysis treatment [3] as the vessels to cannulate have particular characteristics deriving from an arteriovenous fistula, a surgical anastomosis between a vein and an artery [4]. Indeed, the fistula prevents the collapse of the vessels due to the high cannulation and causes the arterialization of the vessel, which allows to obtain extra pressure and extra blood in lumen as well as an increased wall thickness. In this work the design, fabrication, validation, and cost analysis of a patient-specific phantom to value its effectiveness as well as the feasibility of such training method is presented. The choice of a patient-specific approach is justified by the recipients of the study. Indeed, as caregivers usually are not qualified personnel, it is extremely difficult to learn the cannulation gesture and it is also useless to teach them to cannulate every kind of patients. A typical surgical training approach is used as it is demonstrated to be useful to exercise on the specific model to prevent patients from extra pain and surgeons from excessive stress during the learning phase [5]. To achieve best results, the phantom was developed in a close collaboration with NOA Hospital in Massa, whose Interventional Radiology department provided the image acquisition and the Nephrology and Haemodialysis one followed the development of the phantom and tested the intermediate and final outcomes.

II. Materials and Methods

A. Phantom design and fabrication

Once identified a case study, images of the vessels and fistula were acquired through a phlebography, a computed tomography of the arm with the use of a contrast dye. The resulting sets were inspected and elaborated in itk-SNAP software. An active contour segmentation was carried out to obtain the model of the main structures (Fig. 1). These consisted of bones, blood vessels and the external volume, which were exported and firstly elaborated in Autodesk® MeshMixer to obtain adequate mesh bodies and then imported in Autodesk® Fusion 360™, to handle their design according to the fabrication strategy chosen.

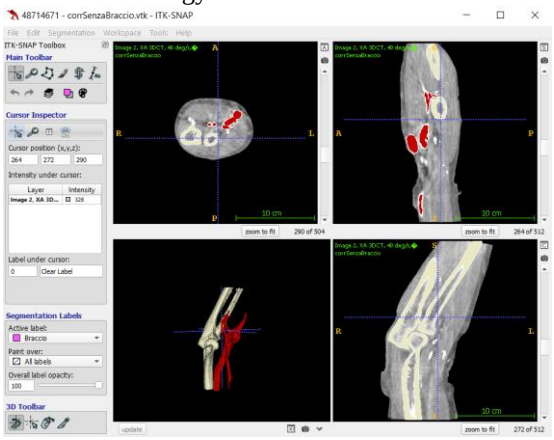

Fig. 1: Segmentation and rendering of bones and vessels in Itk-SNAP software

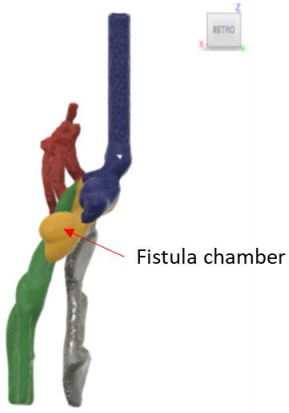

Fig. 2: CAD model of the blood vessels, divided into five components

The blood vessels were divided into five components to reach an almost linear structures and simplify the following fabrication process (Fig. 2). The bones, instead, were filled as they presented an internal cavity and from the whole arm structure a mold design was obtained (Fig. 3). This was divided into two halves (Fig. 3A) as it should allow the placing of bone and vessel before being filled up with the soft-tissues mimicking material. The mold was 3D printed in Acrylonitrile butadiene styrene (ABS) reflecting the negative shape of the arm with some positioning pins to grant the proper pose of the halves. Bones and vessels were placed into the mold to reproduce the correct anatomy of the patient (Fig. 3B) and fixed to the mold walls with adhesive tape to be easily removable after the phantom de-molding.

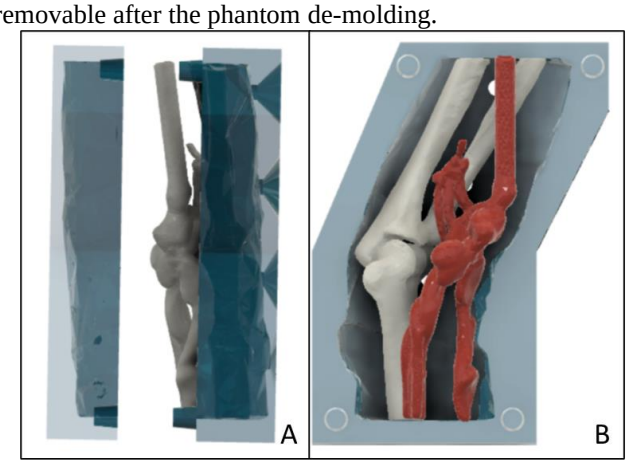

Fig. 3: A) Arm phantom mold design – B) Bones and vessels placed in the mold

At the same time, several trials were carried out in collaboration with the healthcare staff to find the best materials in reproducing target tissues (vessels and soft tissues). To this end, cubic specimens with a cylindrical hole representing an internal vessel (mold for silicone casting shown in Fig. 4) were fabricated using different materials, as shown in Table I, and cannulation tests were performed to identify the most natural feedback.

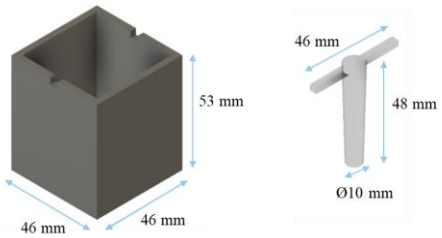

Fig. 4: Mold design for cubic specimens fabrication. The cylindrical hole is obtained placing the core (on the right) in the mold.

TABLE I: MATERIALS TESTED FOR PHANTOM FABRICATION

Vessels	*Soft tissues*
Smooth-On Dragon Skin 10	Smooth-On Ecoflex 0010
Smooth-On Dragon Skin 10 + 0.25 % Thi Vex	Smooth-On Ecoflex 0010 + 50 % Slacker
Smooth-On Dragon Skin 10 + 0.5 % Thi Vex	Smooth-On Ecoflex 0010 + 5 % Thinning
Smooth-On Dragon Skin 10 + 1 % Thi Vex	
Formlabs Elastic 50A Resin (1, 1.2 and 1.4 wall thickness)	

Bones were 3D printed in ABS without joints to avoid any possible movement of the articulation as they only have the role of sustaining the phantom and representing a secondary landmark.

Once selected the proper materials and assembled the mold, it was closed with clamps and the chosen silicone was casted through four countersunk holes and left to cure for 72 hours.

Finally, to mimic the blood and improve the venous return during the cannulation procedure, a 7% w/v alginate solution was used.

B. Phantom validation

Following phantom fabrication, it was validated, in order to evaluate its correctness in terms of geometry and consistency, both in a generic context and in the faithful reproduction of the patient chosen as a case study. It consisted in three phases: an objective, a subjective and an experimental one [6]. The first one was carried out evaluating the reliability, comparing the rendered images of the patient arm and the resulting phantom, since it was not possible to obtain a phantom CT to compare the outcomes in medical images and rendered volumes due to COVID19-pandemic. The second part was about face and content validity and consisted of a questionnaire, which was submitted to the health staff during the final phase of the validation, and which evaluated the morphological and perceptive correctness and the appropriateness of the phantom. In particular, the following four questions were submitted to be scored from 0 to 5:

1. How much the resulting anatomy approximates a generic model of a patient with an arteriovenous fistula?
2. Do the materials properties correctly resemble the real arm?
3. Is the perception returned by the cannulation consistent with the real experience?
4. Can the patient-specific simulation constitute a sufficient training for the caregiver?

The experimental test was used to verify the construct validity and the effectiveness of training and involved an expert and a non-expert group (11 elements) cannulating the phantom. The test was repeated twice.

C. Cost analysis

Finally, a cost analysis was carried out to evaluate the feasibility of this kind of simulators and the eventual impact of a phantom-based training for home haemodialysis on the National Health System. The cost of the phantom includes manufacturing, materials, image acquisition and processing. For a better estimation, the difference between traditional and home treatment, which is valued more than € 40000 per patient per year considering direct, indirect, and social costs, has to be taken into account [7].

III. RESULTS AND DISCUSSION

A. Phantom design and fabrication

Following the preliminary tests outcomes, Smooth-On Ecoflex 0010 was assessed to be the best option in reproducing

soft tissues and Formlabs Elastic 50A Resin for the vessels (1.4 mm wall thickness as shown in Fig. 5), thanks to its capability to reproduce the adequate thickness and a vessel mimicking resistance. Vessel components were thus fabricated using stereolithography with a Formlabs Form 2 printer.

Fig. 5: Vessels internal section with a 1.4 mm wall thickness

After that, they were glued together (Fig. 6) using liquid Elastic 50 Resin, photo-polymerised using a 405 nm lamp. A layer of universal silicone was added on the vessels in order to prevent the liquid from spilling out after cannulation.

Fig. 6: Vessels assembled: the 5 components fabricated by stereolithography were glued together using liquid Formlabs Elastic 50A resin and a 405 nm lamp.

Bones and vessels were then placed in the mold (Fig. 7A), filled up with Ecoflex 0010 silicone (Fig. 7B).

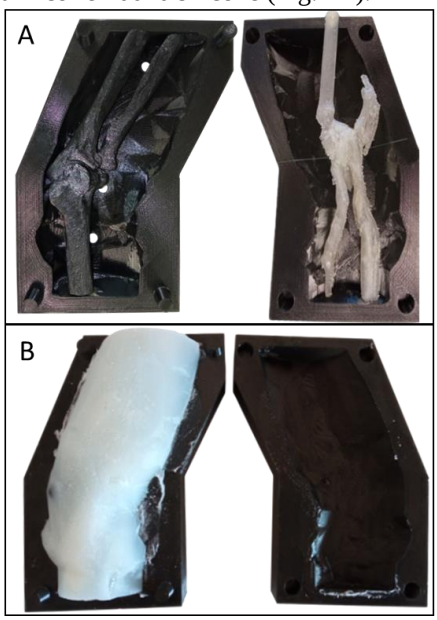

Fig. 7: A) Bones and vessels placed in the mold before silicone pouring – B) Phantom de-molding after 72 h curing

Vessels were then filled up with the alginate solution to add the blood return feedback.

The result of this process returned an anthropomorphic phantom of the interested section of the arm resembling patient's anatomy. To improve the visual perception, a mannequin arm was used to create the upper section of the arm itself as well as hand and wrist (Fig. 8).

Fig. 8: Final assembly of the arm

B. Phantom validation

Considering the objective analysis, it was carried out by comparing the arm images obtained from the phlebography with pictures taken from the assembled phantom. From a qualitatively point of view, the external morphology of the phantom was correspondent to the segmentation obtained in itk-SNAP software, as shown in Fig. 9.

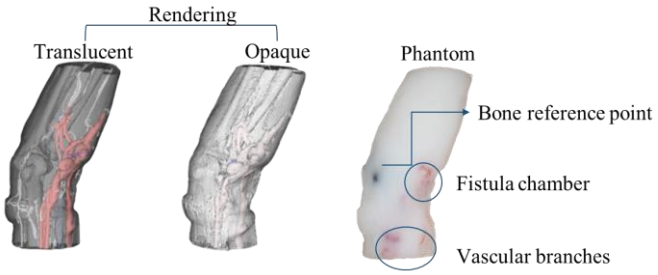

Fig. 9: Comparison between the arm rendering obtained from the phlebography and the real phantom. Correct morphology and pose of the bones are shown.

Looking at the top view (Fig. 10) the bones resulted in a correct position while vessels were subjected to a 36° rotation respect to the target. This is due to the pouring of the silicone that caused the shifting of the soft structures towards the bottom of the mold. This value can be improved by better fixing the vessels in the mold (*e.g.*, using glue) before filling.

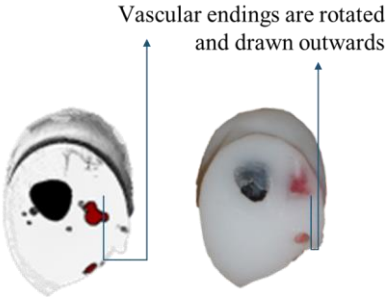

Fig. 10: Comparison between the arm rendering obtained from the phlebography and the real phantom: top view. Vessels are 36° rotated.

Nevertheless, the outcomes allowed to verify the likelihood of the phantom and the validity of the cannulation training carried out (Fig. 11). In fact, the phantom, despite the imperfect positioning of the vessels in relation to the patient's anatomy, was correctly cannulated from the expert staff with a 95% success rate (construct validity), unlike the non-expert group, of which only 20% succeeded. However, the outcomes

of the second trial showed a success rate of 90% for the non-expert group against the 100% of the experts. The differences with their first attempt made thus possible to verify the effectiveness of the training carried on using the phantom.

Fig. 11: Cannulation test on the phantom: the test was repeated twice by an expert and non-expert group proving the effectiveness of the training

Considering the survey taken among experts after the cannulation test, the trend of the answers (Fig. 12) confirmed the morphological correctness and a perception and usability similar to the real arm.

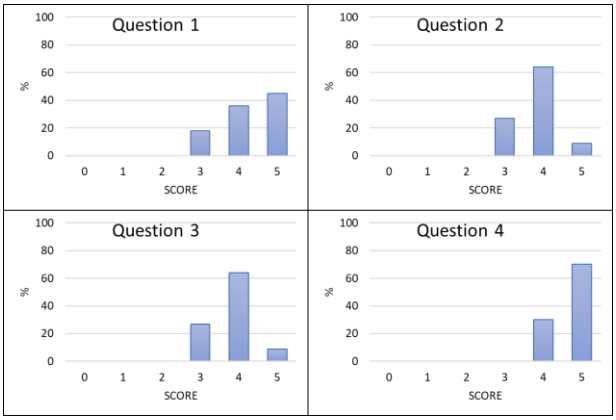

Fig. 12: Answers to the survey taken among experts after the cannulation tests

C. Cost analysis

Due to the importance of the patient-specific approach, a cost-minimising series production is not applicable. Furthermore, the costs of design and manufacturing directly depend on the case study. The total costs for the phantom fabricated in this study are reported in table II.

TABLE II: PHANTOM COSTS

	Info	*Cost*
Image acquisition	Monolateral phlebography of the upper limb	€ 207
Image processing	Image segmentation and CAD design (10 h)	€50/h
Materials	Resin+ABS+silicone	€108.40
Manufacturing	Average cost for manufacturing (11 h)	€30/h
Total		€1145.40

The resulting cost should be related to the health impact of the transition from hospital to home haemodialysis, and it has to be compared to three sessions of treatment. Considering the typical treatment of three services per week, a year of home haemodialysis saves the Italian Health System about €42700 per person [7], compared with traditional in-center handling. This would largely justify the choice of a novel approach to training using patient-specific phantom in the face of a major initial cost. In fact, the phantom should be considered part of a systematic approach to encourage the home haemodialysis. In this way, after just one year the total savings from the new therapy approach would be recognizable.

IV. CONCLUSIONS

In this study we presented the fabrication of a patient-specific phantom for the training of the caregiver towards home haemodialysis. The phantom was fabricated, and cannulation tests were made by both expert and non-expert users. Main limitations of this approach were found in the imperfect positioning of all anatomical components, although this did not compromise the functionality of the phantom. The outcomes achieved during the test phase, in fact, met expectations and with the good response of the health staff demonstrated the feasibility of this new training approach. In addition, the strong economic impact resulting from home haemodialysis saving can justify the initial investment on caregiver training, thanks to its shown effectiveness and the capability of enhancing the transition from in-center to home haemodialysis.

A response surface-based approach to predict spinal rod contouring parameters

F. Berti[1], L. Carpenedo[1], C. Boldrin[1], and L. La Barbera[1,2]
[1] *Laboratory of Biological Structure Mechanics, Dept. Chemistry, Materials and Chemical Engineering, Politecnico di Milano, Italy*
[2] *IRCCS Istituto Ortopedico Galeazzi*

***Abstract*— Rod contouring can be intraoperatively performed by surgeons to obtain bent spinal rods that better fit the physiological curvature of the spine. However, this procedure exploits the material plastic deformation, which is known to affect fatigue behavior *in vivo*.**

Numerical models allow the assessment of the residual stress field due to contouring, but at a high computational cost, which is not compatible with the extensive use of *in silico* models in preoperative clinical planning.

For this reason, after preparing a finite element analysis of titanium rod contouring, a response surface-based approach is proposed to correlate contouring-related parameters with residual stress field and rod curvature.

***Keywords*— Spine, spinal fixation, finite element, residual stress, fatigue failure.**

I. Introduction

Spinal rods are commonly used during spine surgery to restore the correct sagittal and coronal alignment in young (i.e. scoliosis) and adult deformity patients. Contouring is the process adopted to achieve the desired spinal profile through a plasticization of the spinal rod. The French Bender is a well-known surgical instrument capable of obtaining very sharp intraoperative contours characterized by a very focused curvature radius. Commercially available pre-contoured rods show a uniform shape characterized by a constant curvature radius.

Several studies demonstrated that the fatigue resistance of spinal rods contoured using several methods is significantly reduced, thus leading to premature rod fracture and revision surgery [1]–[4]. Recent studies also used *in silico* finite element (FE) modeling coupled with *in vitro* experiments both static and dynamic, to demonstrate that deformations in the plastic range involve high residual stresses and, thus, reduce the fatigue resistance of the spinal rods [5], [6].

The usefulness of models relies on their ability to describe the reality of interest and, at the same time, their usability: indeed, models of spinal fixators consist of multiple parts (e.g. rods, screws, connectors), which might be very onerous to simulate due to their interactions [7]. However, long simulation times are not compatible with the intraoperative decision-making process, which would require processing detailed results in the order of tenths of seconds to adjust to real-time surgical planning.

The aim of the present study is twofold:

i) to perform a detailed full-factorial FE analysis describing titanium rod contouring via a four-point bending set-up, which replicates in controlled laboratory conditions the procedure performed by manufacturers (Uniform Contouring). Even though Different rod diameters and applied displacements were simulated as independent parameters to calculate relevant contouring outputs (i.e. residual curvature radius, residual stresses) as dependent parameters;

ii) to extend the validity of the previous discrete FE simulations by preparing a continuous response surface using the dependent parameters as a function of the independent ones.

II. Materials and Methods

All simulations were prepared and run using Abaqus Standard CAE 2022 (Dassault Systemes Ri, Simulia Corp. Providence, RI, USA).

A. Contouring simulations

1) The setup model

A four-point bending setup was chosen for replicating the uniform contouring. This contouring method was prefered over other technique as previous studies already demonstrated that the result in terms of residual compression and tension were similar [5]. The distance between the upper pins (loading pins) was set to 30 mm while that between the lower ones (support pins) was set to 80 mm. Exploiting intrinsic symmetries, the model was reduced to ¼ (Fig. 1a): the model was partitioned along the x and z axes considering half of the length and the cross-section to reduce the computational cost. All pins (d=4 mm) were modeled as linear-elastic material with stainless-steel properties (E=210 GPa, ν=0.3). The rod-pin contacts were described by surface-to-surface interaction with hard normal behavior and a friction coefficient of 0.175, [8]. All the parts of the model are discretized with linear hexahedral elements (C3D8).

2) Titanium spinal rods model

The elastic-plastic material properties of the rods were assessed through experimental tensile tests (E=110 GPa, ν=0.3, σ_Y=886 MPa, σ_U=1134 MPa, ε_U=5.35%) (Fig. 1b) [5].

Three models were prepared according to the rod diameters more often used in clinical practice, namely 5, 5.5, and 6.35 mm. A mesh sensitivity study led to the choice of linear hexahedral elements with incompatible mode formulation (C3D8I), with a global size of 0.45 mm and higher refinement of 0.15 mm in the area of the central rod and rod-pin contacts (Fig. 1c).

1) Simulation and outputs

The contouring step consisted of a loading phase followed by unloading: during the first, the upper pin moved vertically in displacement control, impacting the rod and causing its deformation; then, an opposite displacement was specified to

release the load. The support pin remained fixed during the whole simulation.

Twenty-one simulations were prepared for each of the rods, with different amounts of applied vertical displacements (u), ranging from 0.2 to 9 mm. This allowed to investigate the rod response to elastic loadings and, especially, post-yield conditions.

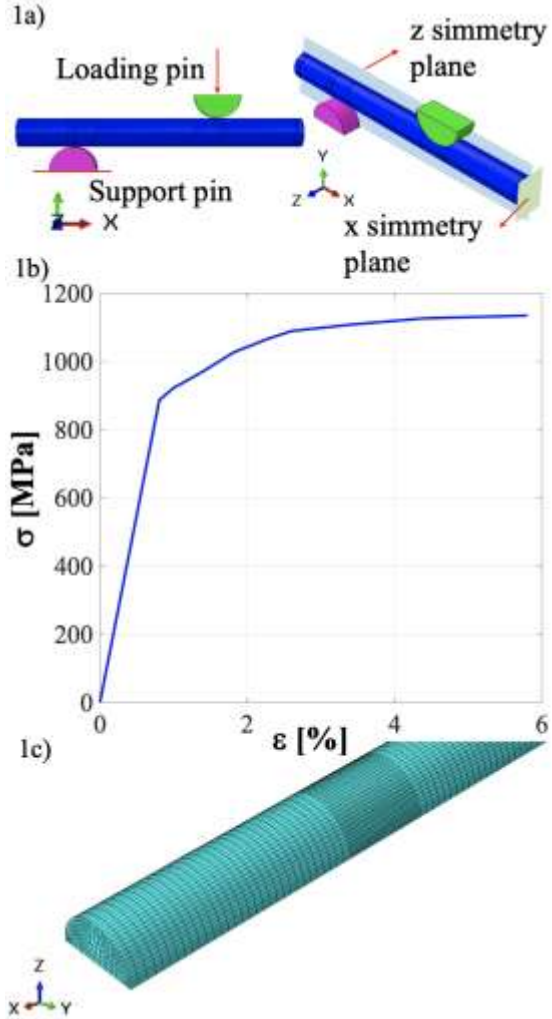

Fig. 1: a) The model of the four-point bending setup, reduced using symmetries; b) elastic-plastic material properties assigned to titanium rods [5]; c) detail of the rod mesh refinement.

In each of the previous cases, the residual curvature radius (RCR) was computed at the end of the unloading phase and stored, together with the residual stress field (σ*) in the central section of the gauge length, according to both radial and circumferential paths.

B. *Generation of the response surfaces*

The response surface-based approach was set starting from the analysis of the FE results, using the Matlab (MathWorks Inc., 2022a) tool *curveFitter*.

In particular, two independent variables, which are relevant input variables that can be chosen by surgeons in the contouring process, were selected:

- rods diameter, D (5, 5.5, and 6.35 mm);
- applied vertical displacement, u (considering only post-yield data).

Five dependent variables, which are the result of the contouring process and the focus of the present work, were identified among the simulation results:

- residual curvature radius, RCR;
- maximum peak tensile residual stress in the central rod section, $\sigma^{*MAX,t}$;
- maximum peak compressive residual stress in the central rod section, $\sigma^{*MAX,c}$;
- radial coordinate of the $\sigma^{*MAX,t}$, $R(\sigma^{*MAX,t})$;
- radial coordinate of the $\sigma^{*MAX,c}$, $R(\sigma^{*MAX,t})$.

The model was in the form of Eq. (1):

$$f(D,u) = p_{00} + p_{10} \cdot D + p_{01} \cdot u + p_{11} \cdot D \cdot u + p_{02} \cdot u^2 \quad (1)$$

where D and u represent the rod's diameter and the applied vertical displacement, respectively.

Notice that polynomial equations up to second order were used to avoid excessive complexity of the response surfaces: the second order appears for u variable only, while the quadratic term was not necessary for D variable. To reduce the effects of outliers, the robust bisquare method was used for the response surface fitting of RCR variable. The coefficients (with 5% and 95% confidence bounds) were then calculated. To quantify the goodness of fit using Eq. 1 (1), coefficient of determination (R^2), root mean square error (RMSE) and Normalised RMSE, computed as in Eq. (2), were used as indicators.

$$Normalised\ RMSE = {}^{RMSE}/_{(\max value - \min value)} \quad (2)$$

The response surfaces were depicted for each dependent parameter as 3D color maps.

III. Results and Discussion

A. *Contouring simulations*

The application of vertical displacements u<2 mm was not sufficient to cause any yield. To reach values in the range of 100÷200 mm, which were compatible with the preformed commercial rods, the vertical displacement had to increase from 5 mm. The higher the rod diameter, the lower the required displacement to get a given curvature radius (Fig. 2).

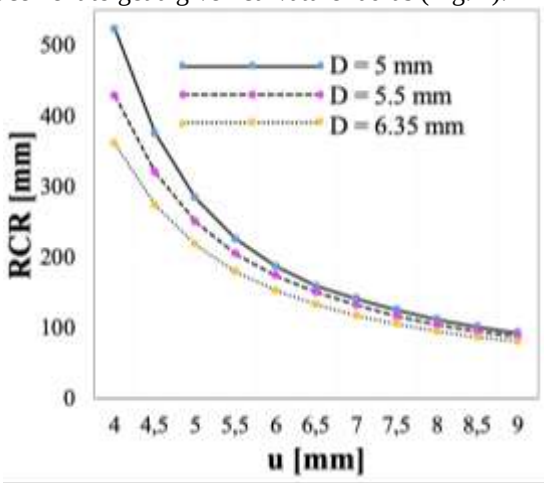

Fig. 2: Residual curvature radius (RCR) in rods having different diameters (D) as a function of the applied vertical displacement (u) in the range 4÷9 mm.

The radial and circumferential paths of residual stresses exhibited similar trends among the different rods, however showing different values and radial coordinates of the peak stresses (Fig. 3).

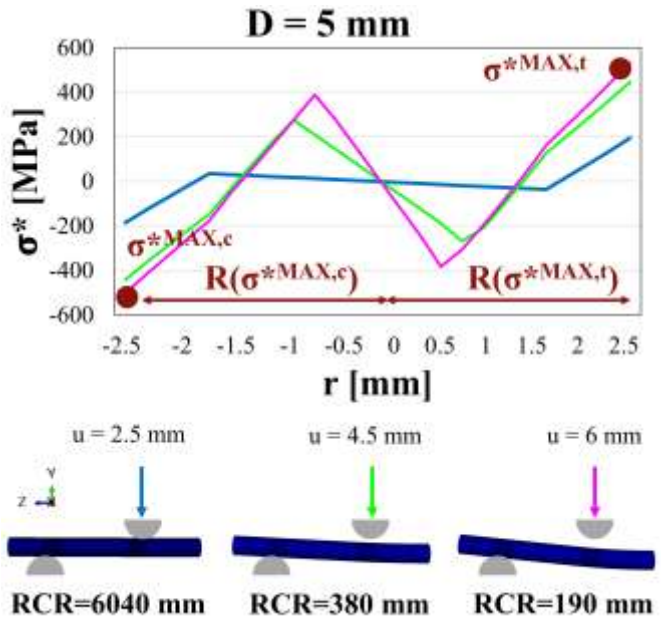

Fig. 3: Computational residual stress fields predicted for a 5 mm diameter rod due to specific applied vertical displacements (u). The dependent variables (RCR, $\sigma^{*MAX,t}$, $\sigma^{*MAX,c}$, $R(\sigma^{*MAX,t})$, $R(\sigma^{*MAX,c})$) used for the generation of the response surface are presented.

B. *Response surfaces*

The resulting response surfaces are depicted in Fig. 4, 5, 6, 7 and 8 for each dependent parameter.

The coefficients for each term of the polynomial response surfaces are summarized in Table I. In the analysis of the residual curvature radius, three points in the range of interest were excluded to avoid analytical biases for very low displacements due to excessively high curvature. This led to a better goodness of fit in the data.

The polynomial terms (Table I) beyond the linear ones only contributed less than 5% for the residual curvature radius, $\sigma^{*MAX,t}$, and $\sigma^{*MAX,c}$. The terms p_{00} and p_{01} contributed, respectively, about 84% and 16% on RCR; while the terms p_{00}, p_{01} and p_{10} contributed, respectively, about 75%, 25% and 10% on the residual stresses. The term p_{10} contributed alone more than 96% on the calculation of the radial coordinate of stresses.

TABLE I: RESPONSE SURFACES COEFFICIENTS

Variable	p_{00}	p_{10}	p_{01}	p_{11}	p_{02}
RCR [mm]	2148 (-1882, 6179)	-121 (-812, 570)	-424 (-1182, 334)	14 (-99, 127)	22 (-14, 57)
$\sigma^{*MAX,t}$ [MPa]	-723 (-979,-468)	99 (55, 143)	233 (185, 282)	-7 (-14, 1)	-12 (-14, -9)
$\sigma^{*MAX,c}$ [MPa]	751 (498, 1004)	-99 (-144,-55)	-261 (-309,-213)	10 (2, 17)	14 (12, 16)
$R(\sigma^{*MAX,t})$ [mm]	-0.020 (-0.023,-0.018)	0.504 (0.504, 0.504)	<<0.001 (-0.001, 0.001)	/	/
$R(\sigma^{*MAX,c})$ [mm]	0.020 (0.018, 0.023)	-0.504 (-0.504,-0.504)	<<-0.001 (-0.001, 0.001)	/	/

Notice that the response surfaces for radial coordinates of both the $\sigma^{*MAX,t}$ and the $\sigma^{*MAX,c}$ are linear planes, as the two peaks are always observed on the outer surfaces of rods. Therefore, for these variables, it might be assumed that their positions will always lie at the maximum radius.

The goodness of fit values are reported in Table II for the sake of completeness.

TABLE II: RESPONSE SURFACES GOODNESS OF FIT

Variable	R^2	*RMSE*	*Normalised RMSE [%]*
RCR [mm]	0.86	407.2	0.2
$\sigma^{*MAX,t}$ [MPa]	0.97	29.9	4.5
$\sigma^{*MAX,c}$ [MPa]	0.96	29.6	5.3
$R(\sigma^{*MAX,t})$ [mm]	1	<0.01	0.1
$R(\sigma^{*MAX,c})$ [mm]	1	<0.01	0.1

The R^2 was higher than 0.96 for most parameters, but for RCR. Although the RMSE showed relatively high absolute errors, the normalized RMSE confirmed that the prediction error in using the response surfaces was satisfactory in general, with maximum residual stress values predicted within 5%.

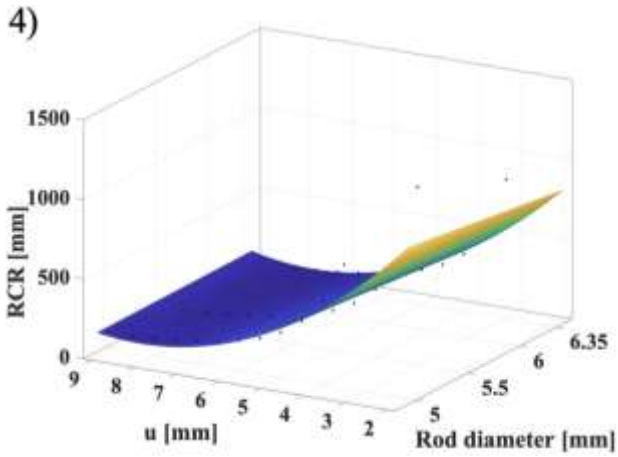

Fig. 4: Results of the response surfaces on RCR. Color map from blue to yellow indicates values from minimum to maximum.

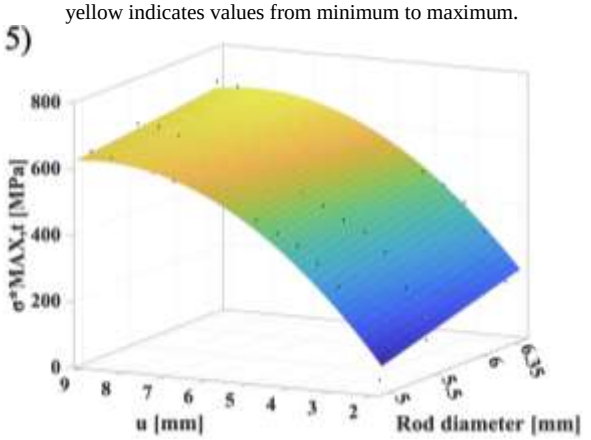

Fig. 5: Results of the response surfaces on $\sigma^{*MAX,t}$. Color map from blue to yellow indicates values from minimum to maximum.

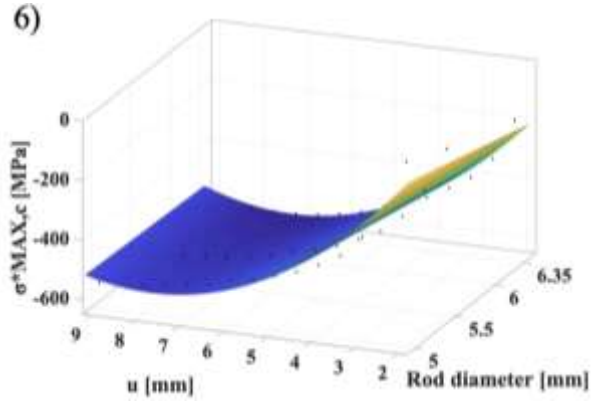

Fig. 6: Results of the response surfaces on $\sigma^{*MAX,c}$. Color map from blue to yellow indicates values from minimum to maximum.

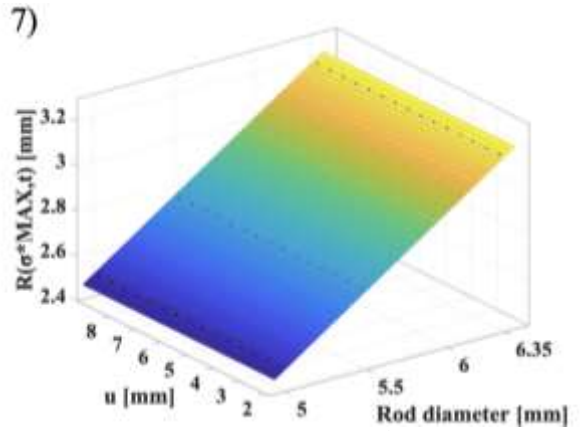

Fig. 7: Results of the response surfaces on $R(\sigma^{*MAX,t})$. Color map from blue to yellow indicates values from minimum to maximum.

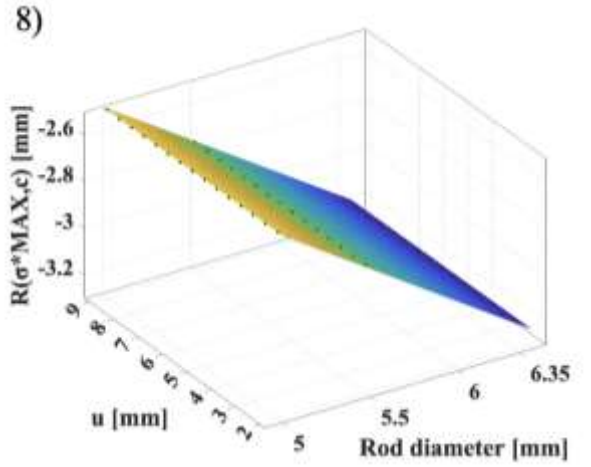

Fig. 8: Results of the response surfaces on $R(\sigma^{*MAX,c})$. Color map from blue to yellow indicates values from minimum to maximum.

IV. Conclusion

The use of FE models allowed for estimating the impact of the contouring process on titanium rods of different diameters. Thanks to the proposed response surface-based approach, data from a reduced number of simulations can be extended to predict the behavior of rods in a larger domain with no need to perform additional computationally demanding simulations. Further developments could be the extension of the approach over different materials and contouring methods to build a complete framework useful for intraoperative strategies. A wider characterization of other contouring processes, such as using the French Bender, could definitely be a future perspective. Moreover, possible cross-correlations between dependent parameters could be evaluated. This first approach was focused on evaluating the effects of the choices made by the surgeon on the mechanical effects due to the contouring process, but a finer analysis could complete the description and supply a total comprehension of how parameters are related.

***Abstract*— Mechanical tests on bone plates are mandatory for regulatory purposes but may require very high execution times from the market point of view. Therefore, an accurate prediction of experimental outcomes can reduce test runtime with beneficial costs cut for manufacturers. In this study, an analytical framework for the analytical runout load computation was realised to predict the fatigue behaviour of eleven bone plate models pending certification. The prediction accuracy was verified by performing a fatigue experimental test campaign on each plate. The developed analytical framework shows promising predictive ability, with R^2 above 0.938, with potential impact in reducing the experimental tests needed for the CE marking of bone plates.**

***Keywords*—Bone plate, four-point bending test, runout load, fatigue life prediction.**

NOMENCLATURE

σ_{max} = maximum stress
σ_{min} = minimum stress
R = stress ratio, $R = \sigma_{min}/\sigma_{max}$
σ_a = stress amplitude
σ_m = mean stress
$\Delta\sigma$ = stress range, $\Delta\sigma = 2\sigma_a$
$\sigma^*_{D\text{-}1}$ = specimen stress amplitude for $\sigma_m = 0$ (R = -1)
$\sigma_{D\text{-}1}$ = component stress amplitude for $\sigma_m = 0$ (R = -1)
σ_{UTS} = ultimate tensile strength

I. INTRODUCTION

NOWADAYS, the development of new plates for osteosynthesis, especially in long-bone surgery, has undergone a broad improvement. Their design has changed over the years, from conventional plates with straight linear geometries to implants with irregular shapes that follow the anatomical profile of the healing bone [1]. Indeed, the complexity of clinical procedures and biomechanical characteristics has given rise to a great variety of bone plate concepts (e.g., locking compression plates, dynamic compression plates, variable angle-locking compression plates) intended for specific anatomical regions.

However, modern plates must also meet safety and performance requirements depending on the local biomechanics. For this purpose, manufacturers and research groups are used to evaluate bone plates before commercialization through test methods published as ASTM or ISO standards [2]. ASTM F382 [3] is recognized in full by FDA and MDR, and it is the most widely used test standard for metallic bone plates. This standard presents a four-point bending test setup that allows the evaluation of the bending stiffness, the bending structural stiffness, the bending strength, and the cyclic bending fatigue performance of the bone plate. Quasi-static tests are useful to determine the loading range of fatigue testing, which have a substantial impact on the total runtime of the experimental campaign. The standard suggests for fatigue tests a load frequency of 5 Hz and one million cycles to reach the runout condition. An overall test time per plate has been estimated at around 180 hours without interruption in the best-case scenario [4]. Indeed, the realization of these test campaigns requires a considerable financial outlay on the part of manufacturers, with very long execution times from the market point of view.

Moreover, ASTM F382 provides a test methodology and defines the setup condition, but insufficient knowledge is available to predict the fatigue behaviour of the fixation device. The main goal of ASTM standards is to establish a reference test method that can be performed in any accredited laboratory, thus providing objective results for direct comparison with predicate devices. The first support comes from a recently issued guideline provided by FDA [5] about the performance criteria accepted for each intended anatomical location when ASTM F382 is applied. Nevertheless, this guideline only refers to static tests and does not contain any indication of plate fatigue limits. In this scenario, it would be useful to define a "harmonised testing approach", as highlighted in [2]: a systematic procedure based on standardized criteria for the development of a test procedure. Because of the wide variety of implants and their features, the test procedures shall be developed for each application and must be compliant with the regulatory requirements of ISO 14602, 7.2 [6]. Strategies based on Finite Element (FE) analyses [7] are usually proposed to speed up and simplify the plate testing procedures. FE models allow to predict test outcomes with a high level of detail, but they may require an important computational power to be quickly performed. Moreover, FE analyses are often used for the calculation of the stress distribution in a static condition, to be inserted into commercial software for the evaluation of fatigue life through analytical methods [8].

This work proposes an analytical framework for the direct estimation of the runout load, to speed up the experimental tests campaign for regulatory purposes. An analytical calculation of fatigue properties was implemented starting from the geometrical and material characteristics of the plate to guide the identification of the runout load for fatigue testing. A complete test campaign was then carried out to evaluate static and fatigue bending properties of eleven bone plate models according to ASTM F382 and verify the prediction accuracy of the analytical framework.

II. MATERIALS AND METHODS

A. Bone plates

Eleven different bone plates were evaluated in the present study. Table I lists for each plate the material, the tensile strength, and the anatomical site for which it was designed.

TABLE I: BONE PLATES INVOLVED IN THE STUDY

Plate	*Material*	*Tensile Strength (MPa)*	*Anatomical location*
01	Stainless Steel	900	Malleolus
02	Ti6Al4V	966	Malleolus
03	Pure Titanium	668	Wrist
04	Pure Titanium	652	Wrist
05	Stainless Steel	960	Distal tibia
06	Stainless Steel	910	Distal tibia
07	Ti6Al4V	1012	Distal tibia
08	Stainless Steel	986	Distal femur
09	Ti6Al4V	942	Diaph. tibia
10	Ti6Al4V	968	Distal femur
11	Pure Titanium	991	Diaph. femur

An ad hoc script was implemented on MATLAB R2020b (MathWorks, Natick, MA) to determine the critical section of each plate. The script allows to segment the bone plate following its curvature and returns the thickness (t), width (w), screw hole diameter (d), and moment of inertia (I) of the section with the minimum area.

B. Analytical fatigue evaluation

The analytical evaluation of fatigue behaviour was carried out considering simplified straight plates, derived from the actual geometries by using the characteristics of their critical sections. Plate curvatures were neglected, while the presence of a screw hole was considered by applying the nominal tension Peterson's stress concentration factors (K_t) for transverse bending of a finite-width plate with a circular hole [9]. Indeed, in static loading, the notch effect amplifies all the stress distribution. In fatigue loading, experimental results show that the stress concentration factor decreases at the fatigue limit [10]. In general, a fatigue-notch factor (K_f) is often determined by modifying the value of K_t (Eq. 1) according to a coefficient called notch-sensitivity index (q):

$$K_f = 1 + q(K_t - 1) \tag{1}$$

The notch-sensitivity index depends on both the mechanical and metallurgical characteristics of the material and the absolute dimensions of the notch. Due to the large dispersion of available data, various formulas have been proposed to obtain more precise values of q; the Neuber equation (Eq. 2) can be applied to steel plates:

$$q = \frac{1}{1+\frac{\sqrt{\rho}}{\sqrt{r}}} \tag{2}$$

where ρ is the average grain size and r is the notch radius.

While the Neuber equation is valid only for steels, there is no clear relationship for titanium alloys. In these cases, it is mandatory to carry out fatigue tests on notched and unnotched specimens to determine K_f [11]. Because materials with a uniform fine-grained matrix are very sensitive to notches [12], in titanium plates K_f was considered equal to K_t (q = 1), in a conservative perspective.

Starting from the static strength of the material (σ_{UTS}), K_f was used to estimate the fatigue limit ($\sigma_{D\text{-}1}$) with no average stress (σ_m = 0, corresponding to R = -1) of each bone plate from the following equation (Eq. 3):

$$\sigma_{D-1} = \sigma^*_{D-1} \frac{\prod C_i}{K_f} \tag{3}$$

where σ^*_{D-1} is the fatigue limit of the specimen, while C_i are factors affecting the component fatigue life, such as size (C_S), surface finish (C_F), or loading mode (C_L). In this study, a unit value has been attributed to $\prod C_i$: no correction due to surface finish was applied (all surface roughnesses were less than 0.8 µm) and a reliability of 50% was considered. A fatigue limit equal to $0.5\sigma_{UTS}$ [12] was applied for all bone plates.

Goodman and Gerber failure criteria [13] were implemented to calculate the mean stress effect due to ASTM F382 testing condition (R = 0.1). The traditional Goodman relationship and the Gerber parabola were represented in the Haigh diagram of Fig. 1 for pure titanium of Plate04. From the mean stress, the maximum stress (σ_{max}) and the maximum bending moment (M_{max}) were calculated with both failure criteria using the following relationships (Eq. 4-5):

$$\sigma_m = \frac{\sigma_{max}}{2}(1 + R) \tag{4}$$

$$M = \frac{\sigma_{max}\, I}{(t/2)} \tag{5}$$

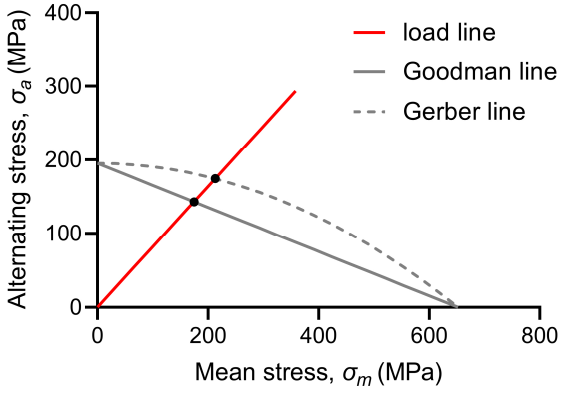

Fig. 1: Haigh diagram of Plate04 in pure titanium. Intersections between the load line and the applied criterion provide the mean stress values for the prediction of the fatigue life.

Finally, two predicted runout loads (L) were determined through Eq. 6 exploiting the loading span of the testing setup (h). These values were used to define the range of the runout load prediction.

$$L = \frac{2M}{h} \tag{6}$$

C. *Standard mechanical testing*

Quasi-static and fatigue bending tests were performed as reported in ASTM F382 to determine the fatigue life of the bone plates. According to A1.6.2.1, rigid extension segments were adopted for plates that did not directly fit into the test configuration, to obtain a sufficiently long section of symmetry.

The testing setup (an example in Fig. 2) was composed of:

- two loading rollers with distance *a* (center span), at least two screw holes must be located between them;
- two support rollers, placed at an equal distance from the loading roller (*h*, loading span); and
- two extension segments (material AISI 630, heat treatment W1.4542 – H900), if required.

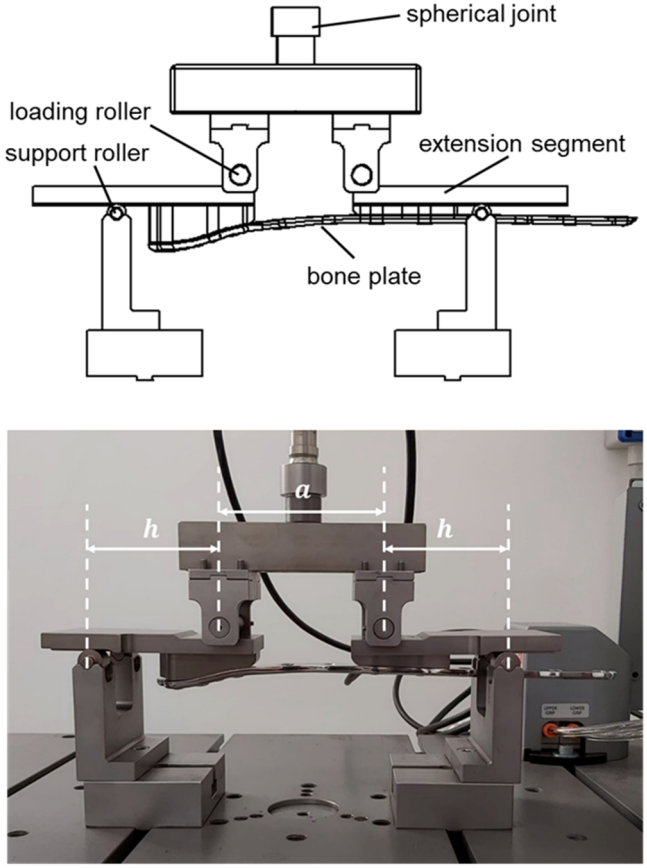

Fig. 2: Testing setup adopted for Plate08: (Top) main components and (Bottom) characterizing distances.

The loading rollers were rigidly connected to a spherical joint, while the support rollers were positioned on holders designed to be used with the testing machine base (Instron E3000). Four plates of each model were tested until failure at 5 mm/min to assess the proof load, obtained from the intersection point of the load-displacement curve and the 0.2% offset displacement line.

The same setup was used for fatigue tests to determine the runout load and the related maximum bending moment of every bone plate. The runout load was determined starting from 75% of the proof load and gradually reducing it until the load that led to one million cycles was identified. The bending moments (M) were computed from the experimental runout load (Eq. 6). The runout condition was repeated on three different samples. As recommended by the ASTM standard, fatigue tests were performed at 5 Hz in load control, adopting an R-ratio of 0.1 (the minimum of the sinusoidal waveform was computed as 10% of the maximum load).

Lastly, predictions realised with the Goodman and Gerber criteria were evaluated with Linear Least Squares (LLS) approach to fit predicted values with experimental results and determine the R^2 coefficients.

III. RESULTS

The prediction of the load required to reach the runout condition for the eleven bone plates was realised and verified through comparison with experimental results obtained by applying the standard methodology described in ASTM F382. Fig. 3 contains the experimental runout loads and their predicted range of values. The predicted range includes in most cases the experimental value of the runout load.

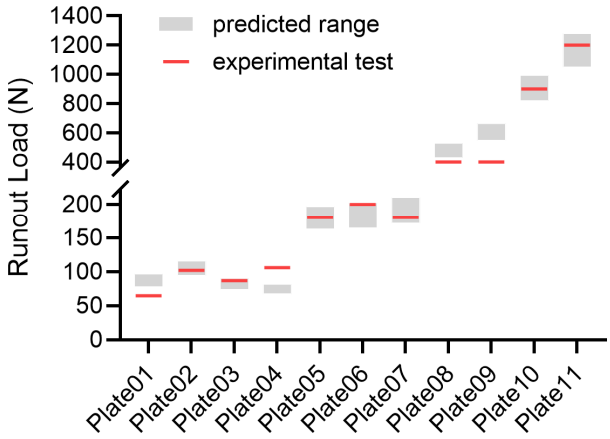

Fig. 3: Experimental and predicted runout loads obtained for each bone plate. Experimental results appear as red transversal lines, while the predicted values are represented by grey boxes.

The Goodman criterion involves a conservative life estimation: values obtained with this approach were considered as the lower limit of range prediction. Indeed, the runout load calculated with the Goodman criterion lay below the experimental load in eight of the tested plates. Runout loads estimated with the Goodman criterion (R^2 = 0.9519) show a better prediction compared to those calculated with the Gerber approach (R^2 = 0.9385). Nonetheless, the latter was useful to estimate the upper limit of the runout load: the experimental runout load fell below the limit estimated with the Gerber criterion for ten bone plates out of eleven.

However, two cases significantly deviate from the expected fatigue values. On the one hand, Plate04 considerably exceeded the expected range: the experimental runout load was approximately 50% higher than the lower limit. On the other hand, the experimental runout load of Plate09 is far below the value predicted by the Goodman criterion. Indeed, the experimental results of this bone plate were rather ambiguous: fifteen fatigue tests were performed and a load equal to approximately 30% of the static proof load was identified to reach the runout condition, suggesting a potential mismatch between the raw material certification and the material actually used to manufacture the batch of tested

plates. Notwithstanding, results reported for Plate09 were useful to analyse the possible implication of fatigue life estimation before starting a test campaign. Although more than 250 hours have been spent testing this bone plate, the runout load was most likely underestimated.

As mentioned before, the analytical methods adopted in this work involve important approximations, which can be reduced, for example, with a specific estimation of the K_f factor for the screw hole on the plate material. Another crucial aspect to be explored is the determination of the fatigue limit, especially for the wide range of multiplication coefficients usually considered for titanium alloys. Beyond these limitations, the implemented procedure can provide a starting point for fatigue testing, and it represents a guideline to avoid the underestimation of the runout load.

IV. Conclusion

In this study, an analytical prediction of the fatigue behaviour of eleven non-certified bone plates was executed.
The analytical predictions of runout loads were then compared with experimental results. Due to the phenomenology of fatigue, it is difficult to estimate a unique fatigue limit with a simple procedure. Indeed, even if the ASTM standard claims the identification of the runout load by gradually decreasing the static proof load, analytical models can be adopted to reduce the range of loads to be investigated in standard fatigue testing. Furthermore, it is important to note that the experimental runout condition does not correspond to a plate fracture at one million cycles, but to the first test where, by gradually reducing the load, one million cycles were reached without breaking. Therefore, in all experimental runouts the load is always underestimated, more or less severely. In this context, a preventive indication of the runout condition could be provided by an analytical framework, which would represent a powerful support to avoid excessive underestimation of the runout load.
In conclusion, this work reported encouraging results showing how the prediction of a runout load range of values could allow the accomplishment of mechanical tests using a limited number of specimens, with a substantial impact on the costs for the manufacturer.

Further works on new bone plates are planned to verify the effective reduction of test execution times through the proposed procedure. Moreover, by calculating the maximum stress through an *in silico* Finite Element replica, it would also be possible to predict the number of cycles of the implanted plate, defining a rationale able to further reduce the regulatory process time.

***Abstract*—This work reports the design, development and characterization of a low-intensity pulsed ultrasound (LIPUS) stimulation system to be used for highly controlled ultrasound-triggered drug delivery in vitro experiments. The use of a versatile signal generator and different types of transducers allows the fine tuning of the stimulation parameters over a broad range. Such transducers were carefully characterized in terms of pressure field shape and intensity, guaranteeing a precise estimation and control of the ultrasound dose delivered to the target. Such a system will be used for controlled drug release tests from ultrasound-responsive systems, such as nano and micro carriers, scaffolds and patches, in the context of the REBORN project.**

***Keywords*—Low-intensity pulsed ultrasound, In vitro ultrasound setup, Triggered drug delivery.**

I. Introduction

ULTRASOUND (US) is a mechanical wave, with frequencies higher than 20 kHz [1]. In the clinics, US is widely employed and accepted as an imaging modality for diagnostic purposes, thanks to its ease of use, low cost and non-invasiveness [2]. Besides this well-known use, US, and in particular low-intensity pulsed US (LIPUS), is recently emerging as a therapeutic tool to induce beneficial bioeffects on cells and tissues in the human body, such as bone fracture healing, osteoporosis treatments and soft tissues regeneration, among other applications [3].

Furthermore, US has also been explored in the state-of-the-art as a biophysical trigger for non-invasive targeted drug delivery from US-responsive carriers such as microbubbles (MBs), polymer micelles, liposomes or acoustically-responsive scaffolds (ARSs), exploiting both mechanical and thermal effects [4]-[8]. Ultrasound is indeed an extremely attractive and promising trigger for on-demand drug delivery. In fact, unlike other biophysical triggers such as light and electric fields, it shows highly effective penetration in the majority of body tissues (soft ones) [9]. US, therefore, would allow safe and non-invasive targeting of drug carriers in the vascular network or of implants in most deep tissues [3]-[4]. Furthermore, US also has the advantage of allowing a good spatial resolution within the body thanks to its high focusing capability and controllability [5], also being highly tunable (in terms of frequency, intensity, duty cycle, etc.).

However, advancements towards a clinical translation of this tool is hampered by a lack of accurate control over the US exposure conditions: most existing in vitro US stimulation setups are indeed highly susceptible to calibration errors and lack control on reflection and attenuation phenomena. It has been demonstrated that this kind of errors due to the use of non-standard configurations can lead to uncertainties up to 700% in the estimation of the actual US dose delivered to the target [10]. This results in low repeatability of the stimulation studies and difficulties in understanding the correlation between US dose and materials response, which heavily hinders the development of controllable drug delivery systems. Furthermore, the literature lacks standardized stimulation protocols and an agreement upon the best stimulation parameters for specific applications, which makes it hard to compare different studies, as obtained results are often contradictory.

Herein, we aim to develop a highly controlled US exposure system, where highly controlled means that this system allows to regulate and quantify with a great level of accuracy the US dose actually delivered to the target, reducing to a minimum the uncertainty with which this value is known. In fact, the careful calibration of the US sources and the elimination of sources of uncontrolled phenomena in the acoustic path allows a significant control over the exposure conditions, paving the way for reliable and repeatable release tests from US-responsive drug delivery systems, such as nano and micro carriers, scaffolds and patches. In particular, the setup described here is intended for LIPUS stimulation, a US modality already approved by the Food and Drug Administration (FDA). The developed systems allow to stimulate multiple samples and to explore a wide range of US parameters, offering the possibility to easily vary intensity (0-2000 mW/cm^2), frequency (38 kHz - 5 MHz), duty cycle, pulse repetition frequency and duration at will, thus allowing the researchers to optimize the best stimulation parameters for each specific application.

II. Materials and methods

A. System design

Two systems were developed, one for low-frequency (38 kHz) and one for high-frequencies (500 kHz – 5 MHz) exploration. The overall configuration of the systems is the same, besides some minor differences, and it is carefully designed in order to avoid reflection phenomena, due to materials acoustic impedance differences, unpredictable generation of standing waves and frequency-dependent perturbations of the transmission of US waves.

The high-frequency LIPUS setup (Fig. 1) consists of:

i) a tank (265 × 245 × 490 mm^3) filled with deionized and degassed water;

ii) one acoustic absorber (Aptflex F28P, Precision Acoustics, Dorchester, Dorset, UK) positioned at the top of the tank to prevent reflections;

iii) a sample retaining system, which was previously demonstrated to guarantee transparency to US waves in

correspondence of the samples and also the complete sealing of the three internal chambers [11];

iv) a linear rail that allows the translation of the retaining system along the z-axis in order to modify its distance from the transducers;

v) piezoceramic transducers (Precision Acoustics, Dorchester, Dorset, UK), with different central resonant frequencies, which are used to cover the high-frequency range (i.e. 500 kHz to 5 MHz range) and are fixed at the bottom of the tank;

vi) a multichannel signal generator (IGT, Bordeaux, France), to control the electric input signal to the transducer (20 W maximum power per channel);

vii) an exhaust valve, to fill and empty the tank, and a degassing system (IGT, Bordeaux, France), which includes a vacuum pumped membrane contactor (3M™ Liqui-Cel™, St Paul, Minnesota, USA), to continuously degas water within the tank.

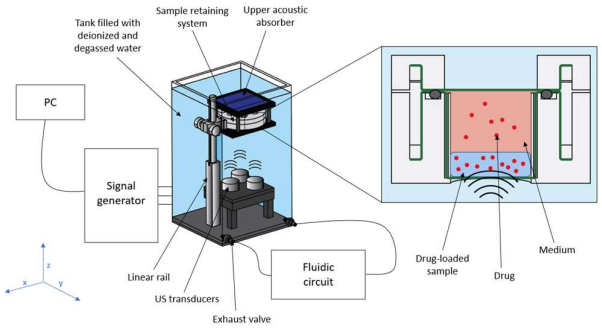

Fig. 1: Scheme of the high-frequency LIPUS stimulation setup, with a zoom on the sample retaining system, to be used for ultrasound-triggered drug release tests

The low-frequency LIPUS setup consists of the same fundamental elements, except for slight variations. Firstly, due to geometrical constraints, only one transducer is fixed at the bottom of the tank, instead of the three employed in the high-frequency system; consequently, the sample retaining system only has one chamber, placed in the center and coaxial with the transducer. Only one type of US transducer (BAC s.r.l., Florence, Italy), centered at a frequency of 38 kHz, was employed and connected to the signal generator (BAC s.r.l., Florence, Italy).

In both systems, the complete immersion of the sample retaining system in deionized and degassed water and the addition of acoustic absorbers in the acoustic path help preventing undesired wave reflections, thanks to the absence of liquid-air interfaces and reflective obstacles along the US propagation direction.

Furthermore, the designed systems allow the investigation of different parameters in the ranges commonly used for LIPUS stimulation, which permits the validation of different stimulation protocols. This is crucial for optimizing the performances of the samples under test, especially considering the general lack of standard protocols and highly contradictory results which can be found in the literature. In this specific case, the setup allows the exploration of frequencies in a broad range (38 kHz - 5 MHz) and intensities varying from few mW/cm^2 up to 2 W/cm^2. The tuning of such parameters can be easily performed by the users thanks to a dedicated software including a user-friendly graphical user interface.

Moreover, temperature control of the water in the stimulation tank can be possible thanks to the use of a heat resistance, thus allowing for example to simulate the in vivo working conditions of the delivery system under test.

In the case of the high-frequency setup, another significant added value of this system is the possibility to simultaneously stimulate three samples in parallel, thanks to the presence of three different transducers aligned with three chambers, which facilitates carrying out the experimental work.

B. Sample holder design and testing

The sample retaining system consists of a polycarbonate disc with three wells (one, in the case of the low-frequency setup) for hosting the samples. Each of these chambers has an open diameter of 16 mm and an open height of 18 mm; their centers are at 7 cm distance from each other in order to prevent possible overlaps between the fields produced by different transducers. At the bottom of each retaining chamber a Stretchlon film of 38 µm thickness was mounted. Elastomeric O-rings were employed to guarantee a hydraulic sealing of the chambers and their compression is guaranteed by an upper polycarbonate plate, which is kept in place through screw nuts and bolts.

The impermeability of the sample retaining system was assessed through a sealing test. It was performed by filling each chamber with deionized water, closing the sample holder and immersing it for 30 minutes in a tank filled with deionized water and fluorescein sodic salt, with the aim to evaluate whether the chamber content was contaminated by fluorescein.

C. Transducers characterization

In order to cover the broad frequency range from 38 kHz to 5 MHz, six different types of unfocused transducers were used: one 50 mm diameter transducer centered at 38 kHz; three 44 mm diameter transducers centered at 600 kHz and used at 500 and 750 kHz; three 23 mm diameter transducers centered at 1 MHz; three 23 mm diameter transducers centered at 2 MHz; three 15 mm diameter transducers centered at 3 MHz; three 15 mm diameter transducers centered at 4 MHz to be used at 4 and 5 MHz.

Calibration of all the transducers was carried out, for each of the aforementioned stimulation frequencies, by means of precise pressure maps and by establishing the relationship between the pressure amplitude at the target and the driving voltage.

The acoustic pressure field was measured using a calibration setup already developed by the authors [12] by means of a hydrophone (Precision Acoustics, Dorchester, Dorset, UK – 2 mm needle; mean sensitivity in the range 0.1 MHz to 10 MHz: 3.5 V/MPa; typical frequency response: flat (4 dB) over the range 100 kHz to 10 MHz).

The intensity calibration was performed by means of the same hydrophone described above for each of the seven stimulation frequencies in the high-frequency range, for finding the relationship between the input voltage and the generated acoustic pressure/intensity. For the 38 kHz transducer, the same calibration procedure was followed, by

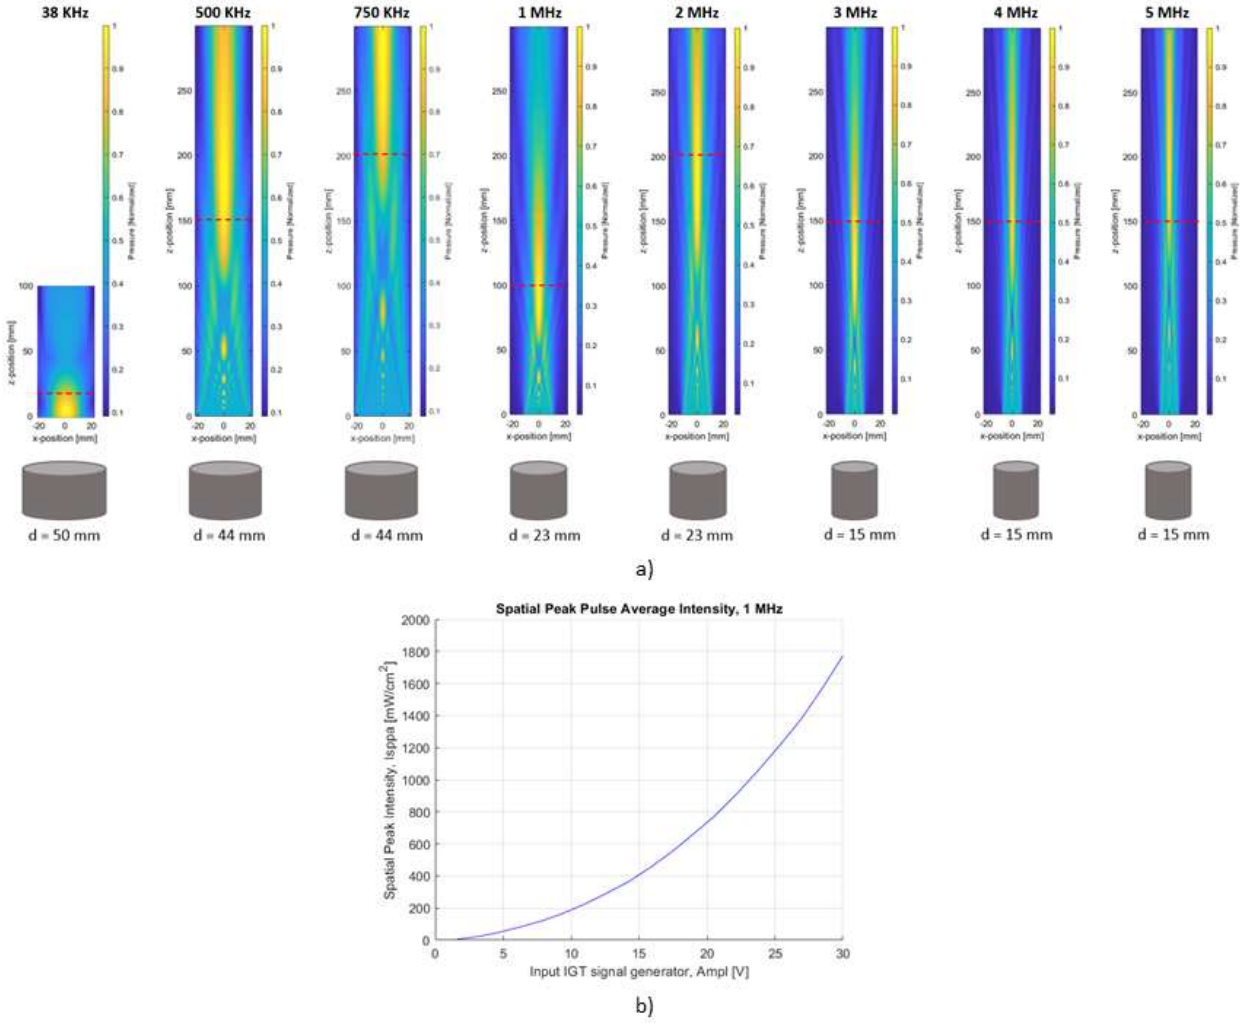

Fig. 2: a) Pressure field maps (in terms of normalized peak-to-peak pressure) for each stimulation frequency in the investigated range. b) Example of a calibration curve expressing the relationship between the applied voltage and the Spatial Peak Pulse Average Intensity (I_{sppa}) measured through a hydrophone

means of an omnidirectional hydrophone (Reson TC 4034, with a frequency response from 1 Hz to 470 kHz (±3 dB)).

III. Results and Discussion

A. Sample holder design and testing

The sample holder was designed and developed to be completely transparent to ultrasonic waves. In fact, the bottom of each retaining chamber was closed through a Stretchlon film of 38 µm thickness, which is smaller than a quarter of the minimum US wavelength employed (i.e. 300 µm, at 5 MHz); this guarantees transparency of the film to the ultrasonic waves, therefore minimizing transmission losses and standing waves formation, which are the typical drawbacks of the commonly used plastic plates.

This US-transparent retaining system prototype was then tested in terms of its sealing ability, performing the test described in paragraph II.*B*. The fluorescence emitted by the liquid inside the chambers resulted to be four orders of magnitude lower than the fluorescence of the liquid filling the tank. Therefore, it was demonstrated that the system possesses an optimal ability to keep the sample chambers isolated from the external environment, and in particular it can effectively avoid water penetration in the wells, which is a crucial requirement for drug release tests, as liquids exchange with the external environment would alter drug concentration assessments.

B. Transducers characterization

The pressure field maps obtained through the hydrophone are shown in Fig. 2a, in terms of normalized peak-to-peak pressure.

The horizontal dashed red lines correspond to planes in the far-field condition, close to the Rayleigh distance, where the pressure field is fully formed and homogeneous, thus representing the optimal distances on the z-axis at which samples under test should be placed during stimulation.

The intensity calibration resulted in the definition of a precise relationship between the voltage provided by the generator to the transducer and the peak-to-peak pressure read by the hydrophone (Fig. 2b), when positioned along the axial direction of the transducer at a distance corresponding to the dashed red lines shown in Fig. 2a.

IV. Conclusion

In this work the design, development and characterization of an innovative system for highly controlled in vitro ultrasonic-mediated drug delivery tests are presented. The setup allows to minimize the typical exposure errors which affect the vast majority of the systems used for in vitro ultrasound experiments, thus allowing to obtain reproducible and reliable results, and providing a precise quantification of the US dose actually delivered to the target. This will enable, in future experiments, a better understanding of the relationship between ultrasound exposure parameters and the effects observed on the tested samples. Furthermore, the system enables the exploration of a broad range of US parameters (i.e. frequency, intensity, duty cycle, pulse repetition frequency) and it can thus be used to investigate different stimulation conditions, allowing parameters optimization for a specific application.

The stimulation setup proposed here could be employed to test a variety of US-responsive drug carriers, such as micro and nanovectors including liposomes and micelles, polymeric particles and perfluorocarbon droplets. Such vectors can be tested in suspension, for intravascular release applications, or embedded in biomaterial structures such as 3D scaffolds and patches constructs with on-demand drug delivery capabilities. Beyond simple carrier testing, this system could also host cells, being able to guarantee the sterility of the internal chambers. This will allow exploring the combined effect of US stimulation and drug release on different cells models.

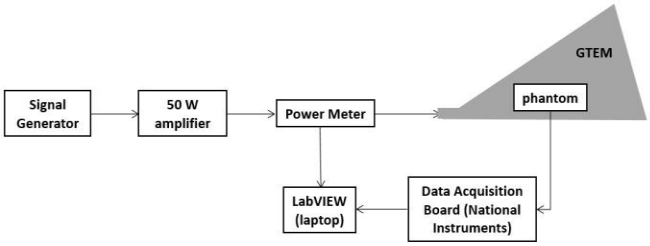
***Abstract*— This study aims at the development of an exposure set-up to investigate AIMDs immunity under far-field exposure conditions, beyond the General Population Reference Levels, and up to Workers Reference Levels, and at the identification of the worst-case condition in terms of lead path and implant configuration. The proposed set up leverages a G-TEM cell to obtain far-field levels above the general population Reference Levels and, for some frequencies, also above worker's reference levels. The proposed set up was able to properly monitor AIMD activity under electromagnetic disturbance inside GTEM cell. Preliminary findings show that the lead path may affect the immunity level of the device at least at frequencies below 600 MHz, and that interferences may not be excluded above- the general population reference levels but still below occupational exposure.**

***Keywords*— AIMD, immunity, electromagnetic exposure, workers.**

I. INTRODUCTION

Nowadays, electromagnetic (EM) sources are rapidly becoming more and more pervasive and active implantable medical device (AIMD) immunity represents a critical issue, not only for general population, but also for workers. In the international standards for AIMDs, at frequencies above 385 MHz, immunity levels are assessed in near-field conditions and expressed in terms of net power at the antenna input (W) [1]. The international standard ISO 14117:2019 Active implantable medical devices — Electromagnetic compatibility prescribes tests to assess AIMD electromagnetic immunity only in near-field configuration, since it mostly takes into account hand-held terminals (e.g. wireless telephones).

On the other hand, the safety limits for the exposure to electromagnetic fields are given in terms of far-field electromagnetic field strength [2]. Thus, the comparison between these two limits is not immediately possible and the immunity level of AIMDs to far-field exposure above 385 MHz is not known. In addition, the international standard [1] states that near-field immunity guarantees a reasonable protection also from far-field EMF up to General Public Reference Values, but no data are available for workers exposure levels [2].



This study aims at the development of an exposure set up able to investigate AIMDs immunity in terms of far-field exposure conditions, beyond the General Population Reference Levels, and up to workers exposure limits, and at the identification of the worst-case condition in terms of lead path and implant configuration.

II. METHODS

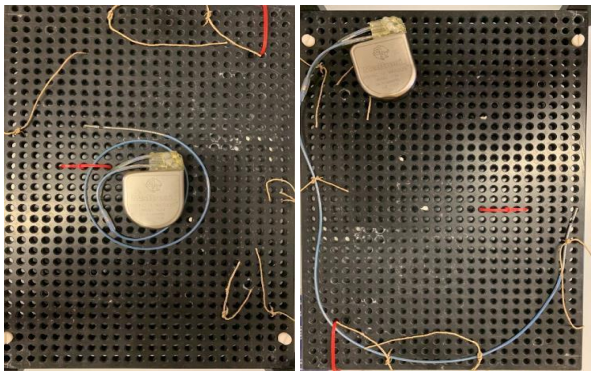
A. Exposure set-up

RF signal generator set up (Fig. 1.a) included: GTEM cell (model GTEM 5311 by Emco) (Fig. 1.b); signal generator R&S 9kHz - 3.2GHz; Amplifier KALMUS 116FC-CE 200MHz – 1GHz 50W, ZHL 50 W-63+ MINI-CIRCUIT 700MHz – 6 GHz; directional coupler Amplifier Research DC7144; RF Power meter 4230 Boonton, 10 kHz - 100 GHz.

The proposed exposure set-up also comprehends a rectangular PVC phantom (Fig. 1.c) for the placement of the AIMD and its leads. The phantom was filled with saline solution (σ=0.27 S/m), and equipped with a grid 1 cm apart from the phantom surface. The phantom was also equipped with four electrodes to monitor the AIMD behaviour during the exposure and to inject a simulated ECG signal. AIMD activity signal was acquired using LabVIEW, after passing through a conditioning and A/D conversion board. The board also generated a heart simulated signal able to inhibit the device. Attention was paid to minimize the coupling between the monitoring cables and the RF field generated inside the GTEM cell.

(a)

(b)



(c)

Fig. 1: (a) schematic representation of the proposed set up; (b) G-TEM cell; (c) rectangular PVC phantom.

B. AIMD implant

An ICD was tested, programmed in DDD mode, at the most sensitive setting (0.2 mV atrial, 0.5 mV both ventricles). Two lead configurations were tested: a spiral configuration (as indicated in [1]) (Figure 2.a) and a loop configuration, forming the loop as large as possible (Figure 2.b). The specific ICD tested allowed also to collect electrograms using real time telemetry, and thus to detect any RF induced malfunctions.

(a) **(b)**

Fig. 2: (a) spiral configuration; **(b)** loop configuration.

C. Test procedure

The following frequencies were tested: 385, 450, 600, 700, 800, 830, 825, 850, 875, 900, 930, 1610, 1850, 1910, 2450, 3000, 3600, 4000 MHz. Both continuous and pulse RF signals were generated. The RF pulsed signal is 100% amplitude modulated at 2Hz (25 ms ON and 475 ms OFF). For each frequency, the unperturbed E-field was measured at 1.4 m from the apex of the GTEM. Then, the phantom was placed where the E-field was measured and the ICD activity was monitored to detect if EMI events occurred (oversensing, undersensing or asynchronous pacing).

Finally, if any EMI event was recorded, injected power was lowered until the EMI was no longer detected. Threshold power level and E field strength at which ICD return to its correct functioning were also collected.

Tests were carried out at the INAIL facilities in Monte Porzio Catone.

III. RESULTS

Table I reports the unperturbed E-field values obtained at the selected frequencies along with the corresponding power injected into the GTEM cell. In the last two columns exposure limits for general public and workers are reported.

The first significant result is that the proposed exposure set allows to obtain EMF levels above general population reference levels, and in some cases even above workers reference levels.

EMI events were detected only at 385 MHz and 450 MHz. The EMI events were oversensing in the atrium channel that triggered inappropriate ventricular pacing. Fig.3 shows the electrograms reporting one of the EMI events observed.

Table II reports the threshold power levels and E field values at which the ICD returns to its correct functioning. Noteworthy, the loop configuration is more susceptible to interference than the spiral configuration.

TABLE I: UNPERTURBED E-FIELD MEASURED VALUES

Frequency [MHz]	*Injected Power [W]*	*E field [V/m]*	*General public exposure limit [V/m]*	*Worker's exposure limit [V/m]*
385	44.4	93.7	28	63.6
450	46.7	76.3	29.2	63.6
600	47.4	60.2	33.7	73.5
800	48.5	88.7	38.9	84.9
825	51.4	110.5	39.5	86.2
850	53.6	96.2	40.1	87.5
875	55.6	100.2	40.7	88.7
900	57.3	112.7	41.3	90
930	58.4	76.1	41.9	91.5
1610	54.0	77.1	55.2	120.4
1850	48.0	90.4	59.1	129
1910	48.8	92.8	60.1	131.1
2450	51.3	87.2	61	140
3000	38.6	81.9	61	140
3600	27.2	63.0	61	140
4000	27.3	78.4	61	140

TABLE II: EMI THRESHOLD POWER LEVEL

Lead configuration	*Frequency [MHz]*	*Threshold Injected Power [W]*	*Threshold E field (unperturbed) [V/m]*
Loop	385	8.8	40.6
Spiral	385	25.9	69.8
Loop	450	19.1	60.4
Spiral	450	>47	>76.3

IV. DISCUSSION

According to international technical standards, AIMDs immunity levels are derived from the European Recommendation 1999/519/EC [2],[3], which set the E-field reference levels for general public at $1.375\sqrt{f}$ V/m in range 400 – 2000 MHz and 61 V/m above 2 GHz. Workers can be exposed to higher values (Directive 2013/35 [2],[4], $3.0\sqrt{f}$ V/m and 137 V/m above 2 GHz). Testing at such high levels is quite challenging.

The proposed set up leverages the use of a G-TEM cell to obtain far-field levels above the general population Reference Levels and, for some frequencies, also above worker's reference levels. Besides the frequencies listed in ISO 14117 standard we include frequencies above 3 GHz, in view of the new RF emitters that are becoming more popular (e.g. 5G systems).

The proposed set up was able to properly monitor AIMD activity under electromagnetic disturbance inside GTEM cell.

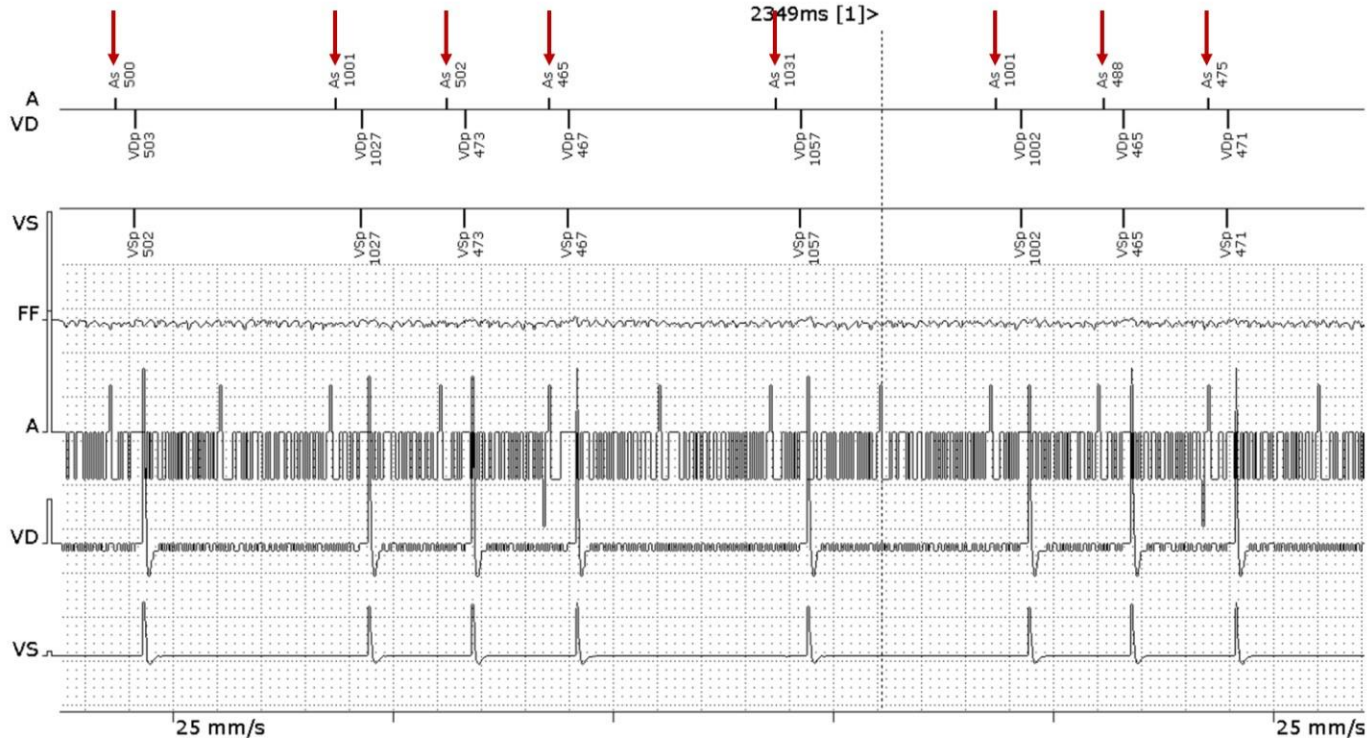


Fig. 3: Electrogram showing the EMI events. Arrows indicate spurious and inappropriate sensing of the atrial activity.

In the specific ICD tested, at 385 MHz and 450 MHz, we observed EMI events at field levels above the general population reference levels but below workers reference levels.

The EMI events observed showed that, at least at these frequencies, the lead path may affect the field level at which the malfunction occurs.

The role of the lead path at higher frequencies could not be assessed since no EMI events were observed.

V. Conclusion

In the international standards for AIMDs, at frequencies above 385 MHz, immunity levels are assessed in near-field conditions. Thus, there is a lack of information about AIMD immunity levels in far-field conditions. This issue is relevant not only for general population but also for workers, since they can be exposed to higher EMF levels. This study proposed a set up to investigate AIMD behavior when exposed to EMF values above general population reference levels.

Preliminary findings show that the lead path may affect the immunity level of the device at least at frequencies below 600 MHz, and that interferences may not be excluded above- the general population reference levels but still below occupational exposure.

Further improvements of the set up are needed to obtain exposure levels up to or above occupational levels for all the frequencies of interest. One limitation of this study is that it was carried out only on a single device and two implant configurations. The main aim of the paper was to propose and demonstrate the feasibility of a novel approach to investigate EMC issues for AIMD in far-field exposure condition. In future studies, a more representative sample of devices and implant configuration will be taken into account, to verify the repeatability of the observed events.

***Abstract*— Type 1 Diabetes is a life-threatening condition for which there is no cure, at the moment. Its treatment consists of multiple daily blood glucose level measurements and insulin injections to keep the blood glucose level in the physiological range. In this scenario, an implantable insulin pump refillable through ingestible insulin-carrying capsules has been proposed. However, successful implantation requires the minimization of the foreign body reaction, a host defense mechanism that ultimately results in the production of a fibrous avascular capsule that isolates the implantable device. In this work, zwitterionic materials are explored as an antifouling coating on the artificial pancreas external case, exploiting the steric hindrance effect of their chains and the formation of a hydration barrier. In particular, the 2-methacryloyloxyethyl phosphorylcholine (MPC) zwitterion was combined with polydopamine to create a coating on poly ether-ether-ketone – PEEK. A novel strategy for the formation of a polydopamine-mediated zwitterionic coating is proposed and compared with other two strategies drawn from the literature. The stability over time of the obtained coating is assessed in a simulated biological environment by measuring the changes in the substrate wettability. The results show that the proposed strategy results in a stable MPC coating on PEEK for up to 8 weeks.**

***Keywords*— MPC, PEEK, implantable device, artificial organs, zwitterionic coating, antifouling.**

I. Introduction

Type 1 Diabetes (T1D) is a life-threatening condition featured by the immune-mediated destruction of insulin-secreting pancreatic β-cells and, consequently, blood glucose regulation [1]. To date, there is no cure for this condition, and its prevalence is dramatically increasing, predicting to reach 13.5-17.4 million people worldwide by 2040 [2].

The mainstay of treatment for T1D is multiple daily glucose level measurements and the injection of appropriate amounts of insulin to maintain the blood glucose level in the physiological range (80-110 mg/dL) [1]. This can be done by the patient with self-injections; however, it results in high glycemic variability that also depends on the patient's ability [3]. Subcutaneous or intraperitoneal closed-loop insulin pumps can decrease this variability [3], [4]. However, on the one hand, subcutaneous insulin delivery has slower pharmacokinetics and dynamics than physiological release [5]. On the other hand, refilling intraperitoneal (ip) pumps is invasive and has to be performed in a clinical setting, increasing the risk of infections [6]. Furthermore, implanted ip pumps (e.g., the Minimed® system from Medtronic) were subjected to a fibrotic reaction, which created a visible bump, raising aesthetic issues [7]. To overcome these limitations, an implantable ip insulin pump refillable through ingestible insulin-carrying capsules has been proposed [7], [8] and tailored for implantation in humans, in an intraperitoneal pouch [9] as shown in Fig. 1a.

In the works published so far on this topic, the possible effects of foreign body reaction (FBR) was not taken into account. FBR is an irrevocable host defense mechanism that starts with the undesired adsorption of non-specific proteins onto the external surface of the implanted device, followed by the arrival of immune system cells and fibroblasts [10]. This process leads to the formation of a fibrous avascular capsule that excludes the device from the rest of the body [10], causing several iatrogenic complications [11] that can result in device failure [12] or aesthetic issues. In particular, in the solution proposed in [8], [9], [13], the device functionality relies on proper positioning and coupling with the intestinal tissue. Thus, an excessive fibrotic reaction can considerably hinder the implant success. Hence, it is critical that the external surface of the device has antifouling properties to decrease the risk of device failure.

II. Selection of Material for the Device Case and Functionalization Strategy

We selected poly ether-ether-ketone (PEEK, Fig. 1a) as the material for the device's external case. Indeed, PEEK has low water permeability, high mechanical resistance, and biocompatibility [14], [15]. Then, we functionalized PEEK with an antifouling coating. We combined the versatility of polydopamine (PDA) with the antifouling potential of zwitterions [16], [17], [18], [19] to create an antifouling coating that could be used on different substrates. Indeed, this approach has already been used to functionalize catheters [20], interfaces for in vivo sensing in the brain [19], and cardiovascular stents [21]. However, because of the different zwitterions and deposition strategies, it is difficult to draw conclusions about the best approach to create an antifouling coating for the polymeric material enclosing an implantable device. In this work, we compared three strategies to form a polydopamine-mediated polymeric zwitterion coating on PEEK to decrease the risk of failure of the artificial pancreas presented in [8], [9]. To this end, we evaluated the wettability of the zwitterionic coating and its stability over time. For this evaluation, the 2-methacryloyloxyethyl phosphorylcholine (MPC), was selected. It is a highly hydrophilic zwitterion that has already been used in several biomedical applications, such as the coating of Ahmed glaucoma valve [22], hip prosthesis [23], and even a glucose monitor device [24].

III. MATERIAL AND METHODS

A. Coating fabrication

Three different strategies to functionalize PEEK were evaluated (Fig. 1b). For each strategy, five independent samples of 3D printed PEEK (Roboze spa, Italy) with a diameter of 12 mm and a height of 1 mm were used, ultrasonicated in a 70% ethanol solution for 15 min [25] and dried overnight.

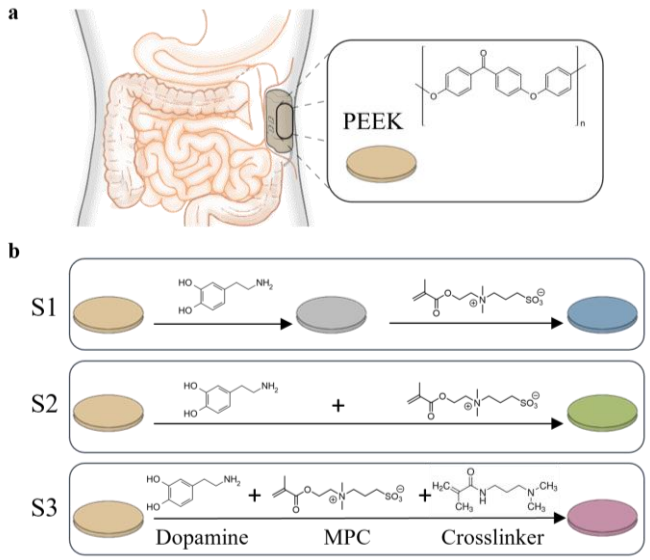

Fig. 1: a) Depiction of the insulin pump implantation site and chemical structure of PEEK, the material selected for the external case of the device. b) Scheme of the three coating strategies (S1, S2, S3) devised for the deposition of the zwitterionic coating on the PEEK substrates and chemical formulas of the components used.

In the *first strategy* (S1 in Fig. 1b), a monomeric zwitterionic layer was obtained in a two-step process. The PDA layer was first deposited onto the surfaces of the substrate, by means of a deep-coating technique [26]. After that, the obtained PDA-coated disks were further functionalized with a zwitterionic layer by Michael addition [16], [19].

Specifically, five cleaned disks of PEEK were immersed in 10 mM Tris buffer solution (8.5 pH) containing dopamine hydrochloride (Sigma-Aldrich) at a concentration of 2 mg/mL at 25°C [16] for 24 h [26]. Then the samples were washed extensively with deionized (DI) water and let dry overnight. After that, the PDA-coated disks were further functionalized by immersing them in a solution of DI water, ethanol, and triethylamine (TEA) with a volume ratio of 400:80:3 and MPC (Sigma-Aldrich) at a concentration of 100 mM. The reaction solution was magnetically stirred at 25°C [18], for 24 h, then the samples were rinsed with DI water and let dry overnight [16], [18].

The *second* and *third strategies* consist of one-step processes, characterized by the co-deposition of a PDA layer functionalized with linear zwitterionic chains and zwitterionic co-polymer respectively, starting from the monomers of dopamine hydrochloride and MPC. In the co-deposition process, the abundant free radicals generated during the oxidative dopamine polymerization trigger the polymerization of zwitterionic monomers [17].

In the *second strategy* (S2 in Fig. 1b), five cleaned disks of PEEK were pre-wetted with ethanol and then immersed in a solution containing 50mM Tris buffer solution (8.5 pH), dopamine hydrochloride, and MPC with a mass ratio of 1:15 [17]. The reaction solution was magnetically stirred at 25°C for 8 h. After that, the samples were washed and soaked in DI water overnight [17].

The *third strategy* (S3 in Fig. 1b), is a novel one that has been devised to create a zwitterionic co-polymer on the substrate. It is based on the same protocol of the second strategy, but with the addition of a co-monomer (N-[3-(dimethylamino)propyl]acrylamide, AmBeed) in the reaction solution, at a concentration of 0.3 mg/mL.

All the coated PEEK samples were stored in Phosphate Buffer Saline (PBS) solution (Sigma-Aldrich) for 8 weeks at 37°C under continuous shaking to mimic a physiological environment and were characterized at different time points (see Section IIIB).

B. Wettability measurements

The antifouling properties of the zwitterionic materials is due to the steric hindrance effect of the polymer chains and the formation of a hydration barrier, preventing the first attachment of molecules on the surface of the implant. For that reason, one well-known indirect method to investigate the presence of a zwitterion coating consists of quantitatively measuring the change in the substrate wettability with static water contact angle (WCA) [19], [27], [28], using a contact angle goniometer (Ossila Ltd., UK).

All samples were tested before and after the coating formation. In the two-step strategy - S1 - the measurements were repeated after each step.

In the WCA measurements, a 7.5 µL droplet of DI water from a microliter syringe was placed on the dried sample, then a camera took a digital photo of the stationary drop. The contact angle of the micro-drop was measured by using the software provided by the company (Ossila Ltd, UK). Then, the sample was stored in PBS solution, as reported in Section IIIA. To investigate the stability of the coating in a simulated physiological environment, the WCA measurements were repeated at different time points (after 1, 2, 3, 4, and 8 weeks).

C. Statistical analyses

A Kruskal-Wallis test was applied to the WCA measurements taken after every time point since the hypothesis of normality was rejected by Kolmogorov-Smirnov's test. Then, the Dunn test was applied as a multiple comparison analysis to compare the changes between the experimental groups. Statistical significance was set at the family-wise error rate of $\alpha = 0.05$.

IV. RESULTS AND DISCUSSION

The functionalization of the PEEK with a polydopamine-mediated zwitterionic monomeric layer (S1) resulted in an increase in hydrophilicity . Indeed, the WCA decreased from 86.5 ± 6.9° (mean ± std) for the PEEK to 46.3 ± 4.0° after the PDA deposition, reaching 42.6 ± 1.9° with the zwitterionic layer (first column of Fig. 2a). This trend is in line with what previously shown on a metal substrate using a similar two-

steps process and the same zwitterion. The wettability measured after each step was lower than the values reported in the literature, which are close to 65° and 51° for the PDA and PDA-MPC layers respectively [21]. However, due to the difference between the substrates, it is difficult to make a direct comparison. After one week in the PBS solution, the WCA significantly decreased ($p<0.05$) to 19.7 ± 7.3°. Thereafter, the hydrophilicity slightly increased over time, reaching the maximum after eight weeks (24.2 ± 6.3°) as shown in the first column of Fig 2b.

The functionalization of PEEK with linear zwitterionic chains (S2) resulted in an increase in hydrophilicity as shown in the second column of Fig. 2a. Specifically, the WCA decreased from 84.6 ± 6.6° to 23.2 ± 6.6°. However, the WCA of the functionalized PEEK resulted slightly higher than the one previously found on a Si wafer [29]. After one week in the PBS solution, the WCA had an initial decrease and then remained stable until week 4, when it significantly increased until week 8 (1-8 weeks: $p=0.047$), as shown in the second column of Fig 2b.

The functionalization of PEEK with zwitterionic co-polymer (S3) resulted in a significant increase in hydrophilicity ($p=0.022$), with a WCA that reached 4.1 ± 0.6 ° (third column of Fig. 2a). Furthermore, this value was stable over time, as shown in the third column of Fig 2b.

In the first and the second strategy, after one week in PBS solution, the PEEK samples functionalized with the zwitterionic coating increased their hydrophilicity. This is probably due to the presence on the surface of salinity left by the PBS solution [30].

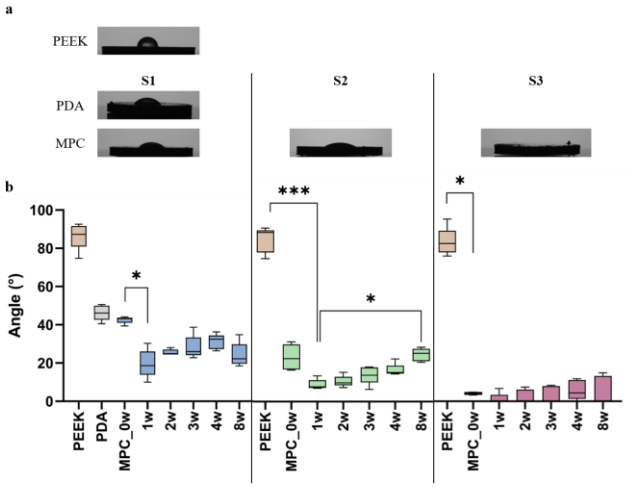

Fig. 2: a) Representative photos taken by the WCA goniometers for the substrate before and after the deposition of the zwitterionic coating with the three strategies. b) Box plots of the WCA measured before (PEEK), after the coating deposition (MPC_0w), and in the intermediate step (PDA) for strategy S1. *=p<0.05, **=p<0.01, ***=p<0.001.

Regarding the comparison of the three strategies for coating formation, the S3 (newly introduced in this work) led to superior results. Indeed, the PEEK functionalized with zwitterionic co-monomer resulted in the highest hydrophilicity, which remained stable up to week 8.

V. Conclusion

In this work, a novel strategy for the formation of a polydopamine-mediated MPC coating was devised and compared with other two strategies drawn from the literature on 3D-printed PEEK. The stability over time of the coated samples in a simulated physiological environment was also investigated. Results show that the newly proposed strategy results in a stable zwitterionic coating for up to 8 weeks, outperforming the other approaches. This strategy can be considered promising for coating the external case of artificial pancreas and other implantable devices. Further chemical and biological analyses will enrich this study. Furthermore, future studies on different substrates could be conducted to further verify the versatility of the poly-dopamine primer and the efficacy of the strategy devised.

Temperature influence on reflectance photometers for bilirubin measurement

L. Zucchini[1], M. Ajčević[1], A. Accardo[1]
[1] *Department of Engineering and Architecture, University of Trieste, Trieste 34127, Italy*

***Abstract*— An accurate and prompt measurement of unconjugated bilirubin in neonates is fundamental to prevent potentially severe pathological conditions, such as kernicterus which can lead to neurological impairments or death. Several methods were developed to measure bilirubin, in particular direct photometry could be promising and useful both inside and outside clinical facilities. Being applicable to portable devices, it is deemed necessary to investigate how this method is affected by the temperature of air surrounding the device itself, considering the diversity of environments in which a portable device may operate. In this work, a set of eight identical two-wavelength reflectance photometers (blue 465 nm and green 570 nm) were used to execute measurements while heating surrounding air from 15 to 30 °C. The measurements were made on purpose-built paper test strips having eight different absorbances instead of using real bilirubin samples, guaranteeing stability over time and temperature variations. Over 90.000 measurements were performed, and the relation between the reflectance data and external temperature was investigated. A high correlation (R^2>0.95) was identified both for blue and green light showing a significant linear and quadratic relation, respectively. The temperature dependency was more pronounced in case of lower absorbances. In conclusion, we identified the dependency of reflectance on temperature in these devices. The results showed that measurements performed at higher temperatures induced reduction of measured reflectance, leading to potential overestimation of bilirubin.**

***Keywords*—Bilirubin, photometry, temperature, reflectance.**

I. Introduction

Bilirubin is the major product of erythrocytes breakdown; under normal conditions unconjugated bilirubin is released in plasma where bounds to albumin, until it's excreted in bile as conjugate bilirubin [1,2]. In neonates, this metabolism is stronger and unconjugated bilirubin forms in higher concentrations: while a temporary and controlled increase is known to be physiological during the first days of life, an abnormal concentration of unconjugated bilirubin can lead to a pathological condition known as hyperbilirubinemia; due to the neurotoxicity of bilirubin, this condition can lead to kernicterus or death [2–4]. More than half of neonates develops benign hyperbilirubinemia during the first week of life, and roughly one in ten newborns develops clinically significative hyperbilirubinemia [3,4]. In these cases, frequent monitoring of serum bilirubin is needed to establish a proper treatment and reduce chances of neurological damage [5,6].

Several methods were developed to measure bilirubin concentration, both with invasive and non-invasive approaches. Currently used invasive methods are based on diazo reactions or vanadic acid reactions with bilirubin, while non-invasive methods, like transcutaneous bilirubinometers, have been on the market since 1980s [7,8]. An alternative invasive method is direct photometry which presents some advantages: a) it operates directly on plasma or serum without reagents and sample volume can easily be minimized to microliters; b) its complexity and cost are reduced due to the use of visible wavelength; c) it is suitable for compact portable devices. On the other hand, disadvantages are: a) some substances in plasma can interfere with bilirubin, such as oxyhemoglobin; b) any opalescence resulting from sample treatment can limit the accuracy; c) it is only valid for neonates due to the presence of other interfering substances, such as carotenoids, in children and adults [8–11]; d) it is influenced by temperature as stated in the Lambert-Beer law.

The use of direct photometry for bilirubin assay traces back to 1960s [11]; since then several invasive and non-invasive applications of this method have been proposed [9,10,12,13]. However, no literature concerning temperature influence on such systems was found.

Bilirubin measurement devices in clinical settings operate under controlled environment rooms where temperature is almost constant but, as aforementioned, direct photometry can be applied to portable and field instrumentation, which can be used both inside and outside clinical facilities, thus in environments with diverse temperatures.

The aim of this work is to determine the effect of external temperature on the measurement of bilirubin concentration using a simple two-wavelength reflectance photometer.

II. Materials and methods

A. The reflectance photometer

A set of eight identical photometers was used to ensure the repeatability of evidence found during the experiment. Each photometer was composed by an optical chamber, two LEDs (KPHHS-1005QBC-D-V and KPT-1608CGCK, Kingbright Electronic Co., Ltd., Taiwan), a photodiode (TEMD6200FX01, Vishay Intertechnology, Inc., USA), and other electronic components necessary for the acquisition of the signal (Figure 1). The LEDs emitted light at 465 nm and 570 nm, hence blue and green light respectively, and irradiated the sample inserted in the chamber; since no light was transmitted through the sample, the fraction of light not absorbed by the sample was reflected towards the photodiode; the output current of the photodiode was converted to a tension, then digitized with 0 to 3 V range. In this way, the photometer acquired the intensity of reflected light: a high intensity indicated high reflectance, or equivalently low absorption, and vice versa.

A temperature sensor with 0.25 °C resolution (LM73, Texas Instruments, Inc., USA) was placed on the electronic board of each photometer, adequately far from heat sources like microcontrollers or power supplies. Such placement was deemed better than using a single sensor for all instruments: the measurement of "ambient" temperature, intended as the

temperature of the environment in which the instruments were placed, could have differed considerably from the air immediately surrounding the instruments themselves; placing a temperature sensor as near as possible to the optical chamber produces more accurate results [14,15].

Finally, each photometer was provided with a 16-bit ADC and a microcontroller (MKL15Z32VFT4, Freescale Semiconductor, USA) that sent intensity values to a single computer that stored all data.

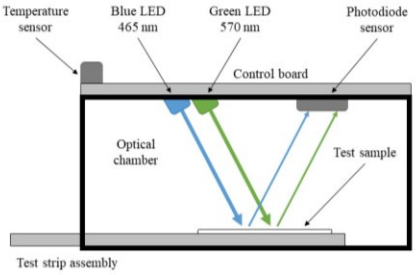

Fig. 1: A schematic representation of one of the photometers used in the experiment. The test strip is inserted into the optical chamber where two LEDs irradiate the sample; a fraction of the light is reflected and detected by the photodiode.

B. The test samples

A set of eight paper test strips was fabricated, simulating different levels of absorption by bilirubin distributed across the input scale of the photometers. Considering that the study is focused on the identification of temperature impact on the measurements, the use of plasma or diluted bilirubin was excluded; this choice allowed to avoid errors due to biological samples preparation, treatment, and conservation. Additionally, "real" samples would not have maintained chemical and physical stability throughout the experiment: bilirubin oxidates when exposed to blue light, bringing further interference to the system [4,6,7].

As demonstrated in Figure 2, eight different patterns were created to form a logarithmic greyscale from an almost white to a very dark shade, then printed with laser printers on normal paper; the patterns were then cut and laid down on test strips assemblies. Since all eight photometers were subjected to the test contemporarily, eight test strips were prepared for each of the eight levels, thus 64 in total. This method had some advantages, two were the most important: a) printing the pattern on paper led to repeatable reflectance values among different strips with the same grey level; b) reflectance values were stable during the whole experiment and any damaged strips could have been replaced easily.

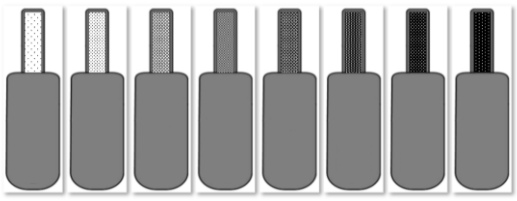

Fig. 2: The greyscale pattern created for the experiment and the test strips, which shape was suitable to fit the optical chamber. The strips were enumerated from 1 to 8 in order of absorbance.

C. Experimental procedure

To measure the influence of external temperature on intensity value, the photometers were placed inside a temperature test chamber. At the beginning of each test, one of the eight groups of test strips was loaded, and the photometers were cooled at 15 °C, maintaining low levels of humidity to avoid condensation of water on the electronic boards and inside the optical chambers. After cooling, they were immediately connected and powered on, and the temperature test chamber was set to 40 °C: in this way, during the heating process, the instruments could reach thermal equilibrium with the test chamber starting from 15 °C or slightly under. Simultaneously, their firmware was started: with a period of 10 s, the instruments executed four consecutive instantaneous readings with the 465 nm LED and another four with the 570 nm LED; the four readings made with each wavelength were arithmetically averaged and sent to the central calculator, as well as timestamp data and temperature data. In other words, every 10 seconds the calculator received eight "rows" of information, one from each instrument, containing timestamp, temperature, blue light intensity, and green light intensity. The experiment was stopped when all temperature sensors provided a temperature above 30 °C. The photometers were consequently powered off and let chill again. This described workflow was repeated eight times, one for each test strip group. To avoid bias errors due to experimental design, such as instruments hysteresis, all the acquisitions for all experimental settings were also performed by starting from 30 °C and cooling the devices until reaching temperatures below 15 °C, hence reversing the described process.

Before and after each test all the test strips and the optical chamber were visually inspected to assess the absence of moisture, condensation, or damages. During the execution of each test both the temperature test chamber and the instruments inside were not moved or handled to avoid producing motion or vibration artifacts.

For each instrument, each test strip, and each wavelength the same procedure was used for the analysis. Any measure below 15.0 °C or above 30.0 °C was excluded from the analysis. Then, 15.0 °C was adopted as reference temperature (T_{ref}): the lower limit of temperature range was set at 15.0 °C as cooling the devices at lower temperatures caused frequent condensation inside the optical chamber of the instruments, or in the paper test strips. For each test, all blue and green measures executed at exactly T_{ref} were averaged in order to find an intensity reference for blue and green data, respectively, identified as $I_{ref,b}$ and $I_{ref,g}$.

As the temperature inside the test chamber increased, each i-th measure was defined by a T_i temperature and an intensity value, $I_{i,b}$ for blue light and $I_{i,g}$ for green light. Consequently, the variation of temperature and blue and green intensity from their respective reference were calculated for each i-th measure:

$$\begin{cases} \Delta T_i = T_i - T_{ref} \\ \Delta I_{i,b} = I_{i,b} - I_{ref,b} \\ \Delta I_{i,g} = I_{i,g} - I_{ref,g} \end{cases} \quad (1)$$

III. RESULTS

Over 90.000 measurements were performed by the eight photometers testing all eight test strip groups. Intensity values for each instrument and each test strip were plotted against time and inspected. The decreasing trend of measured intensity was observed for higher external temperature values, highlighting an increase in absorbance for higher temperatures. Figure 3 shows the temporal trend of intensity and temperature for the lightest strip (Strip 1) irradiated with 465 nm light in one of the eight instruments.

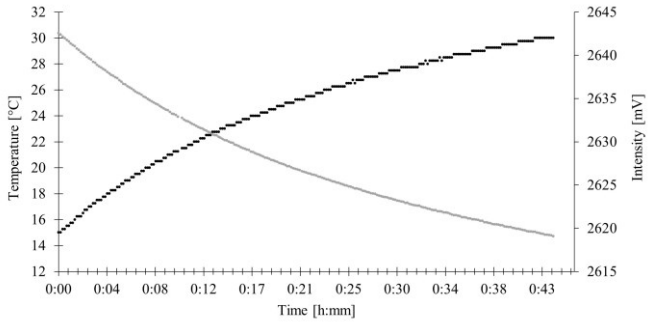

Fig. 3: An example of the typical temporal trend resulting from the experiments, intensity vs. time (grey) and temperature vs. time (black).

In Figure 4 an example of ΔI for blue and green light plotted against ΔT is reported, regarding one of the instruments measuring the lightest strip. A negative relation can be observed between intensity and temperature causing underestimation for temperatures higher than the reference one.

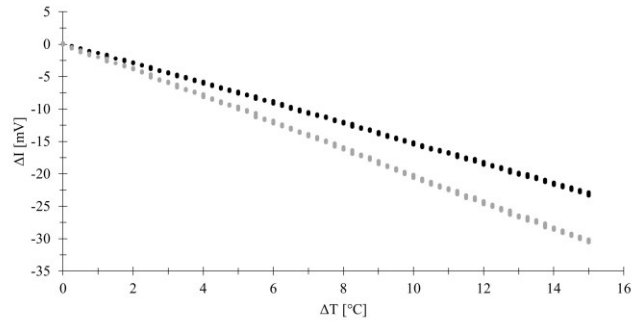

Fig. 4: ΔI_b vs. ΔT (black dots) and ΔI_g vs. ΔT (grey dots). The quadratic behaviour of the relation between green intensity and temperature is noticeable especially in ΔT included in the range 0-4 °C. Data is extrapolated from one of the instruments and refers to the lightest strip.

Blue intensity was differently affected by temperature with respect to the green intensity, with the latter showing a more pronounced quadratic behaviour especially for small ΔT, while the first being linear. Linear functions were then used to approximate the relationship between ΔI_b and ΔT, while quadratic functions were used to approximate the relationship between ΔI_g and ΔT; in every test the approximation resulted in a coefficient of determination R^2 greater than 0.95.

Lighter test strips caused wider deviations from the intensity reference, while darker ones were less influenced by temperature. Table 1 indicates that the relation between ΔI and ΔT depended on the test strip group, hence from the concentration of the sample: for higher concentrations the effect of temperature decreased. This was valid for both blue and green data despite the difference in terms of approximation function degree; the first-grade polynomial coefficient (*m* for blue, *b* for green) exhibited a coherent dependence on strip type.

Finally, the analysis of reversed experiments, therefore with temperature starting at 30 °C until 15 °C, showed no significant differences with the regular setup suggesting the absence of instrument hysteresis effects.

TABLE I: POLYNOMIAL INTERPOLATION RESULTS

	Blue light (465 nm)		*Green light (570 nm)*		
	m	*q*	*a*	*b*	*c*
Strip 1	-681.647	43.862	6.808	-1077.09	0.672
Strip 2	-488.149	64.625	5.915	-811.407	21.209
Strip 3	-421.097	61.836	5.108	-718.362	19.693
Strip 4	-384.226	43.467	3.79	-642.316	52.764
Strip 5	-358.341	33.193	3.913	-607.721	44.35
Strip 6	-351.935	8.435	3.035	-558.412	-17.251
Strip 7	-311.295	39.456	5.058	-564.956	29.77
Strip 8	-335.417	9.1	5.184	-562.882	-13.577
Mean	-416.513	37.997	4.858	-692.893	17.203
±SD	±32.998	±58.271	±1.05	±35.098	±46.433

Strip 1 is the lightest, while Strip 8 is the darkest. For blue light *m* is the first-degree polynomial coefficient, and *q* is the zero-degree one. For green light *a* is the second-degree polynomial coefficient, *b* is the first-degree polynomial coefficient, and *c* is the zero-degree one. Stated values are the result of the average of the values provided by the single photometers.

IV. DISCUSSION

Neonatal hyperbilirubinemia is known as one of the burdens of developing countries, affecting tenths of thousands of newborns and inducing permanent damages to many of them [2]. In developed countries instead, where the incidence is much lower and management protocols are well-established, it is essential to provide effective solutions for reducing costs related to diagnosis and treatment [7].

For these reasons a broad range of methods for the measurement of bilirubin in neonates have been developed, reflectance photometry being one of them. Although being a promising method no evidence was found regarding temperature influence on such systems; this aspect is believed to be fundamental, especially when considering that this method is applicable to portable instruments, which could be used in various environments and not only in clinical laboratories. Previous literature facing temperature influence on optical sensors and spectrometers was found, even though not involving medical systems but agricultural systems [14,16].

The focus of this work was to correlate external temperature and reflectance readings of a series of photometers for bilirubin measurement application. Placing temperature sensors directly on-board allowed to measure the temperature of air immediately surrounding the instruments rather than generic air temperature. Investigating photometers behaviour at temperatures from 15 to 30 °C was necessary to cover different scenarios of use, inside and outside clinical facilities; a large amount of data was consequently produced and allowed a robust analysis.

A first result was how blue and green light were influenced by temperature regardless of the strip type: blue light showed a linear behaviour, while green light was correctly interpolated by quadratic function. In any case, the common feature was a reduction in reflectance for higher temperatures: a reduction of reflectance by the sample is associated to an increase of its

absorbance, hence to greater concentration of bilirubin in the sample itself. In other words, as temperature increases the instrument tends to overestimate bilirubin concentration.

Since blue and green LED measures were executed with a delay of just tenths of a second from each other on the same strip and at identical external conditions, the difference could be traced back to the LEDs characteristics: 465 nm LEDs are less sensitive to temperature than 570 nm LEDs or, in other words, the relative luminous intensity of the first is less dependent from temperature and more linear than the latter.

The second result is how test strips type correlates with temperature, or equivalently how the result of the measurement of a sample varies with temperature. Table I demonstrates how a lighter sample, which reflects most of the incident light, is more temperature dependent than a darker one, producing a steeper relationship. This phenomenon should be associated with the relationship between sample absorbance and temperature: a sample containing a certain concentration of bilirubin provides a certain absorbance dependent to its temperature, as defined by the Lambert-Beer law.

In conclusion, we identified the dependency of reflectance on temperature in these devices. The results showed that measurements performed at higher temperatures induced reduction of measured reflectance, leading to potential overestimation of bilirubin. Future research should be focused to develop mitigating strategies to compensate the effect of temperature on reflectance photometers designed for bilirubin measurements.

***Abstract*— Medical students must master many different skills prior to starting clinical practice. As practicing on real patients is no longer an option for ethical and working time issues, one possibility medical training can be exploited is through simulations involving manikins. However, manikins need to be surrounded by a fully simulated environment to increase engagement and realism to the simulation. A possible alternative is Virtual Reality (VR); yet, VR applications do not provide realistic haptic feedback, which is fundamental for dexterity training. To overcome these limitations, we designed and developed systems coupling the advantages of VR with those of traditional manikin-based simulations. We developed two educational tools: a Mixed Reality Simulator for Trauma management, MR STEVE, and a Simulator for Newborn Life Support Training, RiNeo MR. Both solutions include a sensorized manikin collecting performance data, a leap motion device to track the users' hands in real time, and a VR headset delivering immersive content. In the virtual environment, the user sees a virtual patient, overlapped with the real one; this way, the user has visual and tactile feedback simultaneously. This is a methodological study highlighting how to combine VR with physical manikins, with the final goal of improving medical training.**

***Keywords*— Virtual Reality, Mixed Reality, Medical Simulation, Trauma Management, Newborn Life Support**

I. Introduction

Patient safety has always been a crucial aspect within the medical field [1]. Historically, students had learned medical skills by practicing on people. However, the learning curve to reach a proficiency level in many medical procedures is steep and strongly subjective [1], and the risk of harming or making patients uncomfortable for lack of practice is no longer being accepted.

For all the reasons mentioned above, medical simulation techniques have been exploited within the last decades [2]. Simulation lets students practice in a riskless and controlled environment [2], and it allows them to practice repeatedly dexterity skills, procedures and soft skills, having the possibility to learn from mistakes [1], [2].

Medical tools include standardized patients, namely, actors who are signed up to teach how to collect clinical history, perform examinations and communicate with the patient. Also, manikins with various levels of fidelity are largely used to teach manual and soft skills [1]. Finally, virtual reality (VR), and augmented reality (AR) applications have garnered more interest in medical training, as they make it possible to create a immersive and realistic experiences in a digital environment [3]. In detail, VR applications are used for procedural training and soft skills training and evaluation; AR is employed for enhancing high-fidelity simulation and to teach basic theoretical skills (i.e., anatomy); mixed reality (MR), namely the combination of virtual and physical elements is typically used in the surgical domain [4].

One of the main limitations of using high-fidelity manikins, is the need for a realistic setting around the manikin. In fact, there are studies reporting that learning and retention are increased if the entire simulation setting is realistic [1]. Also, stress management and communication skills need a realistic and engaging scene to be properly simulated [5]. As opposite, VR lacks of realistic haptic feedback which can affect the learning outcome [4].

To overcome these limitations, a possibility would be to combine a real manikin with a VR application, resulting in an MR system [4].

To date, some research groups are developing MR simulators for adult Cardiopulmonary Resuscitation (CPR) [6]–[8]; however, the works are still at a prototype stage and their use and effectiveness have not been fully investigated yet [4]. Furthermore, to the best of our knowledge, research in other medical fields is even more limited, with several VR applications, but no MR simulators.

Within this framework, we have designed and developed two MR simulators, i.e., coupling VR with a real manikin. This way, one can be immersed in a highly realistic and engaging environment and, at the same time, have haptic feedback. With this approach, manual, procedural and soft skills can be trained with the same tool and at the same time, without the need for a fully equipped simulation centre.

II. Objectives

The goal of the project was to design and develop educational tools which combine the advantages of VR with those of traditional manikin-based simulations. In other words, we aimed at combining different techniques to create simulators which are a fusion between high-fidelity manikins (i.e., full body manikins equipped with sensors to monitor the user's action and provide feedback) and VR applications, that

deliver highly immersive environments.

The proof of concepts presented in this work are the result of a multidisciplinary collaboration between biomedical engineering students, medical students, and paediatric residents. This collaboration has been promoted through the institution of the Joint lab for Emerging Technologies in Simulation (JETS), which is a joint lab between the Department of Informatics, Bioengineering, Robotics and System engineering (DIBRIS), and the Simulation and Advanced Education Centre of the University of Genova, Italy. Indeed, JETS has the goal to (i) implement and test new prototypes of medical simulators; (ii) investigate how disruptive technologies can enhance medical education; (iii) study the processes underlying medical and surgical skills; (iv) carry out feasibility and efficacy studies.

As a first step, we identified domains that could benefit of having both a VR environment and a physical manikin. We selected (i) trauma management and (ii) newborn life support, as they both lack VR-based solutions [4], [9] and require users to both train manual and soft skills [1].

The different points of view of engineers and clinicians led us to define the main features the simulators should have, which can be summarized as follows:

- Train and/or assess manual skills performed on a manikin;
- Monitor the user's actions in real time;
- Provide feedback on the trainee's actions;
- Respond to the learner's maneuver;
- Immerse the user into a realistic scenario;
- Train soft skills (e.g., stress management, time organization);
- Train/Evaluate procedural knowledge;
- Provide a realistic interaction with the elements the trainees should interact with, such as the manikin and the medical instruments.

Additional properties of the simulator are its ease of installation and use by people without specific technical skills, as in the case of healthcare providers; the possibility of having modular systems, usable in different modalities (i.e., VR applications without the manikins, or manikin with a simple screen-based Graphic User Interface), with the possibility of adding additional modules such as a scoring system, additional scenarios, or manoeuvres to be simulated.

III. Solutions

The two systems we realized include (Fig. 1):

- High-fidelity manikins (an adult for the trauma management simulator and a newborn for the NLS one).
- HTC Vive VR setup (HTC Corporation, Taiwan).
- Leap Motion (Ultraleap, UK) device to track the user's hand in real time.
- Sensors to assess trainees' performance.

Fig. 1 System Setup. The simulators include a sensorized manikin, an immersive headset, and a VR application. Data from the manikin are sent in real time to the VR application via Wi-Fi

As we wanted to implement systems usable in different modalities, according to the educational need, we designed two configurations: 2D (non-immersive) to let the user practice manoeuvres on the physical manikin, while receiving real time feedback on a computer screen; 3D (immersive) that allows the user to be immersed in a virtual environment and practice in a realistic setting. With the 3D configuration, the users can physically interact with the some virtual objects of the scene, as the virtual and real worlds are overlapped.

Both 2D and 3D configurations share the same manikin, equipped with sensors to monitor user performance in real time. Sensors acquire data and send them to the VR application in real time via Wi-Fi. The application can either provide performance feedback in real time, as in the case of the training, or saves them to deliver an evaluation at the end of the simulation.

A. MR STEVE: Mixed-Reality Simulator of Traumatic EVEnts

MR STEVE is an educational tool for first aid and trauma management training and evaluation. The VR application of the simulator includes five different scenarios in which the VR simulation can occur (Fig. 2): a helicopter; an outdoor upland scenario; an indoor scenario of a pub; an urban scenario; a hospital setting. Moreover, new scenarios can be easily integrated.

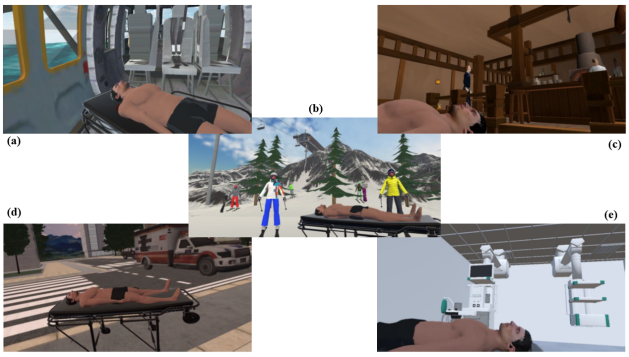

Fig. 2 Scenarios of the MR VR applications. The user can choose from five different scenes: (a) helicopter; (b) outdoor upland scenario; (c) indoor scenario of a pub; (d) urban scenario; (e) hospital setting

The system also includes a sensorized manikin, which monitors the following actions:

- Head and collar positions (through three VR trackers)
- Chest compression (infrared sensor)
- Tourniquet application (using resistive force sensors) [10].

In the immersive version, the trainee is in the same room as the physical manikin. By wearing the VR headset, he/she is immersed into a virtual room and can select a simulation scenario by virtually touching the corresponding button, thanks to the Leap Motion Device. As soon as the simulation starts, the trainee sees the simulation scenario with a virtual patient, which is mapped onto the real manikin (Fig. 3).

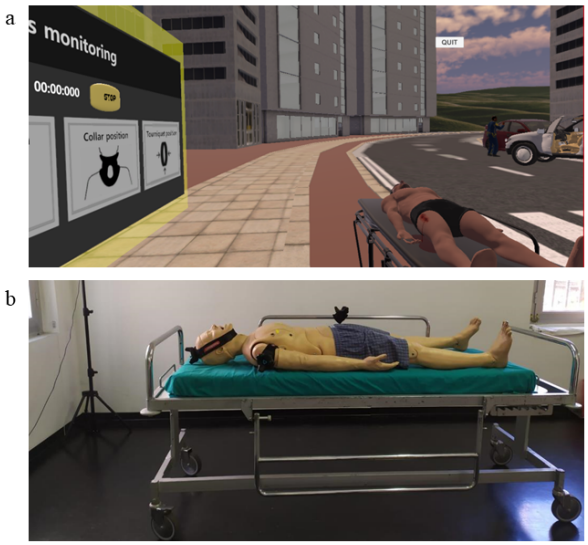

Fig. 3 Setup of MR STEVE. (a) virtual environment that the user can see during the immersive simulation. On the left there is a screen showing the users' performance in real time (b) real high-fidelity manikin that is overlapped with the virtual replica, moving accordingly.

This way, the user can physically touch the real manikin and all their actions are replicated into VR, thus obtaining a coherent mixed reality environment [11]. In other words, the correspondence achieved between the virtual model and the manikin allows the users to have visual and tactile feedback simultaneously. Finally, the instructor can control the simulation (e.g., by selecting different types of wounds). During the training phase the user can see his/her performance in real-time thanks to a screen in the scenario (Fig. 3). Finally, the 2D version shows the information collected by the sensors on a monitor screen, as in the case of traditional high-fidelity simulations.

B. RiNeo MR: Simulator for Newborn Life Support

For NLS simulation, we have created an hospital setting consisting of two rooms: (i) Hallway, which acts as a familiarization scene to help the user become comfortable with the virtual environment (Fig. 4); (ii) Delivery room: which is the place where trainees have to perform NLS [12].

Fig. 4: RiNeo MR, Virtual familiarization environment. The user can explore the hallway to understand how to move in the digital world.

As for MR STEVE, the system is equipped with four different sensors:

- An inertial measurement unit (IMU) to monitor the head position.
- Two magnetic sensors to detect mask position.
- A force sensor to measure positive pressure ventilation.
- An infrared sensor for chest compression.

Even in this case, trainees have coherent virtual and tactile feedback (Fig. 5), and real time feedback is provided on a screen, either inside the virtual environment (3D mode), or on a monitor (2D mode).

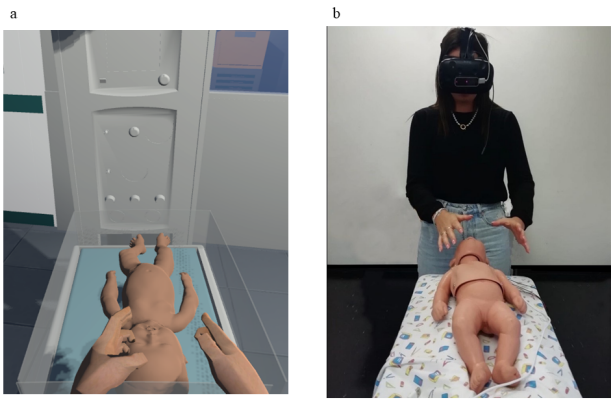

Fig. 5: RiNeo MR steup. (a) user's view of the virtual environment; (b) corresponding real world.

IV. CONCLUSION

This study presents the first steps toward the development of MR simulators for medical training. We developed two preliminary proof-of-concepts: a simulator for first aid training and trauma management and a simulator for newborn life support training and evaluation. Preliminary tests to assess

usability, user experience, and comfort occurrence report that both simulators seem to be promising tools for medical training. Indeed, subjects felt the virtual environment quite realistic and found simulators easy to use. Moreover, no discomfort has been detected after the immersive simulation.

This work is still at a preliminary phase. More data are needed to further investigate simulators usability, and experiments involving healthcare providers will be carried out to assess whether this combination of technologies can be beneficial for medical training.

At the current stage, we have sensorized the manikin to monitor simple tasks, such as chest compression or mask positioning. However, additional manoeuvres can be monitored to have a more complete educational solution.

Similarly, a multi-player version of the two simulators could be developed, such that the systems could be used to train manual skills, as well as team management, communication skills, and stress management.

Finally, once the full development phase is complete, we will compare the effectiveness of the simulators by conducting a comparative study with two groups: one group will follow the training using the proposed solutions, while a control group will use traditional simulation modalities (i.e., manikins). The data collected will be compared to assess the efficacy of MR reality simulation in the training of procedural, manual, and soft skills.

Importantly, indicators and metrics must be used quantitatively assess the proposed solution. One of the possibilities is through validated questionnaires that can provide meaningful information on User Experience, and sense of presence of users inside the virtual environment (e.g., User Experience Questionnaire [13], Igroup Presence Questionnaire IPQ [14]); as well as on the usability of the simulator (e.g., System Usability Scale [15]), also in terms of physical discomfort (e.g., Simulation Sickness Questionnaire, SSQ [16]), and workload (e.g., NASA Task Load Index [17]).

In conclusion, this methodological study, assesses the feasibility of combining two technologies into a single tool, to create complete educational solutions providing both anatomically accurate haptic feedback, and an engaging and immersive scenario which can enhance medical training.

Usability of a multi-sensor array for the application of electro-phonocardiography in home care

N. Giordano[1], G. Balestra[1], S. Rosati[1] and M. Knaflitz[1]
[1] *PoliToBIOMed Lab and Department of Electronics and Telecommunications, Politecnico di Torino, Italy*

***Abstract*—In the latest years, the potentiality of a combined use of electrocardiography (ECG) and phonocardiography (PCG) for the assessment of the electromechanical coupling of the heart has gained interest within the scientific community. The availability of this technology in a home care context would enable the timely monitoring of patients where the electromechanical coupling is impaired, such as in heart failure. Nevertheless, the domiciliary use of electro-phonocardiography is at date prevented by the critical positioning of the electronic stethoscope, which cannot be reliably performed by inexperienced users. In this work, we propose a usability analysis of a multi-sensor array that we developed for this purpose. The multi-sensor array is a flexible pad embedding 3 electrodes and 48 microphones, distributed over the left hemithorax with a high spatial resolution. In our experimental protocol, we simulated a real home care scenario: volunteers with no technical nor clinical skills were enrolled in couples and alternatively performed the recordings on each other, simulating the roles of patient and caregiver. Results show that a Signal-to-Noise Ratio (SNR) higher that 13 dB was always achieved, even before any digital filtering. Moreover, the influence of the body structure of the patient, quantified in terms of Body Mass Index and thoracic circumference, on the quality of the signals was assessed. A moderate significant negative correlation was found, as expected, but in the overall the body structure did not prevent from obtaining reliable signals even in cases of severe overweight. We believe that the presented findings lay the foundations for the use of electro-phonocardiography in telemonitoring applications.**

***Keywords*— usability, telemonitoring, wearable sensors, electro-phonocardiography.**

I. Introduction

PHONOCARDIOGRAPHY (PCG), i.e., the digital recording of heart sounds, and electrocardiography (ECG) are two of the most widely used techniques in the clinical practice for the assessment of the health status of the heart. Due to the nature of the signals, ECG and PCG provide complementary information: whereas ECG is an expression of the electrical behaviour of the heart, PCG reflects its mechanical behaviour [1]. The combination of the two techniques enables the evaluation and monitoring of the status of the electromechanical coupling of the heart, which is difficult to obtain otherwise [2], [3]. The latter can be obtained by estimating the latency of the time of closure of the four cardiac valves in the PCG with respect to the ventricular depolarization event in the ECG [4].

The monitoring of the electromechanical coupling of the heart in a home care setting would open to a range of brand-new possibilities. One of the main possible foreseen applications is the monitoring of the status of compensation of patients affected by chronic heart failure (HF). In fact, both the quality of life and the life expectance of HF patients are mainly affected by the occurrence of acute episodes of decompensation, correlated with a deterioration of the electromechanical coupling of the heart [5], [6]. The availability of a method to timely monitor the patients at their domicile and promptly detect a worsening in their conditions could enable the prevention of the acute episodes and strongly improve the prognosis.

The use of a combination of ECG and PCG looks extremely promising for the scope. In fact, both ECG and PCG can be embedded in low-cost and portable devices, suitable for use outside a clinical setting.

The main technical challenge is posed by their usability by inexperienced users, which is an essential requirement for their application in a home care context. The main problem resides in the recording of heart sounds: it was previously proved that the positioning of the electronic stethoscope over the chest of the subject is critical to obtain a good quality signal, and the best auscultation point depends on the valve of interest [7], [8]. Finding the correct auscultation areas requires trained skills and an inexperienced user cannot be relied on performing an accurate positioning.

We propose a possible solution to the stated problem based on multi-source PCG. Instead of recording a single signal from a specific point of the chest, we propose to record multiple signals, from multiple points of the chest, with a high spatial resolution. In this way, we hypothesize that the positioning of the device can be performed by the patient or a caregiver: the algorithms will be in charge for selecting the most relevant signals, among the multiple recorded ones, for the application of interest. For the purpose, we custom designed a flexible multi-sensor array, embedding electrodes for ECG recording and multiple microphones for PCG recording.

The goal of this study is to validate our work hypothesis that the multi-sensor array is usable by inexperienced users. Moreover, we aim at proving on a sample population that the usability is not affected by the subject's body structure.

II. Materials and Methods

A. Design of the multi-sensor array

Figure 1 proposes a graphical schematic of the architecture of the multi-sensor array.

For PCG recording, the array embeds 48 electret condenser microphones (TOM-1537L-HD-R by PUI Audio), each equipped with an analog front-end for pre-amplification. The microphones are located over a surface of approximately 180 cm^2 which should roughly cover the subject's left hemithorax. The microphones have a diameter of 4 mm and the minimum distance between closest neighbours is 12 mm, to obtain a sufficiently high spatial resolution. The microphones are more

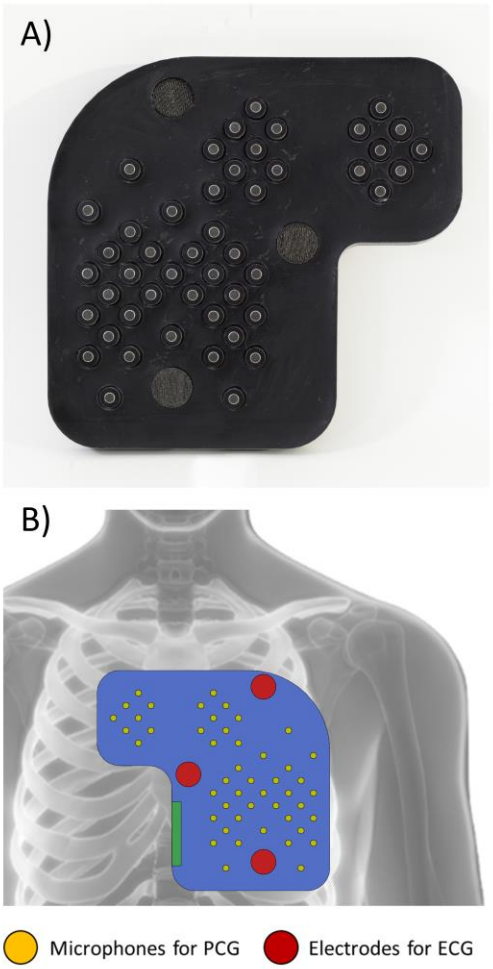

Figure 1. Picture of the designed and realized multi-sensor array (A) and schematic of its positioning over the left hemithorax of the subject.

densely located over the areas corresponding to the traditional auscultation areas. A sensitivity of -37 dB is guaranteed over the bandwidth 20 Hz to 20 kHz.

The recording of a 1-channel ECG relies on 3 custom-made electrodes in stainless steel, conditioned via the well-known Right Leg Driven circuit. The positioning of the electrodes is not critical for the application of interest, which does not involve a morphological analysis of the ECG waveform.

Electrodes and microphones, along with their front-end circuits, are soldered on a flexible PCB realized in Kapton. The flexibility of the array is a key aspect because it enables a good contact between the sensors and the surface of the chest of the subject. The contact is guaranteed by fixing the device to the thorax by means of an elastic band.

Both the ECG and PCG signals are simultaneously sampled at 1 kHz, multiplexed, and transferred to a commercial signal acquisition board (NI USB 6210 by National Instruments). This performs the A/D conversion and the acquisition through a computer, where the following analysis takes place.

B. *Experimental protocol*

The key point to validate the usability of the device in a real-life home care scenario is to have it used by inexperienced users without the help of any clinical nor technical staff. To simulate the latter scenario, we enrolled 12 couples of volunteers, for a total of 24 volunteers. Two exclusion criteria were applied:

1. no known history of cardiovascular disease;
2. no skills in auscultation.

The first criterion is meant to ensure that no pathological condition affects the analysis. In each couple, subjects were assigned the role of subject A and subject B. In the first phase, subject A played the role of the caregiver and subject B played the role of the patient. Subject A was given very simple written instructions on how to use the device (simulating a basic user manual). In the meanwhile, subject B was asked to lay on an examination table in a supine position with a bare thorax. Then, subject A was asked to position the multi-sensor array on the thorax of subject B and fix it with the elastic band. A 5-minute recording was then performed on subject B. At the end, the roles of subject A and subject B were changed, and the experiment was repeated with subject A playing the role of the patient and subject B playing the role of the caregiver. No feedback was given to the subjects concerning the correctness of the use of the device.

The experimental protocol was approved by the Research Ethics Committee of Politecnico di Torino.

C. *Signal processing and quality assessment*

The scope of signal processing is to assess and improve the quality of the heart sounds signals. The ECG signal was first filtered in the bandwidth of interest for the detection of the QRS complex. Filtering involved a moving average filter with a window length of 100 ms to remove baseline wandering, in cascade with a low-pass FIR filter with a cutoff frequency of 35 Hz. Then, the QRS complex was identified by means of a modified version of Pan-Tompkins algorithm [9] and R-waves were taken as reference for heartbeat segmentation.

Each of the 48 PCG signals was filtered with a Chebyshev I filter between 20 Hz and 100 Hz, bandwidth of the two main heart sounds. The signals were then segmented taking R-waves as reference.

The assessment of the quality of the signals was based on the Signal-to-Noise Ratio (SNR), which was computed separately for each of the two heart sounds and for each heartbeat, according to the following formula [10]:

$$SNR = 20 \log \frac{A_S}{4\,\sigma_N} \quad (1)$$

where A_S is a measure of the signal amplitude (peak-to-peak value of the heart sound of interest) and $4\,\sigma_N$ is a measure of the noise amplitude (width of the 95% band of the noise time series, extracted within the 70% and the 85% of the cardiac cycle, when no heart sound is expected to occur).

The assessment of the quality of each recording was based on the mean SNR value over the heartbeats, computed separately for each heart sound (SNR S1 and SNR S2).

D. *Evaluation of the usability*

The proposed evaluation of the usability of the device is two-folded.

On one side, the usability by inexperienced users was assessed. To achieve this, for each subject, we selected the

signal with the highest SNR and compared it to a threshold of 14 dB. The threshold was defined according to the results of a previous study [10], where we experimentally found that a SNR higher than 14 dB for the first heart sound and 13 dB for the second is sufficient to estimate the time of closure of the four cardiac valves with an uncertainty lower than the resolution of the acquisition system (1 millisecond). The metrics used to validate the usability of the device by inexperienced users is the percentage of good-quality recordings, i.e., of recordings with an above-threshold SNR.

On the other side, the usability on patients with a wide range of body structures was assessed. Three anatomical parameters were identified, which can influence the quality of the recordings, namely:

- the biological gender (male or female);
- the Body Mass Index (BMI);
- the thoracic circumference.

To evaluate if either of the abovementioned parameters influences the quality of the recording, we computed the correlation between each parameter and the SNR of the recording (separately for the first heart sound S1 and the second heart sound S2). We used the Pearson correlation coefficient to test the correlation against continuous variables (BMI and thorax circumference), and the point biserial correlation to test the correlation against categorical variables (gender).

III. Results and Discussion

A. *Characteristics of the sample population*

The sample population is composed of 24 healthy subjects who alternatively played the role of the patient and the caregiver. Concerning the gender, 12 males and 12 females were enrolled to ensure gender balance. Figure 2 presents the violin plots of the distribution of BMI and thoracic circumference, separately for female and male subjects, over the sample population.

As it can be observed, enrolled subjects presented all possible body structure from normoweight to obesity (BMI > 30 kg/cm^2). In particular, the presence of subjects with an above-average BMI and thorax circumference is particularly important, since a bigger chest volume may lead to a higher attenuation of the acoustic waves of the heart sounds and hence to signals of lower quality [11], [12]. Therefore, the sample population, despite its rather small size, can be considered representative of the overall population, and in particular of the most critical segment.

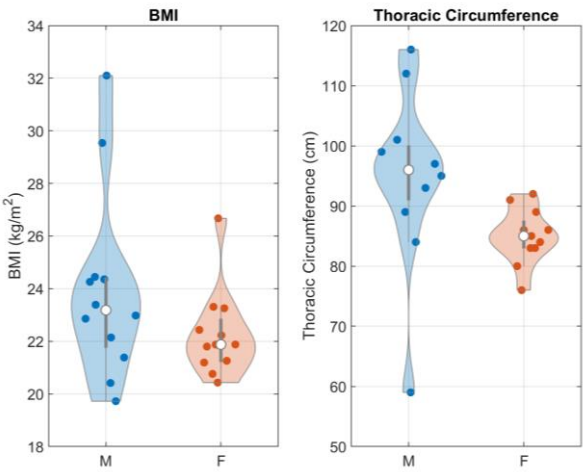

Figure 2. Violin plots of the distributions of BMI and thoracic circumference, separately for female and male subjects, over the sample population.

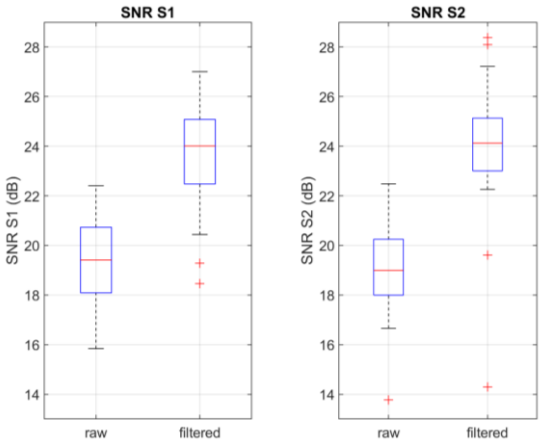

Figure 3. Boxplot of the distributions of the SNR of the recordings, separately for the first and the second heart sounds, before and after digital filtering.

B. *Usability by inexperienced users*

From a qualitative perspective, all the enrolled subjects playing the role of the caregiver could easily perform the positioning of the array according to the instructions. To evaluate if the recordings were of sufficient quality, Figure 3 shows the distribution of their SNR, computed separately for S1 and S2.

It can be observed that all the recordings achieved an SNR higher than 14 dB for S1 and 13 dB for S2, even before any digital filtering is applied. A median SNR of 24 dB was obtained after filtering, which is more than sufficient to reliably carry out any kind of processing. It can be concluded that all subjects were capable of performing a suitable positioning, regardless their inexperience.

C. *Influence of the body structure on the signal quality*

Figure 4 presents a graphical plot of the SNR of the recording in function of respectively a) biological gender, b) BMI and c) thoracic circumference.

Table I summarizes the correlation coefficients computed between each of the three anatomical features and the SNR of the heart sounds.

TABLE I: Correlation between anatomical features and SNR

Anatomical feature	*Correlation with SNR S1*	*Correlation with SNR S2*
Gender	-0.06	0.09
BMI (kg/cm^2)	-0.34	-0.50 *
Thoracic circumference (cm)	-0.38	-0.40

Correlation coefficients computed as Pearson correlation coefficients for continuous variables (BMI and thorax circumference), point biserial correlation coefficients for categorical variables (gender). The * symbol shows what correlations are statistically significant with $\alpha = 0.05$.

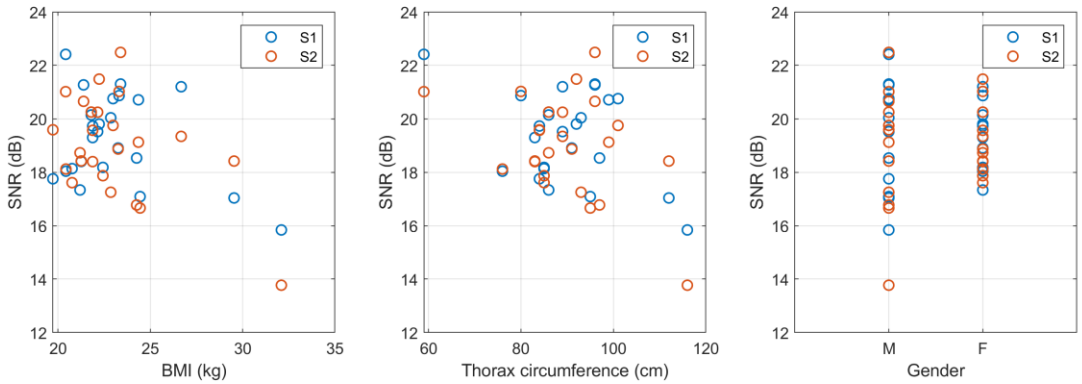

Figure 4. Signal-to-Noise Ratio of the recordings in function of the three anatomical parameters of interest, namely BMI, thorax circumference and gender.

As it can be observed, no correlation was found between the gender and the quality of the recordings. This is a relevant finding because it proves that the shape of the device allows a feasible positioning regardless different shape of the chest which characterizes males and females.

Concerning the body structure, a significant negative correlation was found between the BMI and the SNR, whereas no significant correlation was found between the thoracic circumference and the SNR. Only the correlation between the BMI and the SNR of the second heart sound was found statistically significant at $\alpha = 0.05$.

The presented findings are coherent with the hypothesis that a wider chest can be associated with a lower signal quality. Nevertheless, good-quality recordings could be obtained even with overweight subjects. We can conclude that the body structure may influence the quality of the recording, but it does not prevent the user from obtaining a good-quality recording.

In the overall, the multi-sensor array proved suitable for successfully performing electro-phonocardiography on a wide range of users with a wide range of anatomical characteristics in a simulated home care scenario.

IV. Conclusion

In this work we proposed an analysis of the usability of a multi-sensor array custom designed and realized by our research group. The multi-sensor array embeds electrodes and microphones for the combined recording of ECG and PCG signals. Its main forecasted application is the home monitoring of patients affected by chronic heart failure, or other pathologies where the electromechanical coupling of the heart is impaired. The usability by inexperienced users is critical for the application of interest and distinguishes our proposed device from other available technological solutions.

Our findings demonstrate that users with no technical nor clinical skills can easily use the device and carry out good-quality recordings. In particular, the SNR of the recordings performed by 24 volunteers proved higher than the required SNR for the estimation of the time of closure of the cardiac valves. Moreover, even though a moderate significant negative correlation was found between the body structure of the patients and the quality of the recordings, a high BMI and/or thoracic circumference did not prevent the user from the possibility of obtaining good-quality signals.

The promising findings presented in this work constitute a preliminary validation of the usability of the device in a home care context by the patient or a caregiver. Based on them, a validation on a larger population (including patients affected by a variety of pathologies) will be object of future work. We believe that the availability of a device directly usable by the patients lay the foundations for the application of electro-phonocardiography in telemonitoring in the near future.

***Abstract*—The validation of a new biodegradable medical device requires the evaluation of its degradative profile. *In vitro* degradation tests are a useful tool to do so, but their protocol needs adequate justification. We propose a method to evaluate the enzymatic degradation kinetics of an enzyme mixture designed to degrade a semi-degradable vascular graft in quasi-physiological conditions.**

***Keywords*—bioresorbable medical device, *in vitro* degradation, enzymatic activity.**

I. Introduction

The use of biodegradable medical devices, meant to be safely absorbed by the body after fulfilling their intended purpose, is becoming increasingly relevant in biomedical research and implantable medical devices' production in particular [1], [2]. Biodegradable medical devices are employed in passive physical support for tissue repair and/or regeneration, e.g., in suture threads, surgical meshes, orthopedic fixation devices, biodegradable stents, and tissue scaffolds [3], [4]. In the case of biodegradable devices, the host response that generally follows implantation is additionally greatly affected by the degradation kinetics of the material composing the device. In particular, by the inflammatory events at the host–implant interface and the degradation products released during the life-cycle of the device [1]. To design a biodegradable device that is functional, but most of all safe, an in-depth understanding of this degradation process and a characterization of the degradation products' release kinetic are needed.

The topic of biodegradation is extensively treated in literature and several methods to test it *in vitro* were proposed, while, on the regulation side, ISO 10993-13:2010 constitutes a standard for the design of *in vitro* degradation tests [5]-[7]. However, since biodegradation is determined by environmental factors, the conditions in which the test is carried out are crucial. In the case of enzymatic degradation tests, non-human enzymes are often used in literature and are proposed as the standard to model hydrolytic mechanisms, e.g., protease XIV, proteinase K, and papain [6]. Additionally, even when human-origin enzymes are used, the concentration used is highly variable in the literature and may be significantly higher than the physiological one. Finally, a crucial factor like the refresh rate of the degradation medium is not regulated and is not always justified in literature. This aspect of the protocol design constitutes a key parameter because the enzyme activity levels should be high enough to steadily degrade the device. In fact, when designing an enzymatic degradation experiment, the activity of the enzymes used can be even more relevant than their concentration. Phenomena such as thermal degradation, aggregation, lysis, and autolysis can alter the enzymes' activity without affecting the protein content. Moreover, the enzymes' activity *in vivo* is further regulated by the presence of physiological inhibitors and proenzymes' activators. For example, in the case of metalloproteinases (MMPs), enzymes that play a key role in wound healing, angiogenesis, and/or fibrotic capsulation of the materials [8], their activity is regulated through the secretion of tissue inhibitors of MMPs (TIMPs) [9], [10].

In light of the above, in this study, we seek to evaluate the enzymatic degradation kinetics of a pool of human-origin enzymes chosen for the degradation of a biodegradable medical device mainly composed of silk fibroin, in physiological conditions, i.e., in the human vascular compartment. Since we sought to characterize the effectiveness of the enzymatic mixture, enzymatic activity and decay were eventually studied using commercially available enzyme activity assays.

The use of a mixture of enzymes is what makes this *in vitro* setup closer to physiological conditions, but the interaction between the different enzymes can potentially alter their activity. We herein describe a methodology to develop an enzymatic mixture in which every enzyme presents the same level of activity in order to easily follow the general activity decay over time. Since the enzyme concentration correlates to the activity measured, enzymes' physiological concentrations were considered, at least initially, as the target ones.

II. Materials and Methods

A. Materials

MMP1, MMP3, MMP9, Chymotrypsin, and Lysozyme were purchased from Merck Life Science (Milan, Italy). MMP activity assay kit (ab112146) and Lysozyme assay kit (ab211113) were purchased from Abcam (Cambridge, UK).

B. Measurement of enzymes' activities

Preliminary studies showed that the MMPs substrate could be used to correctly detect Chymotrypsin activity, thus MMP activity assay kit was used to measure the activity of MMP1, MMP3, MMP9, and Chymotrypsin, while the Lysozyme activity assay kit was used exclusively for Lysozyme.

Each enzyme was first resuspended in Phosphate Buffer Saline (PBS) and tested at different concentrations with the corresponding substrate according to the manufacturer's instructions with slight variations. Briefly, the MMPs and Lysozyme substrates were thawed to room temperature (RT) in the dark, diluted 1:100 and 1:16, respectively, in the specific assay buffer, and vortexed. Substrate control and background control wells were filled with PBS and PBS diluted in assay buffer respectively. Sample wells were filled with each enzyme's dilutions in PBS. Diluted substrates were added to the corresponding sample wells and substrate control wells only right before the measurement.

The activity kinetics was assessed over 1 hr at 37 °C (readings every 5 min) by measuring the fluorescence using a microplate reader (Synergy H1, BioTek, USA). According to the substrate used, the following wavelengths were used: λ_{EX} = 490 nm, λ_{EM} =525 for MMPs substrate and λ_{EX} =360 nm, λ_{EM} =445 nm for Lysozyme substrate.

The quantification of the enzyme activity was, thus, obtained considering the first linear part of the progression curve (generally 30 min - 1 hr), both in terms of the fluorescence emitted at a given time point, expressed in terms of Relative Fluorescence Units (RFUs), and by the velocity of the reaction, expressed in RFU/min. The slope of the linear part of the fluorescence *vs.* time plots was obtained from the linear regression of the values of the first 30 min using GraphPad Prism software.

C. *Effect of temperature on enzyme activity*

To assess the effect of temperature on enzymes activity, an enzymes solution containing MMP-1 (1 µg/mL), MMP-3 (2 µg/mL), MMP-9 (0.4 µg/mL), chymotrypsin (0.05 µg/mL), and lysozyme (20 µg/mL) (hereinafter referred to as enzymes cocktail) was prepared into a 1.5 mL Eppendorf tube and mixed thoroughly with a pipette.

The obtained enzymes cocktail was split into 3 vials and incubated at 3 different temperatures: i) 4 °C, ii) 25 °C (room temperature, RT), and iii) 37 °C under shaking (300 rpm) in a thermomixer for 72 hrs. Following incubation, enzyme activity was evaluated with the 2 substrates as described hereinabove (section II.B) at the corresponding wavelengths.

The activity of the untreated enzyme cocktail was considered a positive control of activity (100 %).

D. *Enzyme inactivation over time*

The enzyme cocktail was prepared in a 1.5 mL Eppendorf tube and mixed thoroughly with a pipette.

The activity measurements were performed after incubation at 37 °C under shaking (300 rpm) in an Eppendorf Thermomixer.

The experiment was iterated multiple times with the following time points: 0, 4, 24, 48, 96, and 168 hrs.

The activity measurements were performed as described in section II.B using both substrates.

The activity of the untreated enzyme cocktail was considered a positive control of activity (100 %).

As a negative control of activity (0 % enzyme activity), the enzymatic mixture was heated at 100 °C for 30 min and subsequently centrifuged for 3 min to obtain the enzymes' denaturation.

Curve fitting on activity decay over time graphs was performed using GraphPad Prism software.

E. *Statistical analysis*

Statistical analysis was carried out with GraphPad Prism software. Comparisons among the three different temperature conditions and positive control of activity were performed by the two-way analysis of variance (ANOVA). Statistical significance was retained when the p-value < 0.05.

III. Results and Description

A. *Design of same level activity enzyme mixture*

The interaction between each enzyme and the MMPs substrate was enzyme-specific. Among them, MMP-9 activity was significantly higher than the others. Therefore, in the enzyme mixture at their physiological concentrations, the MMP-9 activity would conceal any other MMPs and Chymotrypsin (Fig. 1).

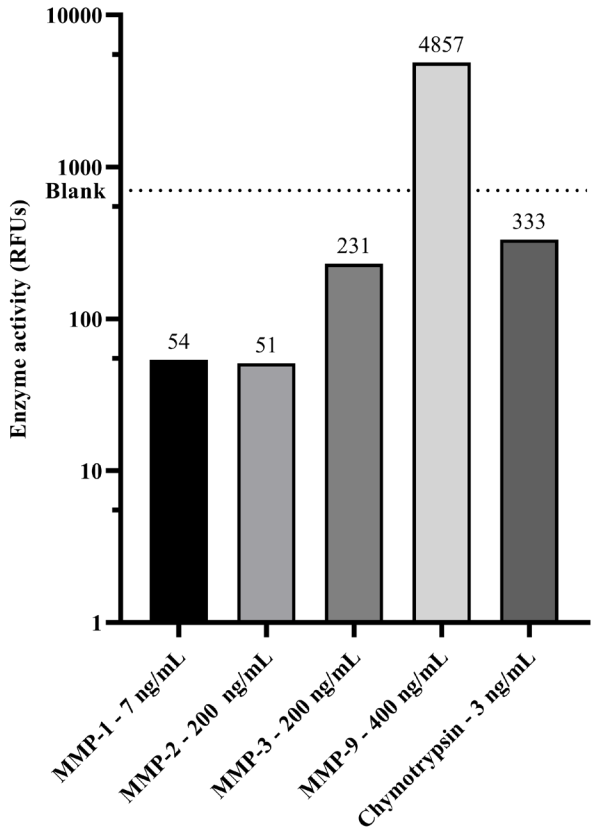

Figure 1: Graph representing the enzymes activity at their physiological concentrations in terms of fluorescence emitted after 30 min (RFU). Among the four enzymes analyzed, MMP9 activity was clearly detectable and produced a fluorescence signal of almost 5000 RFU. Instead, concerning the other three enzymes, their signal was below that of the blank. In particular, MMP-1 activity at its physiological concentration was hardly distinguishable from the blank.

Considering the above results, the MMPs and Chymotrypsin concentrations were purposely varied to give an equal contribution to the overall activity of the enzyme pool. More in detail, as MMP-9 showed the highest activity at its physiological concentration, we decided to increase the concentration of any other enzyme to obtain the same activity level. Enzymes' concentrations were tuned in order to enable an activity level of approximately 4,000 RFU after 30 min, corresponding to the activity of MMP-9. Of note, this value differed sharply from the blank (≈ 700 RFU) and was high enough to monitor the kinetics over time of all the enzymes together.

Concerning Lysozyme, since its activity was detectable at its physiological concentration, this was the concentration selected to carry out the following experimentation.

The final enzymes' concentrations are reported in Table I and compared to the physiological ones [12]-[17].

TABLE I: ENZYMES' CONCENTRATIONS

Enzyme	*Physiological concentration*	*Concentration in same level activity mixture*
MMP-1	7 ng/mL	1 µg/mL
MMP-3	200 ng/mL	2 µg/mL
MMP-9	400 ng/mL	400 ng/mL
Chymotrypsin	3 ng/mL	50 ng/mL
Lysozyme	20 µg/mL	20 µg/mL

Enzymes' physiological concentration and working concentrations of any enzyme in the mixture on the MMP-9 activity.

B. *Effect of temperature on enzymes' activity*

The residual activity of MMPs, chymotrypsin, and lysozyme after a 72 hr-storage at different temperatures is shown in Figure 2. The enzymes' activity of every condition considered resulted to be significantly different from the positive control of 100 % activity. Of note, lysozyme activity decreased over time irrespective of the storage temperature, as at the end-point the residual activity was invariably close to 60 %. On the other hand, the residual activity of MMPs and chymotrypsin in the enzyme cocktail incubated at RT and 37 °C was invariably 30 %, while, when stored at 4 °C, the residual activity of MMPs and chymotrypsin was of 50 %.

Overall, such results demonstrated that the storage temperature plays a significant role in MMPs and chymotrypsin activity, whereas it is less relevant for the maintenance of lysozyme activity.

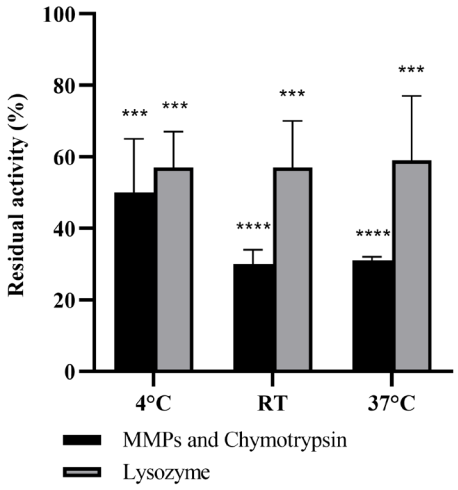

Figure 2: Residual activity of MMPs, Chymotrypsin, and Lysozyme after 72 hrs stored at 4°C, RT and 37 °C. ***p< 0.001, ****p < 0.0001 between every condition and positive control (100 % activity) (two-way ANOVA).

C. *Enzyme inactivation over time - Lysozyme*

The time-dependent decrease of lysozyme's activity is shown in Fig. 3. A one-phase decay curve was fitted to the data obtained suggesting a monophasic inactivation behavior. Following a burst decrease during the first hours of incubation, the enzyme's activity reaches a plateau at approximately 70% of residual activity.

Since it was shown that the activity of this enzyme decreased irrespective of the storage temperature, the lysozyme inactivation might have been caused by the interaction with another enzyme present in the mixture and, thus, by enzyme-induced cleavage. Of note, lysozyme is a known substrate for chymotrypsin [18].

The negative control showed no activity when tested with lysozyme substrate, demonstrating that the residual activities shown here above were not an artifact.

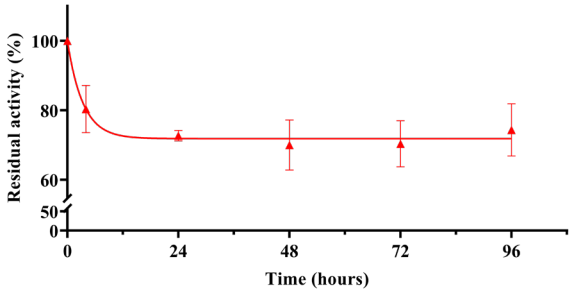

Figure 3: Residual activity over time of the lysozyme in the enzymatic mixture. After a sudden decrease during the first hours of incubation, the residual activity followed a one-phase decay and plateaued at 70 %.

D. *Enzyme inactivation over time – MMPs and Chymotrypsin*

Differently from the decay of Lysozyme, the MMPs and Chymotrypsin combined activity followed a biphasic inactivation behavior (Fig. 4). In fact, after a similarly abrupt decrease in the first hours of incubation, the residual activity further decreased until 30 %. This could be due to the fact that the MMPs substrate was used to observe the inactivation of four enzymes at the same time. Since different mechanisms are involved in this phenomenon, i.e., thermal denaturation, auto-, and cross-hydrolysis, it is reasonable that they elicit a different, time-dependent effect on the enzymatic pool activity. In particular, one acts extremely fast in the very first part of the curve, while the other is slower, resulting in a nearly linear decrease. Moreover, it is important to consider that it was already demonstrated how storage temperature significantly affects MMPs and Chymotrypsin activity.

As for the Lysozyme substrate, the negative control showed no activity when tested with the MMPs substrate.

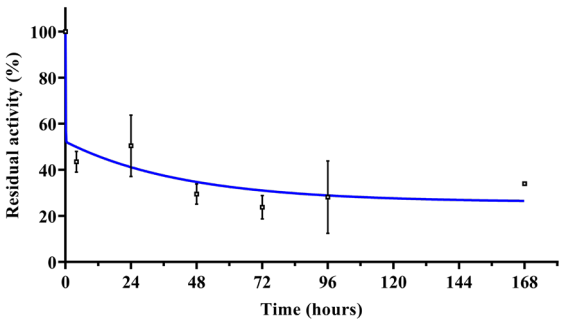

Figure 4: Residual activity over time of the MMPs and Chymotrypsin in the enzymatic mixture. A two-phase decay curve was fitted with GraphPad Prism

to the data obtained. After a sudden decrease during the first hours of incubation, the enzyme's activity slowly decreases until 30 % of residual activity.

IV. Conclusion

The methodology proposed permits easy following the general activity decay over time of a mixture of enzymes designed for the *in vitro* physiological degradation of a medical device. The protocol was developed to evaluate the biodegradation of Dialybrid's Silkothane® Arteriovenous Graft (SAG) a semi-degradable electrospun device manufactured from a new hybrid (natural/synthetic) material, which is a combination of silk fibroin (SF, a biodegradable protein found in silk) and polyurethane (PU, a non-degradable polymer) [19], [20].

Considering the medical device's final purpose, the proposed cocktail was composed through the selection of the enzymes that are known to hydrolyze SF and are present in the human vascular district. Regarding the physiological conditions mentioned in this study, they referred, when available, to renal pathological conditions.

The experimental setup presented represents the worst-case scenario in terms of enzymes' auto-lysis and cross-lysis. First, the increased concentration, with respect to physiological levels, could potentially exacerbate these phenomena [21], [22]. Secondly, an *in vitro* degradation study would obviously be performed in the presence of the graft, which represents a substrate for the enzymes, thus reducing the opportunity for the auto- and cross-lytic process to occur [23], [24]. Nevertheless, even in these conditions, the activity of the enzyme pool was sufficiently high to be detected after 1 week.

The results showed that enzyme cocktail activity decreased significantly in the very first hours of incubation at 37 °C and gradually diminished thereafter. In this light, it is reasonable that in a future degradation experiment, a replacement of the enzyme pool once per week would ensure the degradation of the graft in the long run.

In order to correlate the results obtained *in vitro* with those coming from an *in vivo* study in large animal, the *in vitro* degradation study will last 6 months and include intermediate time points. Large animal models are best for the *in vivo* evaluation of a novel vascular graft and 6 months represent an adequate follow-up time considering the application [25], [26].

***Abstract*— One of the most common cause of failure in oxygenator systems consist of the thrombogenic risk associated with the interaction between the blood and the engineering material. For this reason, the use of membrane oxygenators is restricted to only 2-4 weeks in the extracorporeal membrane oxygenation system (ECMO). Using computational fluid dynamics, this study aims to investigate the mechanisms underlying the shear-mediated platelet activation in an oxygenation system. This was accomplished by first developing a multiscale model for the oxygenator system, followed by the estimation of the thrombogenic risk by mathematical modelling. High values of particle stress were found at inlet and outlet of blood flow. Computational flow analysis has revealed important insights into the thrombogenic mechanisms, suggesting that numerical analysis can be an effective tool to improve the design of oxygenator systems and reduce the time-to-market and animal trials.**

***Keywords*—computational fluid dynamic, oxygenation systems, ECMO, thrombogenic risk.**

I. Introduction

The oxygenation system is the main component of extracorporeal membrane oxygenation system (ECMO) and artificial lungs [1-4]. In particular, the oxygenator is the artificial lung of the heart-lung machine and substitutes the biological function of the alveolar membrane, adding oxygen and removing carbon dioxide from the blood. A heat exchanger is usually coupled with the oxygenation system to lead hypothermia to the patient, maintain the correct temperature of the blood's patient and also slow down her/his metabolism to reduce blood and nutrients contribution to tissues. Both oxygenator and heat exchanger are composed by polymeric hollow-fibres membrane, usually polyethylene (PE) or polypropylene (PP).

Computational fluid dynamic (CFD) methods can be used to improve the design process of cardiopulmonary devices such as artificial lung for adult [5] and paediatric patients[6], heart valves [7, 8], ventricular assist device [9-12]. There is however a lack of knowledge in the computational haemodynamic of oxygenator systems. One of the major challenge in the design of oxygenator is represented by the flow-mediated platelet activation at the basis for thrombogenic mechanisms and ultimately device failure. Shear stress is a well-recognized mediator of thrombosis and haemolysis, with physiological values ranging from 0.1 Pa to 10 Pa [13, 14]. The presence of artificial surfaces and hemodynamic disturbances are predisposing factors for thrombosis in oxygenator systems [15]. At the present, the utilize of pharmacological treatments based on anticoagulants and surface-treatment strategies of materials exposed to blood flow are the best options to decrease the risk of thrombosis. However, the flow-mediated mechanism is a complex multifactorial and multilevel mechanisms occurring at different time scale and length [15]. In-vivo animal modelling and in-vitro bench tests may shed insights into the mechanisms underlying the platelet activation. Computational modelling can potentially reduce the need for animal testing and accelerate innovation leading to safer more cost-effective oxygenator devices.

This study aims to understand the flow-induced mechanisms of platelet activation by quantifying the blood cell stress in two commercial oxygenators used for ECMO therapy. Specifically, we developed a multiscale computational fluid dynamic (CFD) model to compute the microscale haemodynamic and then combine the velocity with a macroscale quantifications. The resulting flow parameters were used to quantify the platelet-like stress history and the damage accumulation using a mathematical model.

II. Materials and Methods

Geometric model of oxygenators was developed in the CAD software ANSYS SpaceClaim (ANSYS Inc, Canonsburg, PA, USA) using dimensions from reverse engineering of the original devices (see Figure 1). Two device models (namely A and B) were investigated.

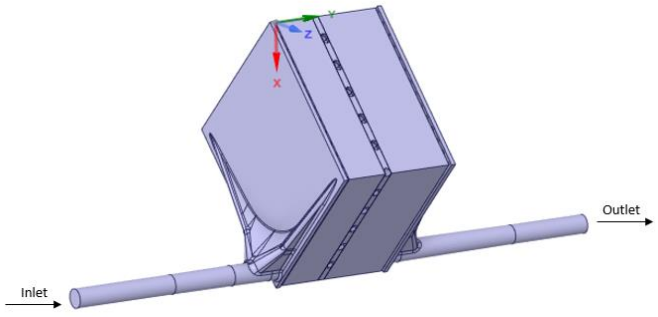

Figure 1: Investigated oxygenators named device (A) and device (B)

For the microscale analysis, the elementary cell unit was obtained considering the orientation, size and fiber package distribution as seen on the oxygenator device. Computational models were developed so that each device had two microscale models. The first one is representative of the flow inlet where the oxygenator cell is followed by heat exchanger cell. The second model considers only the oxygenator cells (see Figure 2)

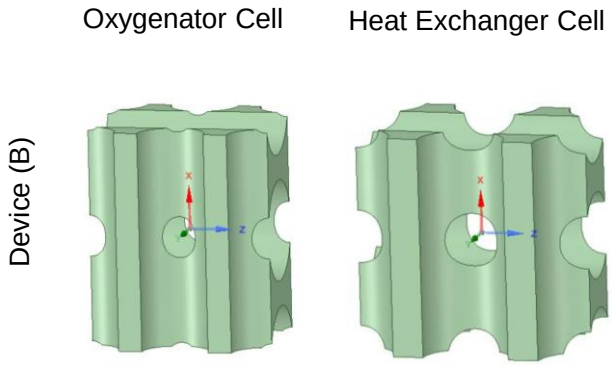

Figure 2: Elementary cell unit for device (A) and device (B)

Both macroscale and microscale simulations were performed with FLUENT (ANSYS Inc, Canonsburg, PA, USA). For the element mesh, we considered n.30 elements for the fiber cell unit while the macroscale models had maximum surface skewness of 0.7 for nearly 4-milion of unstructured tetrahedral elements. The blood was assumed as a Newtonian fluid under laminar flow condition using density of 1052 kg/m^3 and viscosity of 0.00236 Pa×s as done for other studies [16-18]. For the solver, the SIMPLE methods for pressure-velocity coupling with second order upwind scheme was adopted to solve the steady-state Navier-Stokes equations. Microscale simulations were carried out using periodic flow boundary conditions and symmetric flow conditions to account for the presence of surrounding fibers. The mass flow of the elementary cell was calculated from the total device flow of 5 l/min, the inlet area, the ratio of superficial flow velocity and volumetric porosity. Then, the mass flow were imposed as a boundary condition for the cell unit, and the flow dynamic was therefore computed. The solution was used to extrapolate the pressure gradient across the cell unit and thus calculate the anisotropic porosity using the Darcy's law. This allowed us to calculate the boundary inflow and outflow conditions for the macroscale model. Specifically, we imposed a mass flow of 0.087 kg/s at the inlet while a zero-pressure condition was imposed at outflow. Though a turbulence model may result inaccurate and may not influence the blood particle motion, macroscale simulations were carried out using the SST-kϖ turbulence model After solution convergence, a discrete phase model (DPM) with particle tracking to mimic the presence of platelets was carried out. After convergence analysis, a total of n.700 particles with diameter of 3 μm and density of 998 kg/m^3 were considered. To compute the platelet activation state (PAS), the scalar stress history acting on each simulated particle in the oxygenator domain was computed using user-defined-functions. Since simulations included both laminar and turbulent flows, two different UDFs were used to calculate both laminar and turbulent stress using the Boussineq hypothesis.

III. Results

Figure 3 shows flow streamlines and pressure drop for the oxygenator devices, respectively. The device had a pressure drop similar to that of experiments (ie, 50 mmHg).

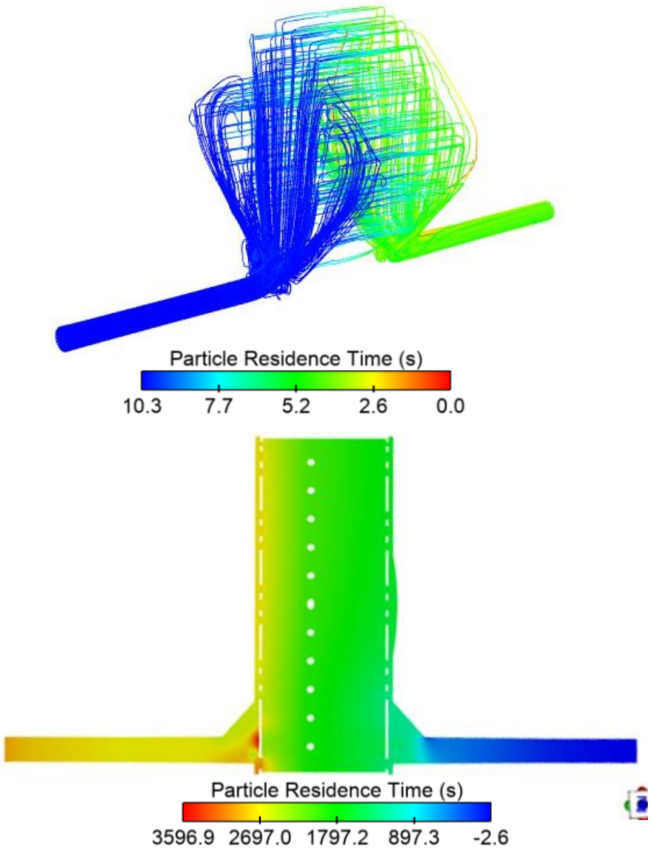

Figure 3 flow streamline as a function of particle residence time and pressure drop for the device A and B

Stress tensor components were used to calculate the total laminar scalar stress and the total turbulent scalar stress acting on each particle using the formulation suggested by Apel et al. [19]. The profile of the variability of particle scalar stress from low (blue lines) to high (green lines) magnitude was computed (Figure 4). Particles with no scalar stress are also shown (red lines).

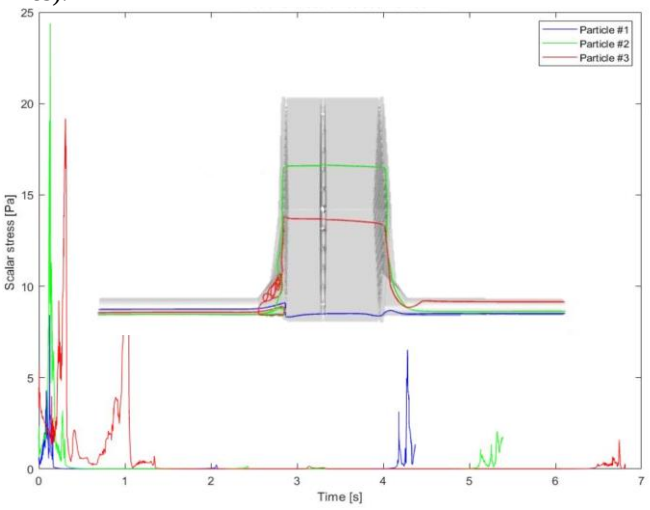

Figure 4: Particle stress as a function of time

Once both the micro- and macroscales were integrated and the particle loading history evaluated, the thrombogenic risk was analyzed using several mathematical models to predict blood damage in terms of platelet activation from the scalar stress and exposure time acting on the platelets. The platelet

activation models considered in this analysis, namely that of Nobili, Soares and Sheriff, are explained in detail in multiple papers [20-23]. Nobili's model [20] for platelet activation uses the PAS metric as dependent variable. PAS is a parameter that varies between 0 and 1 for a population of platelets. "Zero" implies no activated platelets and "One" implies full activation of the platelet population. Both Soares et al. [22] and Sheriff et al. [21] models includes the effects of non-steady stress that may act on the platelets. Thus, Figure 5 shows the boxplot of PAS for the oxygenators systems.

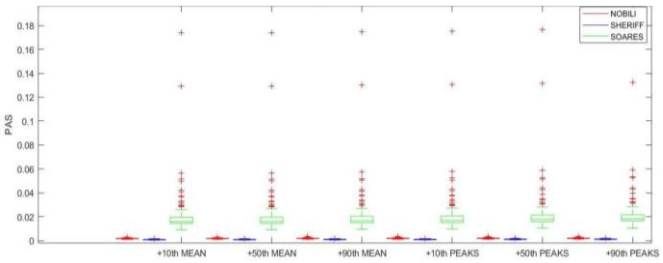

Figure 5: Boxplot of PAS for device (A) and device (B); mean and peak values are shown at 10th, 50th and 90th percentile

IV. Discussion

The aim of this work was to analyze the hemodynamic performance and thrombogenic potential of two commercial oxygenator systems using computational fluid dynamic. Flow analyses allowed us to quantify the flow pattern and pressure drop across the oxygenators. Predictions of the pressure drop were found in agreement with in-vitro data (result not shown). In a different way, the computational analysis overestimated the predicted permeability of porous fiber as compared to in-vitro data. The scalar stress was used to estimate the blood damage and the location where particles are highly stressed. The assessment of scalar stress are fundamental to improve the performance of the oxygenators. The high the scalar stress is, the lower the device permeability is. Using DPM, we computed the thrombogenic risk by computing the platelet activation with several mathematical models. We demonstrated that the Soares et al. [22] model leads to high values of PAS when compared to the mean and peak values estimated by Sheriff et al. [21] and Nobili et al. [20] models. This study extends the use of computational flow simulations to optimize the hemodynamic performance of oxygenators and evaluate their thrombogenic risk.

Despite the abundance of studies on computational flow analysis for assessing the design of cardiopulmonary devices such as heart valves [24, 25], VAD [9-11] and endograft [26], there is limited literature on the mechanical factors initiating platelet activation and thus thrombus formation in oxygenators. Gartner et al. [15] demonstrated that low velocity regions qualitatively matched regions with a high incidence of thrombotic deposition. The computational analysis was however limited to a 2D investigation and not considering the microscale effects. Other studies focused on the experimental quantification of the effects of platelet activation by evaluating the dimension of platelet aggregates [27, 28]. Similar to our study, Pelosi and collaborators [29] determined the thrombogenic potential of a hollow-fiber oxygenator with integrated heat exchanger during extracorporeal circulation. Using computational modeling, both the micro- and macro scales were considered to the order of magnitude of PAS in the device, which was found in agreement with experimental data. The advantage of calculating the PAS was the utilize of a more relevant metric than the scalar stress to quantify the level of platelet activation and ultimately the thrombogenic potential. It should be also considered that the mathematical model proposed by Nobili [20] was validated against experimental data over a range of shear stress obtained in our simulation.

V. Conclusion

In this work, a computational flow method was proposed to quantitatively determine the thrombogenic potential of commercial oxygenators as a result of flow-mediated mechanisms. We estimated the flow velocity and pressure drop at macroscale as well as the hemodynamic of the fiber cell elementary unit at microscale. The thrombogenic risk was evaluated using several mathematical models and revealed that the Sheriff et al. [21] model overestimates the values of platelet activation. This study extends the use of computational flow simulations to optimize the hemodynamic performance of oxygenators to evaluate the thrombogenic device risk.

[3] Centro 3R, Italy

***Abstract*—Traditional contraceptive methods based on intrauterine devices typically results in woman being constantly exposed to hormones or copper. The aim of this study is the design of a copper intrauterine device able to modulate copper ions release thanks to pH-sensitive hydrogels. The working principle exploits physiological pH variations in the vaginal fluids, which increases from 3.5-4.0 up to 7 during intercourse. Medical devices are subject to strict approval processes, thus considering regulatory aspects starting from the device design concept is essential. Using the UBORA platform, the device was classified as Class III. Standards for compliance with the European Medical Device Regulation 745/2017 were identified accordingly. Computational and experimental tests were performed on polyacrylamide and chitosan hydrogels to assess the feasibility of this technological solution.**

***Keywords*— pH sensitive hydrogels, controlled release, intrauterine device, smart medical device**

I. INTRODUCTION

Around 257 million women worldwide do not use modern and safe contraceptive methods; of these, 172 million do not use any method [1]. Moreover, the use of traditional methods results in woman being constantly exposed to contraceptive substances. Intrauterine devices (IUDs) currently on the market are based on the release of copper ions as a spermicidal agent, or of progestin hormone, which causes the thickening the mucous membrane of the cervix. In addition, the presence of a foreign body elicits an inflammatory response which contributes to spermicide action. Copper toxicity and the inflammatory response are also responsible for changes in the lining of the uterus preventing oocyte attachment to the endometrium during fertilization. The copper IUD is also used as an emergency contraceptive because it can prevent up to 99% of pregnancies if inserted within 5 days of unprotected intercourse [2, 3].

For these reasons, the aim of this study is to design of a controlled-release copper IUD, according to relevant standards identified using the tools provided by the UBORA platform (https://platform.ubora-biomedical.org/). The rationale is that the normal vaginal pH of 3.5-4.0 increases up to 7.0 within seconds during intercourse and this value is maintained for up to 48 hours to ensure sperm survival [3,4]. Thus, copper release can be modulated exploiting physiological pH variations.

Different pH-sensitive hydrogels were investigated as possible copper coatings able to reduce the exposure to copper ions and promote ion release only after intercourse. Hydrogels are polymeric materials able to retain a significant fraction of water within their structure. This ability is related to hydrophilic functional groups attached to the polymer backbone, while their resistance to dissolution comes from cross-links between network chains [5, 6]. Alteration of environmental pH changes their ionization leading to their swelling or shrinking. These hydrogels are classified into polyacid (or anionic) and polybasic (or cationic) due to the type of ionic functional groups able to accept or donate H^+ ions in response to changes in environmental pH [5-8].

Among these, polyacrylamide hydrogels (PAAm) and chitosan are widely employed for controlled-release formulations in biomedical applications. PAAm gels are obtained by radical copolymerization of acrylamide monomers (Aam) and N,N-methylenebis (Bis-acrylamide). The molar ratio of the monomer to the crosslinker ranges from 10 to 10^4, and the volume fraction of water ranges from 70 percent to 90 percent. Due to its stability in aqueous environments, polyacrylamide is one of the preferred hydrogels in this field [9-11]. Chitosan is a linear polysaccharide, composed of randomly distributed D-glucosamine and N-acetyl-D-glucosamine units, which is obtained by partial deacetylation of naturally available insoluble chitin obtained from exoskeletons of crustaceans, fungi and insects. Chitosan is nontoxic, stable, biodegradable, and can be sterilized. These properties make it a very versatile material with wide application in the biomedical field [12-15]. Computational simulations and experimental tests were thus performed with these gels to assess the feasibility of the technology.

II. ANALYSIS OF DEVICE RISK CLASSIFICATION AND CONFORMITY TO THE EU MDR REGULATION

IUDs can be classified as class III medical devices in accordance with Rule 15 of Annex VIII of the Medical Device Regulation (MDR) 745/2017 [16].

The regulatory aspects of the device were evaluated using the regulation checklist tool of the UBORA Platform. The following are some of the standards that should be used to ensure compliance with Annex I of MDR 745/2017 [16] regarding safety and performance requirements as required by the CE marking process:

- ISO 14630:2012 NO Active surgical implant [17];
- ISO 7439:2023 Copper-bearing contraceptive intrauterine devices —Requirements and tests [18];
- ISO 14971:2019 Medical devices — Application of risk management to medical devices [19];
- ISO 10993-1:2020 Part 1: Evaluation and testing within a risk management process [20];

TABLE I: List of main risk (R- risks; S severity index; O probability of occurrence; RMC risk mitigation index).

Hazardous situation/ foreseeable sequence of event	*Harm*	*O*	*S*	*RMC*	*RMCindex*	*R*
Wrap damage, non-sterile IUD	*Microbiological contamination*	1	1	*Enclosure condition check*	0.4	0.4
Non-sterile IUD after sterilization process	*Microbiological contamination*	1	1	*Sterility control*	0.4	0.4
Non-biocompatible material	*Uterine cancer or cell death*	1	3	*Use of biocompatible material*	0.2	0.6
	Tumor outside the placement site	1	3	*Use of biocompatible material*	0.2	0.6
	Skin irritation or tissue necrosis	1	2	*Use of biocompatible material*	0.2	0.4
	Genotoxicity	1	3	*Use of biocompatible material*	0.2	0.6

- ISO 10993-3:2014 Part 3: Tests for genotoxicity, carcinogenicity and reproductive toxicity [21];
- ISO 10993-5:2009, Biological evaluation of medical devices - Part 5: Tests for in vitro cytotoxicity [22];
- ISO 10993-10:2023, Biological evaluation of medical devices – Part 10: Tests for skin sensitization [23];
- ISO 10993-11:2018 Part 11: Tests for systemic toxicity [24];
- ISO 13485:2016 Medical devices — Quality management systems —Requirements for regulatory purposes [25];
- ISO 11137-1:2015+A2:2019 Part 1: Requirements for development, validation and routine control of a sterilization process for medical devices [26];
- ISO 11137-2:2015 Part 2: Establishing the sterilization dose [27];
- ISO 13408-1:2015 Aseptic processing of healthcare products [28];
- ISO 15223-1:2021 Medical devices — Symbols to be used with information to be supplied by the manufacturer — Part 1: General requirements [29];
- ISO/TR 24971:2020 Medical devices — Guidance on the application of ISO 14971 [30].

Risk analysis was performed referring to guidelines of standard ISO 14971:2019. The risks (R) associated with hazardous situations were estimated by multiplying the severity index (S) and the probability of occurrence (O) and risk mitigation (RMC) index (Table 1). Then, a 5x5 risk matrix was used. Considering R≤4 as a threshold for risk acceptability, the identified risks resulted acceptable. Only a small excerpt of possible risks related to the use of the medical device are shown in Table I.

III. Materials and Methods

A 15.6% w/v Acrylamide, 0.02% w/v Bis-acrylamide (Bis), 0.086% w/v Ammonium persulfate and 0.056% v/v TEMED solution was prepared and degassed for 2 min. Then, the solution was poured into custom cylindrical molds (diameter = 13 mm, hight = 4mm), and incubated at room temperature for 90 minutes.

1% w/v Chitosan solution in 2% w/v Acetic Acid and 0.5% v/v Glutaraldehyde (GTA) were prepared and poured into the same molds, which were placed in the freezer overnight.

Swelling tests were performed on both polyacrylamide and chitosan samples. Samples were placed pH 4 and 7 buffer solutions based on Sodium Phosphate Dibasique 0.2M and Citric Acid 0.1M (respectively 39%-61% v/v and 82-18 % v/v) and weighed at different time-points. All experiments were performed in triplicate. 4 days cyclic swelling tests were also performed to assess the reversibility of the swelling/deswelling with pH.

Degradation tests were performed on both PAAm and chitosan samples. Samples were placed in pH 4 buffer solution and weighed for 25 days. The 'Curve Fitting' tool was used to derive a mathematical expression for degradation over time, which was used to extrapolate gel degradation considering a 10 year typical device lifetime.

Computational studies were performed on COMSOL Multiphysics® using the Dilute Species Transport Module. A 3D model was developed importing uterus and IUD geometries (Table II) designed using Autodesk Fusion 360®, a CAD (Computer Aided Design) software. A commercial copper IUD (NO-Gravid, kindly gifted by I.r.med S.r.l., Italy) was adopted as a case study. The 515 mm^2 copper surface was covered with a cylindrical hydrogel layer. A parametric study was thus performed to identify the gel thickness which ensure no copper release at pH 4 and a concentration of at least 10^{-6} M at pH 7 (minimum concentration required for contraception), considering a 50 µg/day average ion release [31, 32]. Radial and axial hydrogels variations derived from the experimental swelling tests were also considered (Table IV).

The diffusion coefficients used in the simulation are shown in Table III.

TABLE II: Dimensions of the uterus and IUD [31]

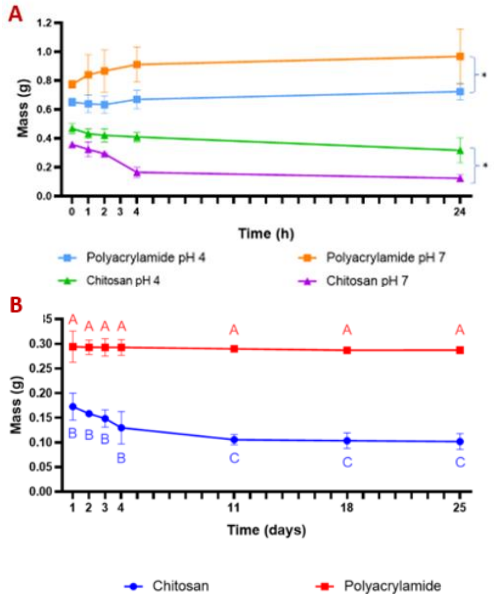
Dimensions		*Values (mm)*
Uterus	*length*	76
	width	45
	thickness	30
IUD	*diameter*	2
	length	20
	wingspan	42

TABLE III: DIFFUSION COEFFICIENTS [33][34]

Material	*Diffusion coefficients at pH 4 (m^2/s)*	*Diffusion coefficients at pH 7 (m^2/s)*
PAAm	$6.3*10^{-12}$	$5.81*10^{-11}$
Chitosan	$3.3*10^{-12}$	$3.3*10^{-13}$

TABLE IV: AXIAL AND RADIAL VARIATION AT PH 7

Material	*Axial variation (%)*	*Radial variation (%)*
PAAm	+27.62	+14.1
Chitosan	-28.57	-18.1



Design and Fabrication: molds for polymer casting were designed on Fusion360®, defining the gel thickness according to computational results. The molds were prototyped in Tough resin 1500 using stereolithography printer Form 3(*Formlabs*).

Copper ion release tests were performed on chitosan hydrogels placed in 10 mL of pH 4 or 7 buffer solution for 4 and 8 hours. The release of cooper ions was measured using the Copper Colorimetric Assay Kit (Elabscience, E-BC-K300-M).

All experiments were performed in triplicate and expressed and mean +/- standard deviation. Statistical analysis was performed using GraphPad Prism software version 8.

IV. RESULTS

As expected, PAAm mass increases with increasing pH, while chitosan mass decreases (Figure 1). The swelling ratios (calculated as the mass variation at pH 7 with respect to pH 4 mass at 24h) were 34 ± 26 % and -61 ± 8% respectively. In particular, the samples start swelling immediately after being in contact with the buffer solution and reach a plateau after 4 hours. Cyclic tests also showed the reversibility of the process. Extrapolating degradation profiles to 10 years resulted in a mass loss of 2.8% for PAAm and 40.8% for chitosan.

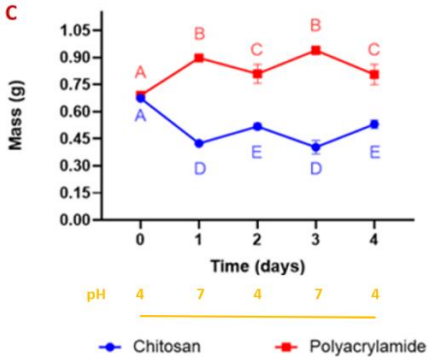


Fig. 1: A - Average mass of the polyacrylamide and chitosan samples at pH 4 and pH 7 at different time points. B - Polyacrylamide and chitosan degradation. C – 4 days cyclic pH variations. * =p<0.05. Different letters indicate statistically significant differences (p<0.05).

Simulations (Figures 2 and 3) suggested that a suitable thicknesses for limiting copper release at pH 4 and for reaching the target concentration for spermicide action at pH 7 is 2 mm.

In particular, at pH 4 the ions are constrained at the copper surface because of the polymer barrier and do not reach high concentrations in the vaginal fluid. On the other hand, at pH 7, the ions pass through the swollen polymer reaching the appropriate concentration for the contraceptive effect in the vaginal fluid. The average concentration of Cu^{2+} in the fluid is indeed equal to $5x10^{-7}$ M at pH 4 and $3.2x10^{-5}$ M at pH 7 in the case of PAAm at to 0 M and $8x10^{-6}$ M in the case of chitosan.

For PAAm, the target concentration was reached after 5h and 30 min; and after 5h and for chitosan. For these reasons, a 2 mm thick mould was design and fabricated (Figure 4).

V. CONCLUSION

In this work, thanks to experimental tests and simulations, we demonstrated the feasibility of using pH-sensitive gels for the design of a smart IUD able to reduce constant exposure to copper and ensuring ion release after intercourse. A preliminary analysis of the device according to MDR 2017/745 and relevant standards was performed. Although the device has great potential, there are still open challenges to overcome for its commercialisation, such as the long-term stability of the gel and aspects of packaging, sterilisation, and the supply chain to reach the end user.

VI. ACKNOWLEDGEMENT

Thanks to I.r.med S.r.l., Italy, for kindly donating NO-Gravid IUDs.

***Abstract*—Cell deformability is a well-established marker of multiple cell states for phenotyping and classification purposes. However, the measurement of rheological/mechanical cell properties is often hindered by complex measurement systems and long experimental times. Here, we present a microfluidic approach, as a simple tool to rapidly deform cells in a highly controlled manner, based on tuneable compressive forces. In fact, by simply changing the fluid-flow conditions, we are able to induce variable compression levels at different timescales, depending on the cell line of interest. In particular, we demonstrate how cytoskeletal structures such as actin cortex and microtubule network cooperate to change the overall viscous content of cells. Starting from a completely label-free tracking of dynamic and morphological biophysical parameters, we are able to define inner cell viscosity changes related to actin cortex and microtubule network alterations. Thus, our microfluidic approach is a versatile and easy-to-use way to probe biomechanical cell properties starting from simple in-flow motion parameters.**

***Keywords*—Biomechanics, single-cell, compression, microfluidics.**

I. Introduction

IT is frequently reported how cytoskeletal or nuclear changes are related to cell deformability [1]. In particular, cell phenotype, development, motility and several biological functions are controlled by mechanical loading. In fact, a prolonged or substantial loading can damage cells, eventually leading to their death. Moreover, loading conditions induce specific mechano-structural and mechanobiological responses in different cell types, affecting their internal architecture and morphology as well as the mechanics of the cell components [2]. It is well known that the major cell constituents involved into biomechanical cell responses are the cytoskeletal components of actin cortex and microtubule network. Thus, comprehending the dynamics and mechanics of the cellular components is prerequisite to explain the molecular origins of cell mechanical properties. In particular, in suspension, cells develop a well-defined spherical geometry free of visible stress fibers with the actin cytoskeleton forming a cortex structure which spans the entire cell [3]. Instead, the microtubule network presents as random at the cell interior while with pronounced bundles at the periphery [4]. This aligned peripheral bundling may be due to collective buckling at the cell's boundary. However, it is well known that the actin cortex and microtubules respond differently and then a precise calibration of the mechanical loading is crucial in time and entity.

Over the past years, a variety of microfluidic devices were used to induce cell deformability at high throughput with high-speed bright field imaging techniques, allowing the direct and rapid measurement of several cell biophysical and biomechanical properties such as cell dimension, viscosity and deformability [5]. Recently, a straightforward viscoelastic-based microfluidic approach was used to in-flow compress cells in a controlled and precise manner and to analyse deformed cells by coupling the classical descriptors of morphological and shape alterations with in-flow orientation angles [6], [7]. Inspired by the motion dynamics laws known for RBCs [8]-[13], we already demonstrated that suspended cancer and healthy breast cells with variable cell deformation (CDs) and aspect ratios (ARs) followed multiple in-flow trajectories defined as rolling (R), tumbling (T) and tank-treading (TT) [6]. Of note, we proposed a direct correlation between the measured ARs and trajectories through the inner cell viscosity evaluation [7]. Moreover, by exploitation of in-flow viscoelastic tuneable compression forces, we recently showed that our cell deformability responses are in the range of large deformation (CD > 5%) at which the cell nucleus actively responds by triggering production/remodelling or destruction phenomena of nuclear constituents, such as Lamin-A and Chromatin [14]. For this reason we decided to investigate how actin cortex and microtubule network cooperate to these biomechanical responses. In fact, at large deformation range it is known that actin constituents disrupt while microtubule network elastically responds [4]. Here, we present the possibility to directly correlate the in-flow analysis of compressed single-cells with respect to the biomechanical response of actin cortex and microtubule network of highly metastatic cancer cells. In fact, we demonstrate that changes in the in-flow measured viscosities of cells correspond to different degrees of actin cortex and microtubule deconstruction expressed in terms of inner structural density.

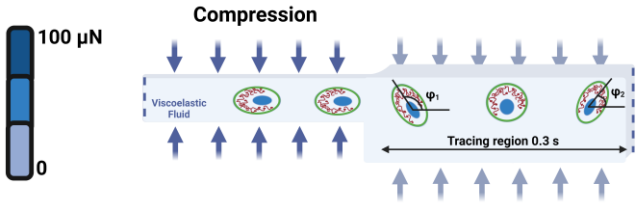

Fig. 1 Sketch representation of the microfluidic device. The exerted viscoelastic compression ranges from 0 to 100 µN, depending on the used PEO concentration. In particular, the final part of the compression region is shown, where deformed cells move before entering into an enlarged region where the brightfield acquisition occurs. The orientation angles (φ_1 and φ_2) are measured at the beginning and the end of the tracing region [6]. Then, after the in-flow measurement, the actin cortex (green) and microtubule compartments (red) are analysed with a confocal microscope after staining procedure. (Created with BioRender.com)

II. Material and Methods

A. Viscoelastic in-flow forces

To induce the compression of single cells under viscoelastic flow conditions, we used a highly biocompatible polyethylene-oxide (PEO 4MDa, Sigma Aldrich). Fluid rheological properties have been previously investigated and properly characterized [6]. We decided to work with two different PEO concentrations, in order to induce two distinct levels of in-flow compressive forces. In particular, we selected PEO 05 and 09 concentrations, which correspond to polymer concentration of

0.53 and 0.88, respectively. A different pressure was fixed for each PEO in order to have the same fluid-flow velocity (~2500 μm/s into the tracing region) to align and compress [6]. To verify the extent of the applied force ($F_{ElMax} \propto U_{Max}^2 \eta_0 \lambda \beta^3$), we tracked cells centroids to estimate such velocity. A good agreement between the measured and the estimated velocity was achieved [6].

B. Experimental setup for the in-flow measurement

The setup includes a pressure pump (P-pump, Dolomite Microfluidics), round shaped flexible fused silica capillary tubing (Molex), an ad hoc designed microfluidic chip, a fluid connector (N-333, IDEX) and an inverted microscope (X81, Olympus) with a CMOS camera (ORCA FLASH 4.0, Hamamatsu Photonics K.K.). Briefly, a pressure pump pushes the sample volume through the capillary in the microfluidic device inlet, while at the end of the chip a reservoir collects the cells. The chip is made of two separate parts made with polymethyl methacrylate, which are placed together by magnetic forces. The main part was machined using a standard CNC based micromilling technique (Minitech Machinery) to develop microfluidic duct sections [6],[7]. of different height, width, and length, while the cover part was simply used to close the chip [6],[7]. In particular, the compression section has the smallest height (W × H: 100 × 25 μm) implying that a well-defined viscoelastic compression over a certain time period on each passing cell is applied, enabling precise cell compression in-flow. Then, a subsequent enlarged section (W × H: 200 × 90 μm) is conceived for the observation and analysis of the compressed cells (Fig.1).

C. Cell culture, immunostaining, and confocal acquisition

We have investigated MDA-MB-231 cells. They were kindly donated by Daidone's group and Dr P. F. Cammarata (Institute of Molecular Bioimaging and Physiology, IBFM-CNR, Cefalù (PA), Italy), respectively. MDA-MB-231 cells are cultured in a 1 : 1 mixture of Dulbecco's modified essential medium (DMEM, Euroclone) and Ham's F-12 medium (Microtech) supplemented with 10% FBS, 1% non-essential amino acid mixture and 100 U ml^{-1} penicillin/streptomycin. Finally, each investigated cell type is diluted in 500 μl of viscoelastic medium to reach a final cell concentration of circa 50 cells per μl. No evidence of mycoplasma infection is present. For immunostaining, cells were fixed with 4% paraformaldehyde (Sigma-Aldrich) for 15 min at room temperature, then rinsed twice with PBS. Permeabilization – with 0.1% Triton X-100 (Sigma-Aldrich) for 5 min– was performed. Thus, the actin cortex was stained at the level of F-actin components with Alexa 488 phalloidin (Invitrogen) at 1 : 200 dilution for 1 h. The microtubule network, instead, was stained with Beta III Tubulin monoclonal antibody overnight at 4 °C with Alexa543 anti-mouse secondary antibody. For the image acquisition of the actin cortex and microtubule network, we used a 63× oil immersion objective (NA 1.4) of a confocal laser scanning microscope (LSM 710, Zeiss) equipped with argon and HeNe laser lines at wavelengths of 488 and 543 nm, respectively. Image resolution was fixed at 512 × 512 square pixels with a 4× zoom factor.

D. Measurement procedure and data analysis

In-flow cell analysis was performed over the full cell tracing length (~0.3 s of measurement in the tracing region), after the compression region (Fig.1). We measured the dynamic in-flow cell parameters, such as the major axis (d_1), minor axis (d_2), circularity (c) and orientation angles (φ) in the range of [−90° to 90°], at each 0.03s. Out of such parameters, the cell deformation (*CD*), cell aspect ratio (*AR*) and angle variation (Δφ, at the beginning and the end of the tracing region) are calculated as follows:

$$AR = \frac{d_1}{d_2} \quad (1)$$

$$CD = 1 - c \quad (2)$$

$$\Delta\varphi = |\varphi_1 - \varphi_2| \quad (3)$$

Where φ_1 and φ_2 are the φ-orientation angles computed at the beginning and the end of the tracing region, respectively. In the specific case of T motion of oblate cells, we computed the variation of the cell orientation angle as function of the viscosity ratio (μ'/μ):

$$tan\big(\varphi(t)\big) = \big(A + B/(A^2 - B^2)^{1/2}\big) \cdot tan(2\pi t/T_{rev}) \quad (4)$$

where,

$$T_{rev} = 2\pi(AR + AR^{-1})\dot{\gamma}^{-1} \quad (5)$$

It indicates a complete period over which a tumbling rotation occurs (0.3 s) and $\dot{\gamma}$ is the shear rate (10 s^{-1} < $\dot{\gamma}$ < 15 s^{-1}). Moreover, $A \propto \dot{\gamma}$ and $B = f(\dot{\gamma}, AR, \mu'/\mu)$ for which μ' and μ are the inner cell viscosity and surrounding fluid viscosity, respectively [13]. Of note, *A* and *B* describe the functional variation of the *AR* of cells with respect to the imposed flow condition in terms of $\dot{\gamma}$.

For a TT cell motion, the equation (4) can be expressed as a stationary angle, only dependent on the fixed $\dot{\gamma}$ and AR:

$$\varphi_{stationary} = 1/2\, arccos(-A/B) \quad (6)$$

Thus, from the known oscillation (φ(t)) of the cell in T or TT motions, we can retrieve the B parameter and then the value of μ'/μ.

For the actin cortex level (Cortex Density) quantification, we normalized the value of the single-channel intensity with respect to the area delimited by the external ring of the cortex itself subtracting it with the nucleus area. Instead, microtubule signal (MT Density) has been computed normalizing the value of the single-channel intensity with respect to the area delimited by the external ring of the cortex itself subtracting it with the nucleus area.

III. Results and Discussion

To in-flow deform cells, we applied a compression ranging from 10^1 to 10^2 μN -05 and 09 conditions- for 5s [6],[7],[14]. Such duration of compression has been established to satisfy time conditions needed to detect viscous behaviour. In fact, since the inner content of suspended cells can be modelled as a viscoelastic fluid, only below a certain length timescale the resulting behaviour is ascribable to purely viscous effects [15],[16]. At stimuli frequencies less than 0.5 s^{-1}, as the ones we used during compression, such viscous behaviour is dominant. Thus, we used an estimation of the inner cell viscosities from the computation of μ'/μ using the T and TT data (equations (4) and (6)).

Here, we decided to test the highly invasive cancer cells MDA-MB-231, for which abnormal expression levels of microtubules and reductions of actin cortex expression have been observed compared to normal cells [18]. In Table 1, we reported the mean values of the biophysical parameter of

interest for the computation of μ'/μ, depending on the identified motion regime [6],[7]. Of note, we indicated the two different T and TT motions which correspond to 05 and 09 compression conditions, respectively.

TABLE I: MDA-MB-231 IN-FLOW RESULTS (N= 31)

Parameter	*Mean ± std. dev.*	*Motion regime*
AR	3.21 ± 1.11	TT, CD ~ (0.15; 0.45)
$\Delta\varphi$	3.39 ± 2.96	TT, CD ~ (0.15; 0.45)
AR	1.43 ± 0.27	T, CD ~ (0.10; 0.21)
$\Delta\varphi$	94.05 ± 25.55	T, CD ~ (0.10; 0.21)

Then, on the viscosity master curve we recently extracted for viscosity computation, we reported the measured *AR*s for which T and TT exist (Fig. 2) describing the resulting μ'/μ variations [7]. The obtained values of μ' are in the order of 10^{-1} Pa·s at T and 10^{-2} Pa·s at TT, meaning a decreasing viscosity after a higher compression (Fig.2).

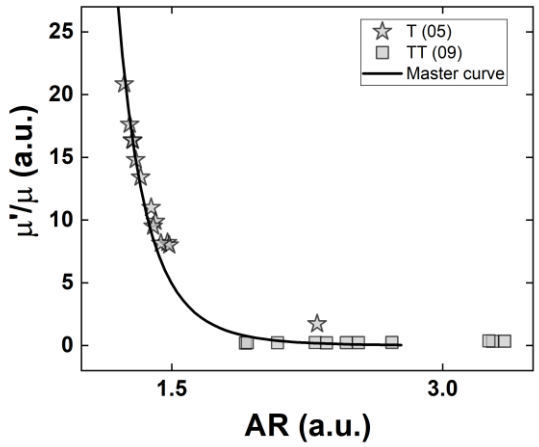

Fig. 2 μ'/μ variations with respect to ARs are shown for the T and TT regimes.

Thus, for such a viscosity decreasing, a possible contribution coming from changes at the actin cortex and microtubule network levels was investigated. A control (Ctrl) condition was investigated to understand the initial states of Cortex and MT densities before the microfluidic compression. Overall, a gradual decreasing of the cortex density is recorded by compression increment (Fig. 3). At the microtubule level, a slight decreasing of the MT density occurs coupled with a spot-like distribution of the relative fluorescence signal into the cell interior like defining a spot accumulation near the nucleus. Of note, microtubule network does not show a relevant change at 05 suggesting a different viscoelastic response to the compression compared to the actin cortex. Instead, the 09 condition results to be critical for both the two compartments. Nevertheless, we already demonstrated that MDA-MB-231 experience a Lamin-A destruction and chromatin de-condensation which lead to a not recovered cell functionality at 09 [12].

IV. CONCLUSION

The proposed microfluidic approach based on viscoelastic compression forces has successfully enabled the possibility to estimate inner cell viscosities in a completely label-free manner, thus correlating such values to alterations of the actin cortex and microtubule networks. Starting from in-flow measured biophysical parameters as AR and $\Delta\varphi$, we extracted inner cell viscosity values. We decided to test the approach on highly metastatic cancer cells (MDA-MB-231). In particular, we demonstrate a gradual decreasing of the inner cell viscosity after an increasing applied loading. Then, we correlated such resulting behaviour with respect to changes in Cortex and MT densities which decrease by increasing the applied compression. Thus, our approach shows how simple motion parameters allow a direct measure of rheological/mechanical properties.

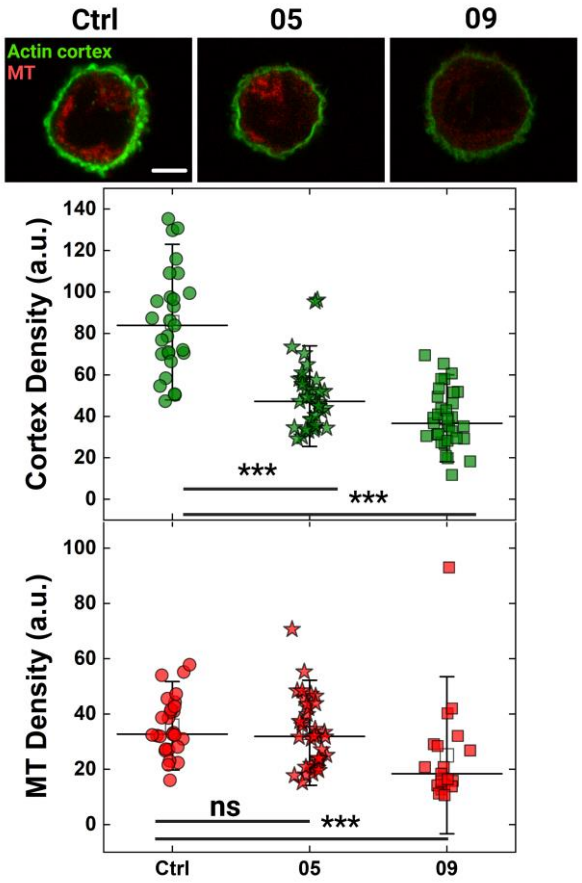

Fig. 3 Actin cortex and microtubule density changes. The 05 and 09 after flow conditions are compared with respect to the Ctrl condition (outflow condition). On the top, the confocal images showing both the two compartments are presented (scale bar 5 μm). On the bottom, the box chart plots of the Cortex and MT density are presented. A Kruskal-Wallis test has been performed for the statistical analysis: $^{ns}p>0.05$, ***$p<0.001$.

***Abstract*—Artificial Intelligence (AI) is the ability to make decisions or perform tasks by machines based on a training process. Among the various sectors in which AI is used, healthcare is no an exception, but the risks associated with its use in medical devices may be unacceptable. This work aims to highlight the main barriers to the application of AI in medical devices to date and how open-source design philosophy can be an advantage in overcoming these barriers, through a practical example, named Palpreast, a device for breast self-examination.**

***Keywords*—Open-source medical devices, Artificial Intelligence, breast self-examination.**

I. Introduction

Artificial intelligence (AI) is defined as a machine being able to perform problem-solving and decision-making tasks like any thinking being. Usually, these tasks involve predicting a certain outcome or reasoning a certain question based on a prior learning process carried out by the machine itself on a dataset [1]. In recent years, there has been an inflation in the use of AI in a wide variety of sectors: from aviation to economics, from social sciences to the energy field [2]. Even the healthcare sector has not been spared from the explosion of AI, as this innovative technology supports the skills of professionals and, at the same time, provides more efficient, more sustainable, and higher quality services [3].

In the field of healthcare, four macro-areas can be identified where AI can be potentially employed: i) clinical services (*e.g.*, oncology radiology, home care, surgery, mental health, treatment plans); ii) biomedical research (*e.g.*, drug delivery, personalised medicine); iii) public health (*e.g.*, epidemiological surveillance and event-based surveillance especially for low-middle income countries); and iv) health administration (*e.g.*, coding, patient flow management). Among clinical services, medical devices (MDs) working with AI are particularly critical because of the direct risk related to their use for the patients and healthcare providers [4]. Risks are mainly linked to the limited knowledge about the internal operation of AI algorithms, that often act as a 'black-box' in which no clear explanation is given on how the algorithm computes its output.

In this context, the open-source (OS) philosophy of sharing the entire project is a valuable tool to mitigate the risks [5]. The OS concept foresees the complete sharing of all source material to allow the project to be peer-reviewed, reproduced and eventually upgraded. Open-source medical devices (OSMDs) are therefore devices for which both the design and development documentation must be publicly available to *"study, modify, distribute, make, and sell the medical devices, and their related software or hardware"* [6]. This sharing approach has led to more reliable and appropriate products, although greater attention must be put on safety in the health field. In this context, virtual tools such as the UBORA platform (https://platform.ubora-biomedical.org) can support the design of ISO compliant OSMDs. OS tools for usability analysis of medical devices have been applied with success to identify use errors with infusion devices, as well as with other medical devices [7], [8].

This work aims to highlight how OS design can be the key for overcoming the barriers and the limitation in assessing the regulatory conformity of MDs working with AI. Palpreast, a breast self-examination OSMD, will be described as a case-study of this application.

II. Barriers and Open-source solutions for AI in medical devices

In recent years, some critical issues have been raised among medical services that could be solved by AI applications, as highlighted by the recent COVID-19 pandemic. The enforced isolation, to which a large part of the population has been subjected, has compromised the continuity of essential services mainly for elderly and people with disability. In this context, AI could have been a way of ensuring the continuation of these services and supporting the work of health workers. The lack of personnel within the facilities was another critical issue encountered, although some activities such as checking up basic parameters for hospitalised patients would be possible tasks to be performed automatically by AI.

TABLE I: Summary of the main barriers related to the adoption of AI in MDs.

Barriers	*Description*	*Reference(s)*
Regulatory Barrier	Absence of Regulation focused on AI application on MDs	[9],[10], [11]
Privacy and Data Protection	Data Management: Collection, Storage, Access Protocols and Policy	[12]
Fairness, social and economic impact	Enhancement of societal gaps (e.g., gender, poverty, ethnicity)	[13], [14]
Transparency and explainability	Unknown operation of the AI algorithm and addressing liability	[15]
Reliability and Reproducibility	Necessity of repeatability	[16]

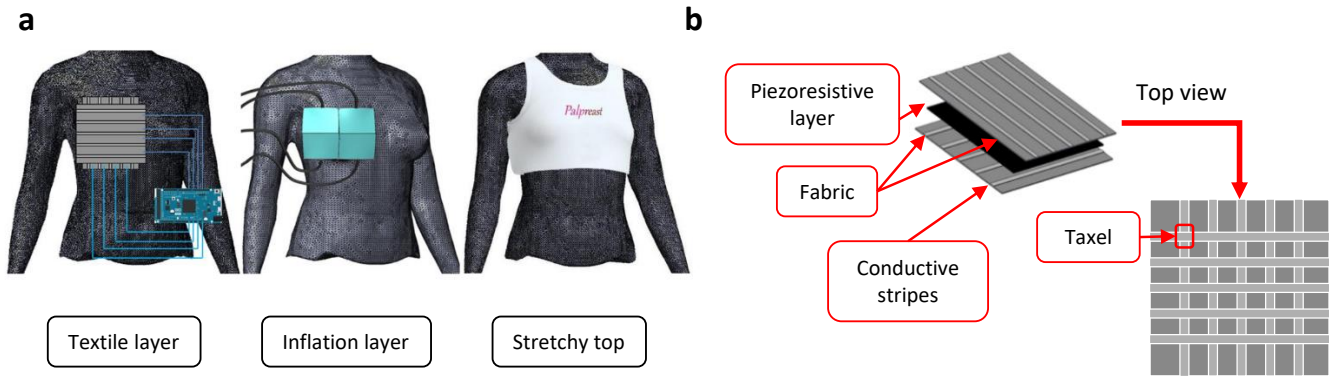

Fig. 1: Overview of the Palpreast OSMD. In (a), the three main elements of the device, including the smart textile layer, the inflation layer (containing the four air chambers per breast), and the stretchy top. In (b), the structure of the smart textile layer, composed of a sandwich structure with two layers of fabric and a piezoresistive material in between. The fabric layers include conductive stripes (with a 90° angle between the top and bottom fabrics) that are used to read the variable resistance of the piezoresistive material. The crossing between two perpendicular stripes forms a taxel, the basic unit during data acquisition.

Despite these potentials in solving relevant clinical needs, there are still gaps to be bridged for these applications to reach the market and guarantee security and reliability, as summarized in Table I. Specifically, the following key points need to be addressed for the adoption of AI in MDs:

- Regulatory barrier: The Medical Device Regulation 745 (MDR 745/2017) [10] and In Vitro Diagnostic Medical Devices Regulation 746 (IVDR 746/2017) [11] enacted by the European Parliament in 2017 do not have specific rules for MDs working with AI. Although compared to previous directives the new ones are more comprehensive, there are no references to this emerging new technology in any of their points. In 2021, the European Commission published a proposal for a regulation on AI. This document is part of a broader plan (Coordinated plan on AI) and divides biomedical applications with AI into tiers based on the associated risk. For these applications, the proposal aims to clear the requirements, the obligations of those who provide the services and those who use them, and includes a draft for conformity assessment. The regulation could enter a transitional period in 2023, while early 2024 is the earliest time for the regulation to be applicable [9]. In US, FDA has provided a risk-based guidance for certifying Software as Medical Device embedding AI [17]. In a regulatory risk-correlated approach divided into four categories (*i.e.*, unacceptable, high, limited, and minimal or no risk), the open and collaborative design approach favours the likelihood of mitigating risks already at the design stage, resulting in safer devices.
- Privacy and Data Protection: The General Data Protection Regulation (GDPR) is the data protection law for citizens of the European Union that regulates the entire management of data, including collection, use, storage, how data are processed, and what protocols are in place to access them. The GDPR should be taken into consideration each time that data flows in AI-based systems, such as i) when input data are entered by users be able to operate, and ii) when countless amount of information is automatically collected to generate the output. The latter, in fact, can be correlated with private aspects of the user, concerning his/her habits, and thus to personal information such as political, sexual, and religious orientation, gender, etc. From a technical point of view, data used in the design stage (i.e., during training and testing of the AI model) must be treated appropriately, as the absence of data integrity would completely change the output of the algorithm [12]. Having access to the source code is an undoubted advantage for ensuring security because it allows i) to control the flow of data (from the collection to the output), ii) to obtain schematics tracing its path (*e.g.* https://www.privado.ai/open-source) and iii) to verify that there are no leakages or any kind of violation of user protection laws.
- Fairness, social and economic impact: The application of AI algorithms must be a step forward for society, not a tool to widen existing gaps. AI must be accessible to all and equally. Starting with the testing of the algorithm, there must be no inquisitiveness, be it gender, ethnicity, disability, poverty, or any possible categorisation [13]. In addition to discrimination, consequences of using unbalanced databases could affect other aspects such as fairness in the market (gaining an advantage over other producers) or consequences on prices [14]. Using open Data for AI training is an advantage on several levels: on the one hand, it limits the monopoly of some companies on datasets, a phenomenon that sometimes severely limits their accessibility and reinforces the bias on *e.g.* gender or race. Open datasets make developers focus on solving problems, rather than on acquiring data, thus mitigating risks and increasing reliability.
- Transparency and explainability: Transparency was set in the ethical guidelines published by the EU Commission's High-Level Expert Group on AI as one of the 7 key requirements for a trustworthy AI. When using an AI system, the user must be aware of how the decision-making system operates and what the predefined rules are. At the same time, the user must always be informed of both the possibilities and limitations of the intelligent system. If the operability of the algorithm is well documented, these requirements are easily fulfilled. However, innovative AI algorithms exploit implicit learning techniques and in this case the transparency requirement for the conformity assessment is difficult to implement because the results of the models are not fully explainable [15]. Article 15 of the GDPR establishes that if automatic decision-making systems are to be employed, the user must have 'meaningful information about the logic involved'. In this context, Explainable AI (XAI) models [18] offer both to designers and users to understand how an AI-based system actually works for generating outputs.
- Reliability and Reproducibility: Reproducibility and reliability are two core concepts for a robust algorithm. An algorithm is robust if it responds correctly to different outputs

and in different situations and under the same conditions it must give the same output. These aspects must always be guaranteed, especially in biomedical applications. The way to guaranteeing this requirement would be to provide a series of appropriate records that allow another research team for instance to reproduce a certain task and verify its reproducibility. However, it is unclear what the appropriate content of these files (called replication files) must be in order for the output to be considered appropriate [16] When designing through an OS approach, the developer shares all source information but also gives the opportunity to study, modify, verify as stated in the definition in the previous paragraph. Having all the resources and being able to study, verify and if necessary, implement changes will make the algorithm more reliable. Reproducibility is the tool to improve the reliability[19].

III. AI IN MDS: THE CASE-STUDY OF PALPREAST

A. Clinical need and device overview

Every year, more than 14 million women are diagnosed with breast cancer, many of them in low- and middle-income settings. Even though substantial treatment advances have been made in recent years, early diagnosis remains the main tool for reducing mortality [20]. Breast self-examination (BSE) is a technique that allows the detection of lumps manually by the patient herself. Although recommended by qualified personnel, a large part of the population does not perform the practice because they do not feel confident to detect the lump.

In this context, in a previous work we presented Palpreast, a non-invasive wearable OSMD, which reproduces BSE procedure [21] is aimed at supporting women in identifying the presence of lumps. As such, the device can be classified as class I medical device, according to the EU MDR 2017/745 as it does not have a diagnostic function, but it only exerts a supportive role. Palpreast, as specified, performs BSE and this practice is not diagnostic. In the event that Palpreast detects any abnormality, this information is not directly related to the presence of a possibly malignant lump, but invites the patient to proceed with more accurate, in this case diagnostic, examinations. The main components of Palpreast are presented in Fig. 1a and include: i) a pressure sensing textile located in direct contact with the skin; ii) an inflation system which uses four air chambers per breast; iii) a stretchy top that covers the two previous elements. The textile consists of a layer of piezoresistive material placed between two layers of fabric with highly conductive stripes. The top and bottom conductive patterns are perpendicular and each intersection between a row and a column corresponds to a sensing element (named taxel), as can be seen in Fig. 1b.

When one of the four air chambers is inflated (herein named ‘quadrant’), a pressure is applied to the textile and thus to the breast, in a similar way to the BSE procedure. By measuring the resistance change in each taxel, a graphic map can be obtained in which the visual information is correlated with the mechanical resistance sensed by the device. The comparison between left and right breast data can be used to infer the presence of the nodule in one of the two breasts [21]. More technical details on the OS device can be found on the UBORA platform, where the project is fully documented [22]. Here we want to explore how AI can assist the identification of lumps, how this support will modify the classification/certification of Palpreast, and how OS can favour the regulatory process.

B. Data collection pipeline

A custom data collection pipeline was implemented to facilitate acquisition, aggregation, and analysis. In particular, after wearing the device, data is collected from the smart textile one quadrant at a time by inflating the corresponding air chamber and reading the voltage difference of each taxel using a voltage divider configuration. The data acquisition is performed by an Arduino Nano 33 BLE board which uses a custom firmware (written in C++). For each quadrant, the Arduino creates two matrices for the two breasts (where each element of the matrix refers to a physical taxel), which are then sent to a computer using serial connection. On the receiving computer, a custom graphical user interface, written in Python using the Streamlit library, allows the visualization of the matrices and their storage to disk with custom identifiers in .csv format for further processing.

C. Development of a preliminary dataset

A preliminary dataset was obtained using the previously described pipeline by mounting the Palpreast device on a mannequin with two breast phantoms. The phantoms were fabricated using Ecoflex 00-10 and Slacker (PartA:PartB:Slacker 1:1:3, Smooth-On, Inc USA) and Dragon Skin 00-10 Medium (PartA:PartB 1:1, Smooth-On, Inc USA) to mimic the mechanical properties of the healthy breast tissue and of the lump, respectively. The phantom was designed in a way that the nodule could be inserted in various positions to ensure greater variability of the data collected. Five lump configurations and one without the lump were tested. For each of the six configurations, multiple repeated acquisitions were performed for a total of 24 acquisitions, which constituted the preliminary dataset for further analysis.

D. Data augmentation using simulated data

Given the large amount of data needed for training the Machine Learning models (see section E), we have planned the implementation of a Digital Twin of Palpreast. A finite element 3D model of Palpreast was implemented in COMSOL Multiphysics. The piezoresistive behaviour of the sensor (*i.e.* the correlation between applied pressure and voltage output), was modelled using an experimentally derived characteristic curve. The model will be interfaced with a virtual model of the data acquisition pipeline of Arduino using Matlab® to fully replicate the entire mechanism from data generation to their processing.

E. Exploratory data analysis

The mixed dataset (simulated and experimental) was preliminarily analyzed to extract relevant per-quadrant metrics, including mean, standard deviation, median, interquartile range (IQR), skewness, kurtosis, and number of outliers (measured as the number of data points outside the IQR). Example plots for these measures can be seen in Fig. 2 for the mean and standard deviation case. These specific measures were chosen as possible explainable variables for further processing using Machine Learning models (e.g., decision tree classifier), which can give insights into the classification process.

F. *Changes in the certification process*

The presence of AI does not change the risk class of Palpreast. The AI algorithm does not modify the intended use of the MD by making it diagnostic, but performs a different data analysis by fusing multiple features of the original signals for highlighting the presence of a lump. However, in the regulatory framework for certifying such MD supported by AI, it is necessary to consider not only the standard benchmarks but also the device's operation with a certain degree of autonomy (DOA) as it is able to generate decision-making outputs. DOA results in an associated risk which have to be reported in the risk management analysis. The IEC TR 60601-4-1:2017 standard offers all the necessary guidelines for identifying the DOA, the associated risk and offers the necessary guidelines for implementing *a detailed risk management and usability engineering processes for medical electrical equipment or systems employing a degree of autonomy* [23].

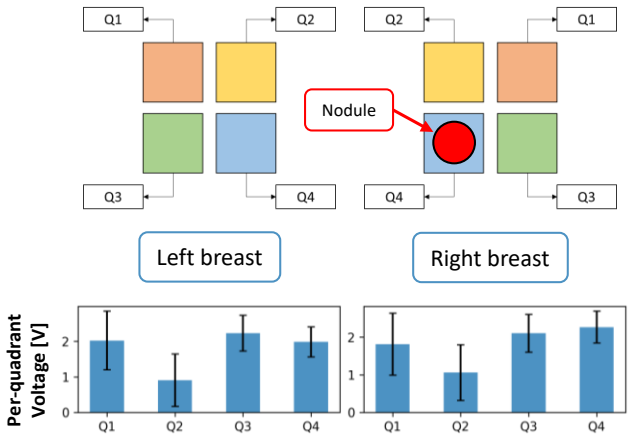

Fig. 2: Example of the measured data during the experiments, alongside a visualization of the per-quadrant mean voltage and its standard deviation, which can be used as an explainable metric for developing AI models. The presented data is related to a nodule placed inside the Q4 quadrant, which corresponds to position 1 in Table II.

IV. Conclusions

This paper highlighted the barriers that currently hind the use of AI in MDs and how the OS approach can help overcome them. The results reported for Palpreast case study are preliminary and still need further investigation in the choice of *e.g.* data analysis metrics and types of comparisons to be made for reliable results. However, it has provided a base for investigating the OS approach applied to AI-based MD.

***Abstract* — The use of multi-use Surgical Instrumentation (SI) kits is the standard that is currently used in hospitals for orthopedic and spinal interventions. Nevertheless, this has several disadvantages such as the high cost, the environmental impact of the sterilization, and different problems related to its reliability, including the failure of the SI during the surgery. So, the aim of this work is to develop a method for the mechanical evaluation of a cervical SI through a combined numerical and experimental approach, to redesign it from multi-use to single-use instrumentation, to make up for the previous problems.**

***Keywords*—Spinal surgical instrumentation, mechanical evaluation, finite element model.**

I. Introduction

NOWADAYS multi-use Surgical Instruments (SI) are used for the implantation of orthopedic and spinal devices. Generally, the kits are composed of several instruments made of stainless steel which can be reused for several operations and stored in the hospital only after sterilization to avoid cross-infection among the patients.

Sterilization processes are generally performed internally at the hospital hosting the kit or by subcontractors specialized in performing sterilization processes, either EtO sterilization or moist heat sterilization. These are energy-intense processes, with each load for a medium- to large-sized hospital sterilization requiring about 20kWh of electricity and 500 l of water [1]. These procedures lead also to complications in hospital management, both in terms of costs and organization, as they require (i) a significant time loss due to the necessity of performing the various safety and hygienic protocols (ii) complicated logistic management of the reusable kits in terms of repeated handling in and out of the hospital (or in and out of the operating room) [2].

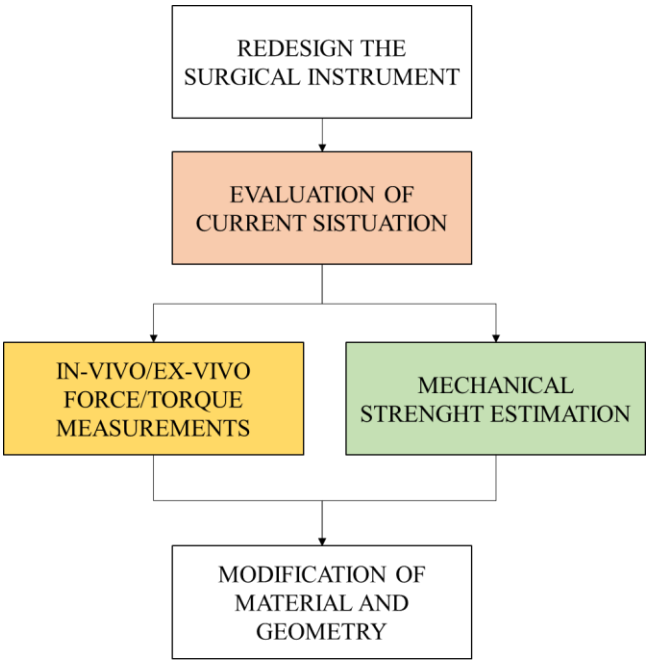

Fig. 1 The workflow for the mechanical evaluation of the SI.

In addition to the high costs due to sterilization, surgical instrumentations can experience a fracture in the operating room, in particular, if used for several procedures.
Dharmashaktu et al. recorded that out of a total of 8132 (6517 major and 1615 minor procedures), 30 (0.36%) cases of intra-operative instrument breakages were noted. The event of an instrument failure may prolong surgery time and add the need for additional procedures such as extra incisions, making fenestration in the bone to remove broken instruments in a destructive and unwanted process [3], [4].

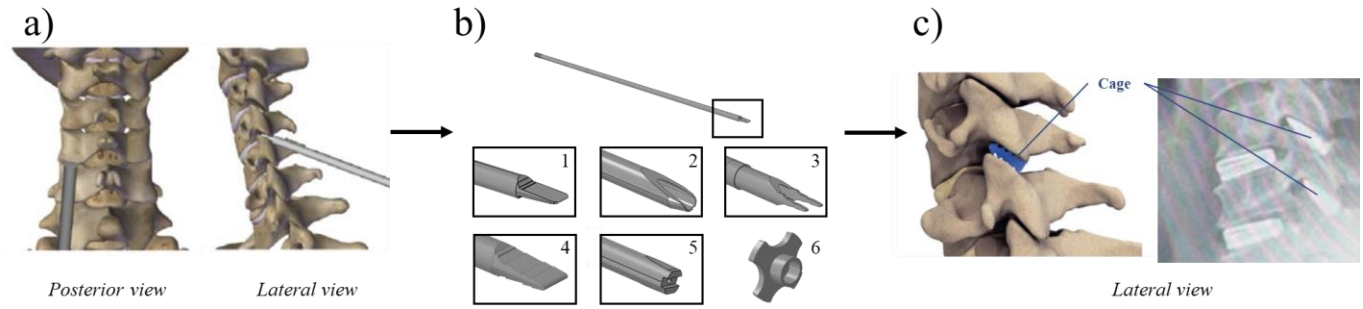

Fig. 2 a) Schematization of a cervical spine section with the instrument inserted between the facet joints, on the left the posterior view and on the right the lateral view; b) the 2B1 kit with in detail the different end tips of the instruments: 1. Chisel; 2. Dilator; 3. Forks; 4. Reamer; 5. Holder; 6. Beat Plug; c) on the left, the schematization of a cervical spine with the cervical cage implanted in detail, on the right, the RX image with in detail the cages.

Tab. 1 Main differences between multi-use and single-use instruments**.**

	Standard SIs	**Single-Use SIs**
Sterilization [1]	500 l every cycle, 327,000 l of leak/year	Save 435 l for every surgery
Always 100% **sterile** [1]	No	Yes
Packaging [5], [7]	↑space and ↑costs	↓space and ↓costs (modular unit)
Logistics in the hospital [1]	Very complicated organization	Not present
More **interventions** per day [4]	Limited kits	Available for immediate use
Transport	↓transport	↑transport
Proper **sizing** of the instrumentation [8]	Not present in the literature	Useful if you change the materials
No damage components and infection [2], [8]	30/8132 cases of intra-operative fractures and more cases of infection	Always new and less % of infections

Within this scenario (Table 1), the introduction of single-use SI can reduce hospital costs, and the risks of breakage of the kit in the operating room and also improve the economic and environmental impact that still occurs with standard instrumentation [1], [3]–[6].

The aim of this work is the development of a workflow able to identify the steps for mechanical redesign from multi-use to single-use SI (Figure 1). For the mechanical design of single-use SI, it is necessary to identify and analyze the current situation of multi-use SI. Instrumentation for cervical cage implantation (Sharkage system manufactured by 2B1 s.r.l, Milan, Italy) was identified as an example for the analysis (Figure 2).

In particular, as reported in Figure 2, the Sharkage kit is composed of several instruments that permit the implantation of the interfacet cage device intended to enhance fusion and mechanical support for the cervical spine (C2-C7 levels).

II. Material and methods

In order to evaluate the current situation of the Sharkage kit in terms of mechanical properties, several activities must be done to identify the various aspect that can be improved.
Firstly, an optical analysis of a used Sharkage SI provided by the manufacturer was carried out to determine the most critical component among those in the kit. Secondly, mechanical strength was evaluated through numerical and experimental analysis of the selected instrument from the previous activity.
Finally, a measurement system was developed to identify under which conditions the instrumentation is used by the surgeon, in terms of forces and torques that are applied to the instruments during surgery.

A. Optical analysis of the Sharkage SI

The Sharkage kit consists of six components used sequentially for the implantation of the vertebral cage. Additionally, a beat plug is also provided in the kit to manipulate the various instruments (Figure 2). An optical analysis on a post-use kit was performed to assess which components were the most critical during surgery. The evaluation was performed using Canon EOS 6D digital camera (20.2 MP) with 2X magnification, to catch any details of geometry. All components were analyzed, with a particular focus on the instrument's end tip, which interfaces with the bone component during implantation (Figure 2b).

B. Evaluation of the strength through a combined numerical and experimental analysis

The mechanical evaluation was carried out only on the most critical component of the Sharkage kit. Specifically, the numerical model was built for the Forks component (Figure 3) using Abaqus 2022 (Dassault Systèmes, SIMULIA Corp., RI), assigning stainless steel material (E=210GPa, υ=0.3) to the instrument according to the manufacturer indications. In order to find the mechanical strength of the device, two types of simulations were carried out: (i) widening of the end spacers (Figure 3a); (ii) shrinkage of the end spacers (Figure 3b). For both configurations an ad-hoc setup was designed and modeled, considering it as undeformable, and an encastre was set on the instrument and on the opposite side as a displacement applied on the surface equal to 7 mm, previously calibrated (Figure 3). A general contact was set between the instrument and the setup, choosing the hard contact (as normal behavior) and the friction coefficient equal to 0.3 (as tangential behavior) [9]. After a mesh sensitivity, 179,467 quadratic tetrahedral elements (C3D10), 5,982 linear quadrilateral elements (R3D4) for the first type of load (Figure 3a) and 8,698 linear quadrilateral elements (R3D4) for the second type of load (Figure 3b), were used for the Forks and the setups respectively.

To validate the FE model in terms of stiffness (K, slope of force-displacement curve) and local strains (ε_{Princ}), specific experimental tests were carried out on prototypes of the Forks component using strain gauge rosette positioned as reported in Figures 3a and 3b and three different experimental tests were performed for each configuration of loading applied to the Forks (Figure 3a and 3b).

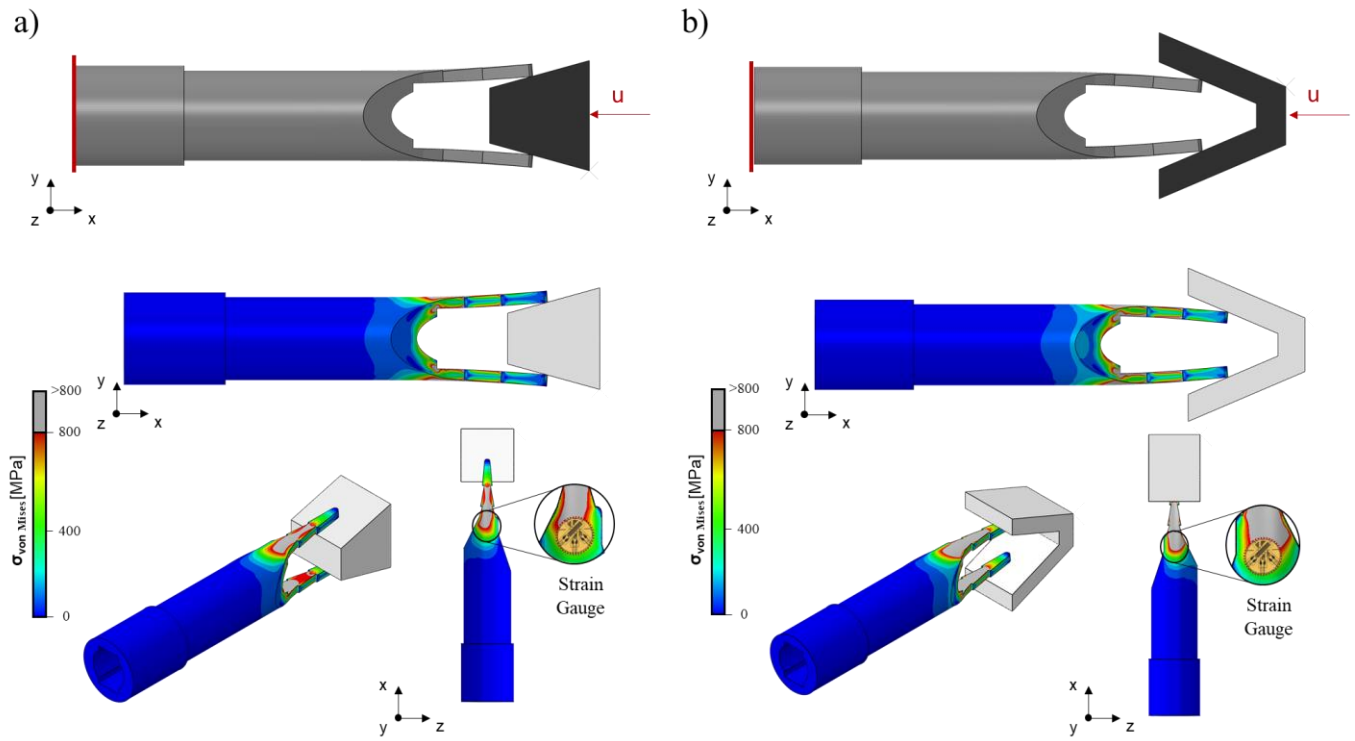

Fig. 3 a) Loading configuration with an ad-hoc setup in order to enlarge the spacer at the end of the instrument. In the bottom part, the results, in terms of von Mises stresses, and in detail the position of the strain gauge applied during the experimental test that matches with the zone where the average value is calculated during the numerical analysis; b) loading configuration with an ad-hoc setup in order to tighten the spacer at the end of the instrument. In the bottom part, the results, in terms of von Mises stresses, and in detail the position of the strain gauge applied during the experimental test that matches with the zone where the average value is calculated during the numerical analysis.

C. Development of the in-vivo measurement system

The Sharkage kit, as described above, consists of several instruments: in particular a beat plug permits and facilitates the insertion and usage of the instruments, including the Forks combined with other components (Figures 2 and 5).

To identify the conditions to which the instruments are subjected during surgery, an *in-vivo* measurement system was developed. In particular, the geometry of the beat plug was modified using Solidworks 2022 (Dassault Systèmes, SIMULIA Corp., RI) and a load cell was purposely designed and realized to be located inside the beat plug in a specific housing (Figure 5).

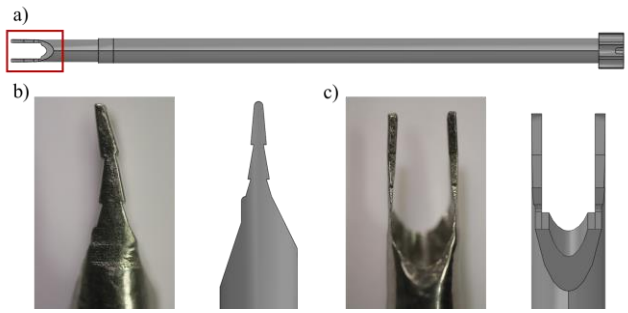

Fig. 4 a) The instrument CAD that shows different plasticized zones, (in the square); b) comparison (lateral view) between optical analysis (2x zoom) vs. CAD model; c) comparison (anterior view) between the optical analysis (2x zoom) vs. CAD model

III. RESULTS

A. Optical analysis of the Sharkage SI

The only instrument, in the Sharkage kit, that presents several deformed parts after use in the operating room is the Forks instrument. That was observed through optical analysis and it is reported in Figure 4a. In particular, it was noticed that the two side spacers of the end part are deformed in both the lateral and anterior planes (Figure 4b and 4c, respectively).

B. Evaluation of the strength through a combined numerical and experimental analysis

As reported in Figure 3, the Forks components have a different zone with von Mises values greater than the yielding stress (equal to 800 MPa) when the force applied is equal to 38 and 32 N for the two configurations respectively (Figure 3a and 3b). The numerical models demonstrated good agreement with experimental static tests with a percentage difference of less than 10% in terms of macroscopic and microscopic behavior (K, stiffness of the system, and ε_{Prin}, local strain respectively).

C. Development of the in-vivo measurement system

The design of the beat plug was modified, in particular, the internal design and the width to permit the housing of the load cell. Indeed, the design was changed to transmit the load from the device to the load cell and to record the data in terms of force and torque (Figure 5). Therefore, the information from the in-vivo measurements will be fundamental in the redesign

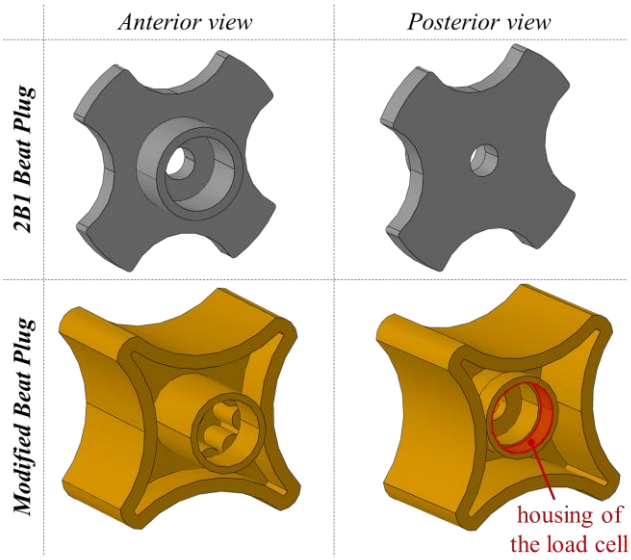

Fig. 5 On the left the anterior view and on the right the posterior view of the 2B1 beat plug and the modified beat plug with in detail the housing of the load cell to recorder the force and torque during the surgery.

and assigning of the new material to the single-use SI. A future step will be to perform the measurement activity during a real surgery or on cadaveric specimens, thus confirming the validity of the simulations in terms of values of applied forces and torques.

IV. Conclusion

This work shows how to mechanically evaluate a surgical instrument with the aim of redesigning it in terms of design and material. In particular, a combined experimental and computation approach was proposed as reported in Figure 1. In addition, the redesign of the instrumentation will reduce the economic and environmental impact associated with the production and life cycle of the current kit [2], [4].

***Abstract*— Biophysical cell properties are a powerful tool for the label-free classification of cells. Here, we report a single cell investigation approach to detect different peripheral blood cell classes in microfluidics using a machine learning based optical cell signatures detection. The utilized microfluidic platform aligns cells in flow and alternatively allows compression and subsequent investigations of cells in flow. In fact, the presented approach can be interesting for a wide spectrum of clinical and diagnostic single cell investigations, such as the detection of circulating tumour cells in liquid biopsy samples.**

***Keywords*—Single Cell Approach, Microfluidics, Light Scattering, Machine Learning.**

I. Introduction

Cells contain specific biophysical information, that can be useful for their classification as well as for a wide range of therapeutic purposes. To reveal potential cell information in a straightforward manner is challenging. We focus on human peripheral blood mononuclear cells (PBMCs), which can be easily isolated from blood of healthy donors or buffy coats and therefore of valuable interest for diagnostic single cell approaches. Although PBMCs have a different composition, phenotype, and activation status than cells in intestinal tissue, they can be seen as liquid biopsy.
Nevertheless, cancer diagnosis and treatment mostly use solid biopsy from primary or secondary tumours, which has several disadvantages both for patient (time), and for hospital (costs). Such difficulties are particularly of interest when dealing with tumours having difficult surgical access and a high mortality rate [1]. Liquid biopsy can drastically revolutionize the field of clinical oncology, offering the possibility of continuous monitoring. Nowadays, cell discrimination is routinely performed by cytometric analysis based on surface receptor expression, which is also cost and time intensive. Alternatively, a label-free cell classification based on a liquid biopsy is highly demanded.
Therefore, we present a simple microfluidic based approach based on light scattering, and machine learning for single cell class prediction in liquid biopsies (see Fig.1).

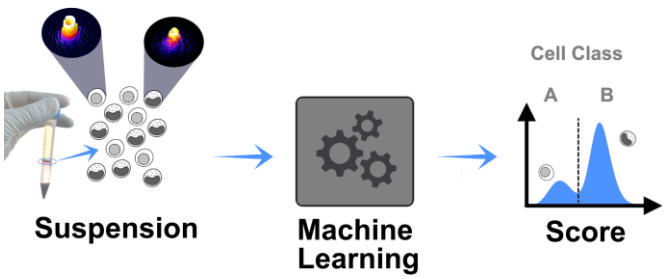

Fig. 1: Working flow of the PBMC type prediction, from optical signatures via machine learning to cell class score.

Briefly, optical signatures of cells (label-free information of biophysical cell information) are recorded by a static light scattering apparatus, which continuously measure scattering profiles of passing living cells. Obtained cell signatures are matched with pre-calculated simulation curves to retrieve the searched for cell properties: dimension of cell and nucleus, optical density of nucleus and cytoplasm. Machine learning uses such cell information as input to predict the searched for cell classes. As proof of concept, a prediction model was trained with ≥100 cells per class covering a wide range of human peripheral blood cell types: Erythrocytes [3], T- and B-lymphocytes [2], Natural Killer cells [4], Monocytes [5], Circulating Tumour Cells (CTC) [6] as well as M0-, M1- and M2-Macrophages [7].
The presented measurement approach allows a distinct classification and selection of single cell types and therefore can be seen as prognostic, easy, accessible, cost saving and accurate pre-screening method useful in clinical routines by searching and detailing CTC from a liquid biopsy sample.

II. Material and Methods

A. Blood samples

We primarily investigated PBMC, which were obtained from healthy donor buffy coats obtained from the blood bank of the medical school of the Federico II University of Naples (Italy). At the time of blood donation, each donor signed an informed consent (model n. 5526 of Azienda Ospedaliera Universitaria "FEDERICO II", Naples, Italy) in which is specified that waste parts of the blood, not useful for medical-therapeutic purposes of blood donation, can be used for scientific research purposes. Moreover, CTC were collected from non-small cell lung cancer patients, which were previously already identified from pathologist examination. The study was conducted according to the guidelines of the Declaration of Helsinki and approved by the ethical committee of AOU Università degli Studi della Campania Luigi Vanvitelli, Protocol number 417 on 22 July 2014. This study was carried out according to the Helsinki declaration and informed written consent was obtained from all patients included in the study. Data regarding medical history and clinical-instrumental work-up were assessed for each patient. Pleural washing collection and storage have been performed during surgical intervention, before any manipulation of the lung and cancer resection, also according, in some aspects of the technique, to previous studies [6], [8].
All the experiments were performed and analysed anonymously, without any biographical reference to donors.

B. Sample preparation

PBMC were collected using standard density gradient centrifugation, with some adaptation to reduce platelet

contaminations [9]. Briefly, the blood sample was gently layered on an equal volume of density gradient fluid (Ficoll) and centrifuged at 300$\vec{g}$ for 45 minutes (without brake). The PBMC ring stratified at the interface between Ficoll and plasma was collected using a Pasteur pipette and washed twice with RBC lysis solution to eliminate possible erythrocyte contaminations of the sample [10], [11]. After separation, the PBMC were washed and diluted in the alignment medium.
A similar procedure was applied for CTC collection. A more detailed description is presented elsewhere [6].

C. *Microfluidic platform*

A microfluidic platform was used for the single cell investigations, assembled by 3D-printer parts, which connect a round shaped glass capillary (alignment section) with a square shaped glass channel (observation section) [2]. The cell alignment in the first section is accomplished by a viscoelastic cell medium (0.2-0.4wt% of Polyethylene-oxide 4MDa) and a pressure driven flow. Thanks to the resulting fluid properties, generated by viscoelastic fluid forces, cells are aligned to the centreline of the round shaped channel and subsequently remain aligned in the centreline of the microfluidic readout channel [12], [13]. Note that fluid forces have been chosen to prevent cell deformation effects, while ensuring sufficient cell focusing in the alignment section. In addition, cross-section of the cell observation section can be tuned to allow precise cell compression in-flow if needed [14], [15]
However, one end of the round shaped channel is immersed in the cell sample: by applying a certain pressure on the sample surface, cell medium is pushed through the channel. Viscoelastic cell alignment can be achieved if the following relationship Eq. (1) is satisfied:

$$\boldsymbol{\Theta} = 3\boldsymbol{Wi}\boldsymbol{\beta}^2 \frac{\boldsymbol{L}}{\boldsymbol{2R}} > -\boldsymbol{ln}\,(\boldsymbol{3.5\beta}), \qquad (1)$$

with $\boldsymbol{Wi} = \boldsymbol{2\lambda\bar{U}\,/\,2R}$, where $\boldsymbol{\lambda}$ is the relaxation time of the fluid, $\boldsymbol{\bar{U}}$ is the average fluid velocity, $\boldsymbol{R}$ is the channel radius, $\boldsymbol{\beta} = \boldsymbol{r_1/R}$, a non-dimensional geometrical channel parameter, with $\boldsymbol{r_1}$ the cell radius and $\boldsymbol{L}$ the channel length [12], [14] The subsequent observation channel allows precise single cell analysis due to is square shape of 400 x 400 µm and preserved centreline alignment. To assure continuity between alignment and observation section, the capillary is collinearly inserted in the squared section and sealed by a soft ferrule. Furthermore, the presented microfluidic concept was applied for barcoded hydrogel readout to detect specific miRNA concentrations in flow to name one alternative application field for single particle alignment [16].
For each investigated cell class, we prepared samples of ~1.25 x10^5 cells mL^{-1} to ensure a throughput rate of ~2 cells sec^{-1} at the readout laser beam. Note that sample concentration and fluid velocities were optimized to avoid possible cell-cell interactions and cell deformation effects. The maximum throughput performance of the presented approach is ~50 cells sec^{-1}. However, at the end of the observation section, cells can be recovered for further studies.

D. *Experimental setup*

We used a static light scattering based measurement approach (see Fig. 2), which can obtain precise optical signature information in a continuous angular range from 2-30°, with an angular resolution of ~0.1°. Briefly, cells aligned in the observation section, pass through a collimated laser beam (λ=633 nm), and the scattered light is collected and mapped on a camera sensor. The hereby-obtained optical scattering signatures (see Fig. 2) are used to retrieve the biophysical information of single cells. In more detail, collected signatures are matched with a look-up table of previously calculated theoretical scattering signatures to retrieve biophysical cell information. Detailed information is shown elsewhere [17], [18]. Machine Learning was implemented with a commercial software (MATLAB, vers. R2020b, MathWorks) to predict different PBMC classes form optical signature information.

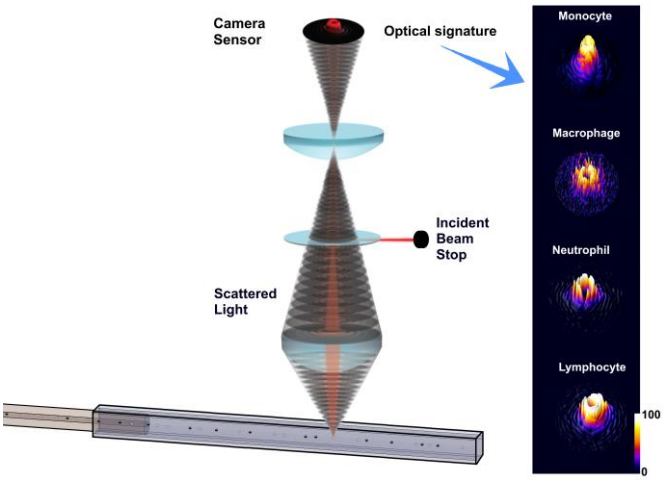

Fig. 2: Experimental setup for the optical signature recording. Illustrative cell signatures are presented for some peripheral blood cell classes.

III. Results and Discussion

First, we analysed previously separated cell types (e.g. Monocytes and M0-, M1-, M2-Macrophage subtypes) with the mentioned light scattering method to obtain single cell based optical signatures. The separate measurement of different cell types allowed us to create a labelled training set (circa 200 cells for each cell type) of cell classes, which is needed for the machine learning based supervised classification. Afterwards, we tested different classification algorithms, regarding single cell type classification accuracy. For instance, a classification accuracy above 80% was obtained using a quadratic Support Vector Machine with one neighbour, euclidean metric distance and equal distance weights. Moreover, we applied a box constraint level of 0.1 and a kernel scale of 1, reducing the penalty imposed on margin-violating observations, and, therefore, preventing overfitting of our test data. We observed the highest misclassification for M1-Macrophages with more than 25%, compared to M0- and M2- Macrophages as well as Monocytes with less than 20%. Indeed, the quadratic Support Vector Machine was found to be the most suitable algorithm according to speed and accuracy (training time ~0.5 sec and a total misclassification cost = 45). Other classifiers resulted into show lower performances: the linear Support Vector Machine trained classifier, fine K nearest neighbour and medium tree, showed an accuracy below 80%. The parallel coordinates plot in Fig. 3 illustrates the correlation between two different cell classes for four extracted biophysical cell features (cell diameter, refractive index of nucleus and cytosol, as well as nucleus over cytosol ratio), where each biophysical cell feature is represented by a vertical line. Due to the different range of each investigated feature, their standard deviations are plotted.

Dashed lines indicate misclassified cells after the model training, while the colour indicate the cell class label. By investigating the highest concentration of misclassified features (dashed lines) the machine learning model performance can be optimized. However, post analyses of cells confirmed that the use of appropriate microfluidics conditions and biocompatible fluids guarantee high cell viability, demonstrating the non-invasiveness of the presented approach.

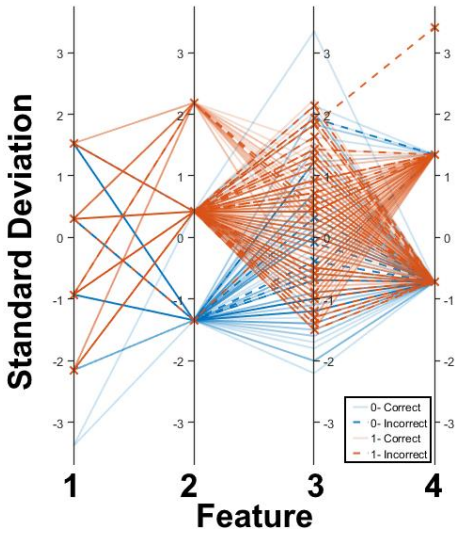

Fig. 3: The parallel coordinates plot indicates the correlation between the four investigates biophysical cell features.

IV. Conclusion

In this work we present an in-flow, non-invasive, label-free approach with supervised machine learning to classify peripheral blood cell subclasses according to their biophysical information. Compared with standard flow cytometric approaches, which are known to have high instrumentation and service costs, the presented optical signature-based method is very simple and cost-effective. Moreover, it permits a classification of cell subtypes without large numbers of cells and resource-intensive labelling. Less than 100 cells of a certain cell PBMC population are needed to precise classify them. More importantly, experiments are realized using a lab-on-a-chip approach permitting the measurement of living cells in suspension, which furthermore are collectable and re-usable for other diagnostic investigations or therapeutic approaches. Measurement times can be drastically reduced with the mentioned measurement approach, while classification accuracy is significantly increased. In fact, by identifying PBMC subsets with high precision our measurement approach could help in accurate pre-screening method useful in clinical routines by searching and detailing cells from a liquid biopsy sample.

***Abstract*—In this work, a radar sensor is proposed and demonstrated *in vivo* for remote vital signs monitoring (measure of respiration rate and heart rate) of a sleeping subject. In addition, a motion artifact rejection signal processing method, based on the wavelet transform, is presented and discussed. A practical setup was implemented in a bedroom with the radar placed on the ceiling above a human volunteer. Experimental results show accurate measurement of the subject's vital signs.**

***Keywords*—Bed monitoring, Doppler, radar remote sensing, vital signs.**

I. Introduction

THE combined senior and geriatric population is expected to increase worldwide, with the total number of people aged 65 years or older projected reach 2 billion in 2050 [1]. Concurrently, in-home care or nursing facilities must scale to support this increase. This will represent an unsustainable burden to society. Technological innovation in *telemedicine* has an important role to play in addressing this problem [2].

Today's devices require sensors that make physical contact and are in the form factor of a wearable device [3]. Current technologies for diagnostics and treatment of chronic diseases typically involve recording of biomedical signals such as brain activity (EEG), heart pattern (ECG), muscle activity (EMG), eye movements (EOG), blood oxygenation saturation (SpO2), and respiration effort [3]. These measurements are made through sensors attached to the patient's skin. Situations exist for which this is not preferable, e. g. patients with severe and extensive burn wounds, premature infants whose skin is easily damaged, or sleep monitoring during which sleep itself can be interfered due to the discomfort caused by the sensing technologies. Commercial alarm systems connecting to medical care units do exist, but they require an action from the person, like pressing a button, e.g., worn as a necklace. However, a person in an emergency situation may no longer have the reflex to press this button or may even no longer be able to do so. One may also forget to put on the necklace or charge the device. Contactless long-term health monitoring is thus preferable. Optical and thermal cameras-based devices represent an option [4], [5]. However, privacy concerns can be present. Furthermore, these solutions can require skin visibility to monitor the vital signs of interest [4] and have typically problems in the case the subjects is (partially) covered by blankets [5]. On the contrary, radar sensors can be mounted in privacy-sensitive areas (e.g., bedroom), being able to monitor vital signs parameters within typical room sizes, also through clothes and blankets [6]. This facilitates a number of highly relevant clinical applications, both in home and clinical environments, such as sleep monitoring, automated nurse call solutions, preventive medicine, etc.

In this work, a radar sensor, based on a frequency-modulated continuous-wave (FMCW) architecture and a signal processing algorithm are proposed for remote in-bed monitoring of the patient's vital signs. Experimental results are shown to demonstrate the ability of the radar in accurately monitoring the vital signs parameters (respiration and heart rates) of a sleeping subject under realistic conditions.

II. Methodology

In Subsection II.A, the FMCW theory is briefly described, while in Subsection II.B, the proposed signal processing method is presented.

A. One-ray Propagation FMCW Model

In this work, it is assumed that there is only a single person lying on the bed at a nominal distance d_0 away from the radar. The FMCW radar transmits, through a transmitting (TX) antenna, a series of *chirps* (Fig. 1) [7]. The *chirps* reach the subject where they are phase modulated by the oscillatory thorax's motion $x(t)$ due to the cardiopulmonary activity [8]. These signals are also reflected back to the radar and collected by the receiving (RX) antenna. After the round trip the delay is equal to $2 \cdot d_0/c$, where c is the speed of the light. Between the transmitted and received *chirps* there is an instantaneous frequency difference Δf which is proportional to the round-trip delay. The *beat signals*, resulting from mixing the transmitted and the received *chirps*, are therefore sinusoidal signals with frequency Δf and a certain initial phase.

The Fast Fourier Transform (FFT) applied to a sine function allows determining its frequency and initial phase information. Thus, it is possible to retrieve Δf and then to determine d_0. The cardiopulmonary activity of a person causes a sub-millimeter motion on the thorax surface which is several orders smaller than the target's nominal distance (i.e., $x(t) << d_0$) [8]. Hence, due to the limited resolution of the FFT, its contribution in estimating Δf is essentially zero. This means that the frequency information cannot be used to monitor the vital signs. The latter operation however can be performed looking at the variation of the initial phases of consecutive beat signals (i.e., Doppler signals). The received chirps are in fact significantly phase modulated by the thorax motion due to the Doppler effect. The instantaneous initial phases of the *M beat signals* are proportional to the instantaneous thorax positions, i.e., $d_0 \pm x(t)/2$, and inversely proportional to the wavelength of the chirps, which is very small in the microwave frequency range. For that reason, even sub-millimeter vibrations involve appreciable Doppler signal. It should be specified that d_0

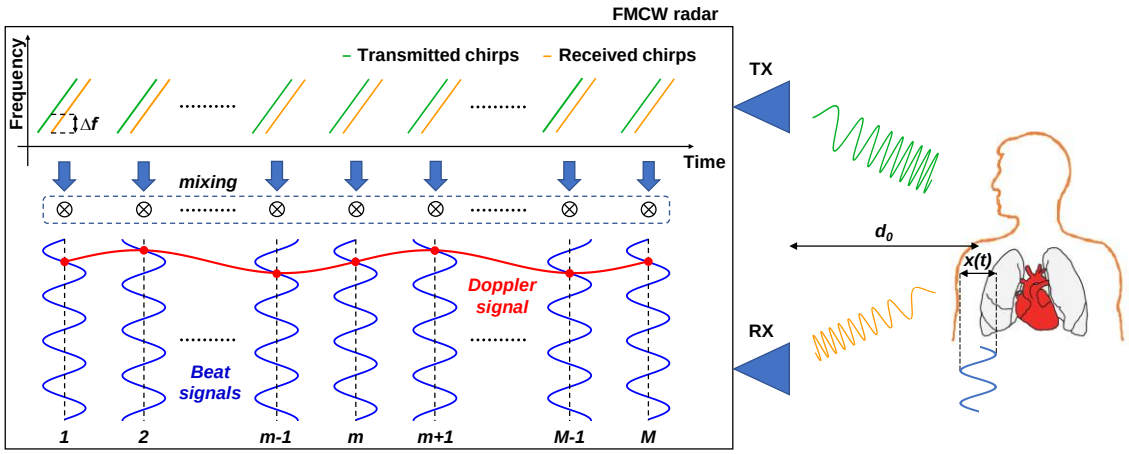

Fig. 1: Block diagram of the FMCW operational principle

involves only a constant phase shift (the subject lies on the bed) whereas, the vital signs involve a variable Doppler (phase) signal.

In order to measure the vital signs parameters, *M chirps* have to be transmitted. The resulting *M beat signals* are acquired, digitized, and arranged in a *N* x *M* matrix, where *N* is the number of samples per beat signal. By applying the FFT per column, a *K* x *M* complex data matrix is obtained (Fig. 2), with *K* being the number of range bins. Calculating the magnitude of the FFT and scanning each column, the spectrum peaks will be only in correspondence of the *k*-th range bin where the subject is present (range bin 4 in the example of Fig. 2). Therefore, the location of the person (distance from the radar) can be determined by multiplying *k* by the predefined radar range resolution. The vital signs information (Doppler signals) can be extracted by determining the *M* phases from the complex FFT samples along the *k*-th row (Fig. 2). However, in real-world room settings, the FFT magnitude cannot be used to locate the target. Furniture and objects (especially if metallic) result in reflections whose magnitudes are much stronger than the reflection from a person. Hence, the subject's peak in the data matrix will be buried by the contributions of furniture and other objects. Further signal processing is hence necessary to extract the weak Doppler information of the subject, rejecting the contributions of static reflectors.

B. Signal Processing

In this work, the variation in the Doppler signal is used to automatically localize the subject (i.e., determining d_0), differencing they from stationary reflectors. The idea is to exploit the evidence that the Doppler information due to the vital signs is a variable signal while furniture/objects involve a constant phase shift. Therefore, the standard deviation is applied to the complex signal per each range bin, i.e., per each row of the data matrix (Fig. 2). The *k*-th range bin with largest variation indicates the location of thorax.

The Doppler information is hence extracted by performing phase demodulation from the complex FFT samples along the *k*-th row. In this work, the linear demodulation technique, proposed in [9], is applied. The respiration and heartbeat signals are finally retrieved after properly bandpass filtering, and the Doppler signal and the corresponding rates are estimated through the FFT.

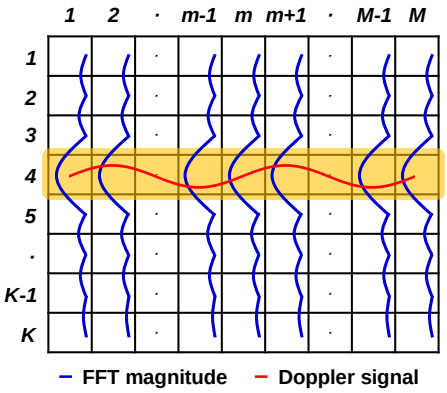

Fig. 2: Data matrix

However, it is expected for subjects to change position or move while sleeping, causing random body movement artifacts. These artifacts, which are several orders of magnitude larger than the sub-millimeter cardiopulmonary motion on the thorax, jeopardize the performance of vital signs monitoring. To address it, the Continuous Wavelet Transform (CWT) is used to locate the artifacts. It provides a time-frequency representation of the signal. Thus, the artifacts, that normally involve signals with a higher frequency content than the ones of the vital sign, can be easily located in time. The artifact episodes can be then discarded from the Doppler signal, avoiding erroneous vital signs estimations. This can be done because, while sleeping, artifacts are expected to be isolated episodes.

III. Bed Monitoring System

A. Radar Signal

The radar transmits linear *chirp* with instantaneous frequency ranging from 7.3 GHz to 8.05 GHz. This total bandwidth of 750 MHz results in a range resolution of 20 cm which is sufficient for localization considering the typical dimensions of the human body. Each *chirp* lasts 102.4 µs. The chirps are not transmitted continuously (i.e., one right after the other) but every 3.027 ms. This results in a sampling rate of the Doppler signal of about 326 Hz, which is higher than the typical vital signs range of 0-3 Hz. The transmitted peak power is of 0 dBm. This, together with the *chirp* configuration (i.e., frequency interval, duration, and duty cycle), allows satisfying

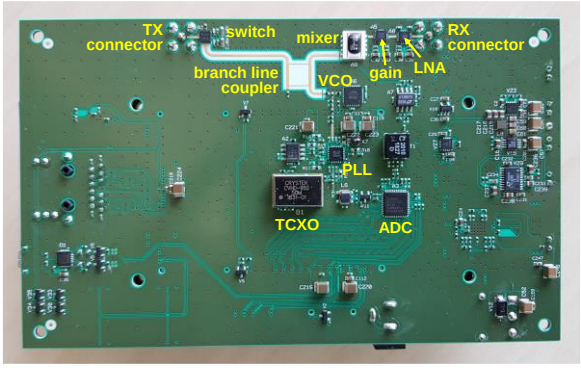

Fig. 3: Radar unit

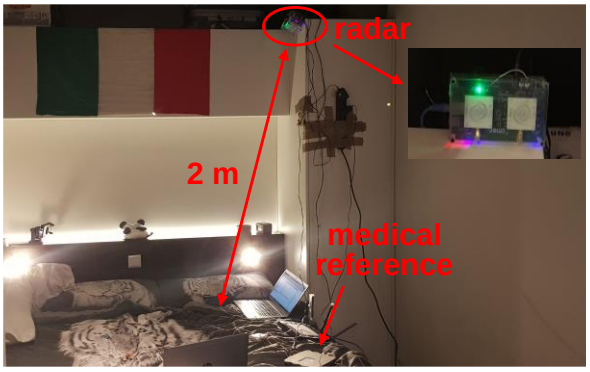

Fig. 4: Experimental set-up

the worldwide UWB indoor radio regulations.

B. Radar Sensor

The radar sensor consists of the radar unit, a processor board and two commercial antennas. A photo of the radar unit is shown in Fig. 3. The FMCW signal is synthesized by the voltage-controlled oscillator (VCO) which is connected to a phase-locked loop (PLL). It feeds a branch line coupler from which two copies of it (with smaller amplitudes) are generated. One is connected to the TX antenna thought its connector and a switch. The latter is used to set the waveform's duty cycle. The other output serves as a local oscillator for the mixer. The reflected signal is received by the RX antenna, amplified by a low-noise amplifier (LNA) and a gain block, before feeding the second port of the mixer. After mixing, the baseband radar signal is filtered, amplified, and acquired by an analog-to-digital converter (ADC). A 50 MHz Temperature Compensated Crystal Oscillator (TCXO) is used to provide the clock reference to the PLL and ADC. This ensures perfect synchronization between chirp generation and acquisition, avoiding phase errors. The processor controls the PLL's synthesizer to generate the *chirps*, controls the switch and sends the ADC's samples to MATLAB by an Ethernet port.

IV. Experimental Results

The experimental protocol was approved by the internal imec – Netherlands Ethical Board. The experiments have been conducted on a human subject in a normal bedroom (Fig. 4). The radar was placed on top of the bed at about 2 m. The volunteer was invited to mimic a realistic sleeping situation, namely lying down on the bed, under the blankets, moving limbs and changing positions (i.e., prone, supine). Different breathing conditions (i.e., holding breath, spontaneous, and paced breathing) have been also mimicked. The g.USBamp device (CE certified and FDA cleared medical device, safety class: II, conformity class: IIa, type of applied part: CF) was used as a reference device to measure heart and respiration activities, through a photoplethysmogram (PPG) finger sensor and a thorax expansion belt, respectively.

Fig. 5 shows the results of an experiment with a spontaneously breathing subject lying on the bed under the blankets. Fig. 5a shows the extracted Doppler signal. It consists of the respiration and heartbeat contributions. The respiration signal is the most dominant. The heartbeat signal is at least one order of magnitude smaller than the respiration

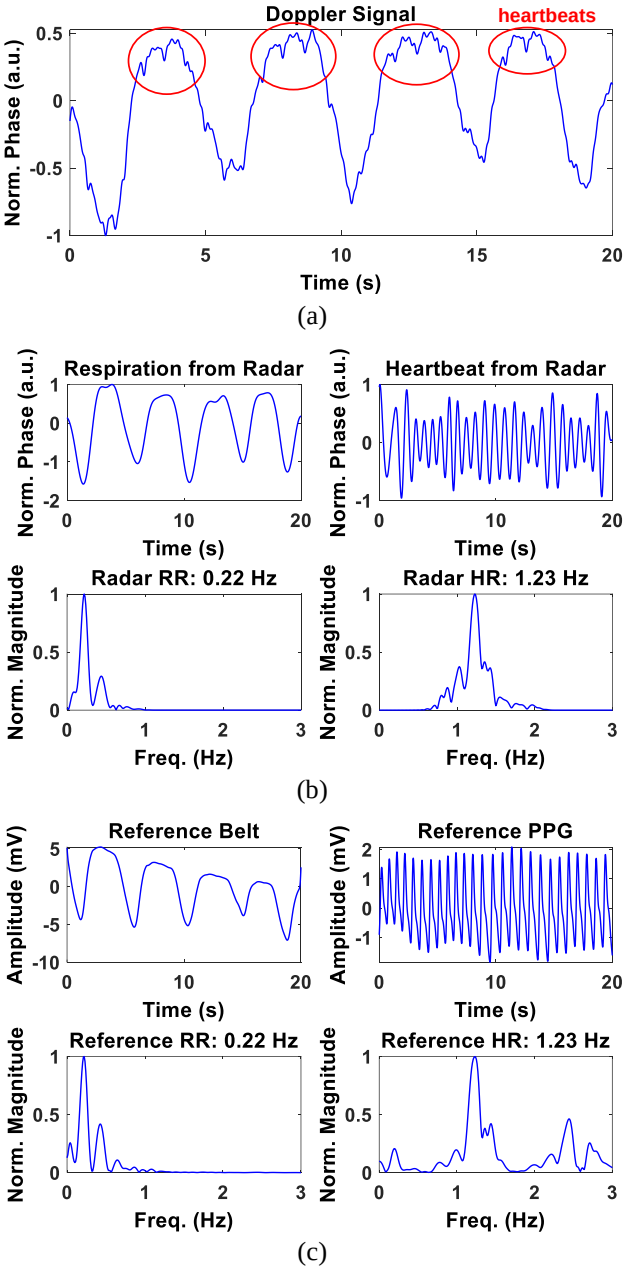

Fig. 5: Experimental results of an asleep (spontaneously breathing) subject. (a) Doppler signal. (b) Respiration and heartbeat signals extracted from the radar and relative spectra. (c) Respiration and PPG signals measured with the reference and relative spectra.

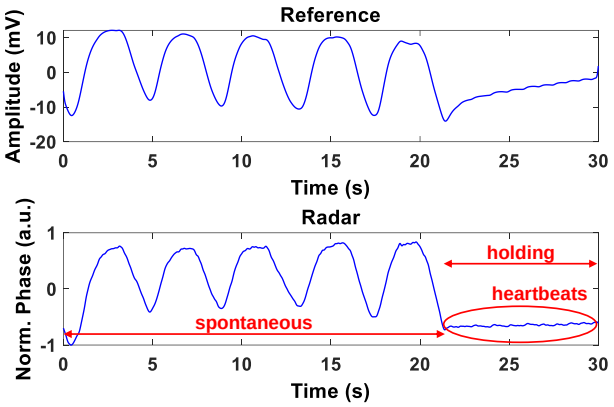

Fig. 6: Breath hold, experimental results. (top) Respiration signal from the belt. (bottom) Doppler signal.

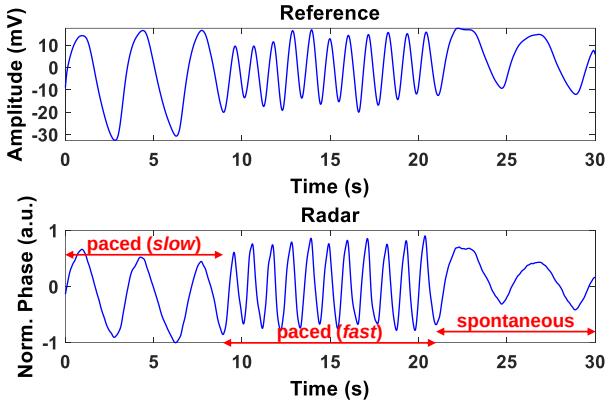

Fig. 7: Paced and spontaneous breathing, experimental results. (top) Respiration signal from the belt. (bottom) Doppler respiration signal.

contribution. For that reason, normally, it is indistinguishable by simply looking at the Doppler signal. It requires, therefore, proper bandpass filtering to be displayed. However, in this example, it can be clearly seen on top of the dominant respiration signal. Figs. 5b and 5c show the respiration and heartbeat signals, together with the relative spectra, extracted from the radar and from the reference device, respectively. It is possible to notice that the radar signals match the respective reference ones.

Figs. 6 and 7 show the results of two experiments during which the subject was invited to mimic different respiratory patterns. Also, in this case, the radar signal fairly matches the reference. In the experiment of Fig. 6, the subject held their breath towards the end of the measurement. In this case, the Doppler signal consists essentially of the heartbeat contribution. The difference in magnitude between the respiration and heartbeat signals is clearly visible in the figure.

Finally, in Fig. 8, an experiment during which the subject was invited to change position from supine to prone is shown. This causes an inevitable motion artifact, corrupting the physiological radar signals. However, this is a temporary effect. In fact, once the movement has ended, the Doppler signal quickly matches fairly the reference and, therefore, the vital signs rates can be accurately estimated. The CWT was used to successfully locate the artifact and the binary mask was built to indicate the segment of the signal to be removed, namely setting 1 if there is an artifact and 0 if not. After this operation, the vital signs can be measured accurately.

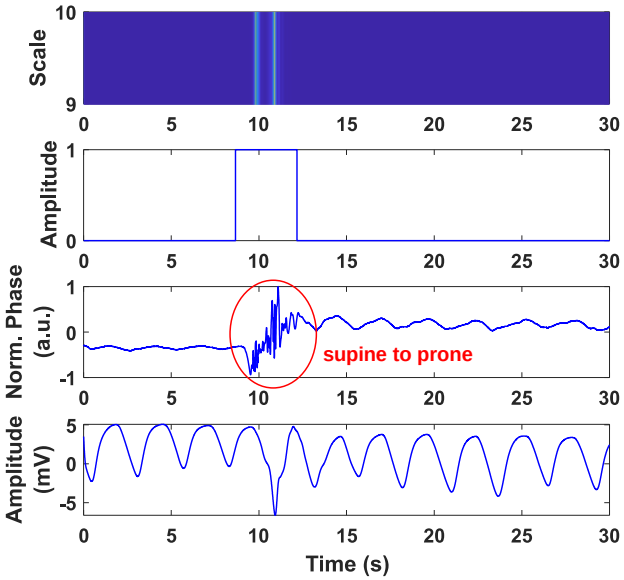

Fig. 8: Experimental results with a subject invited to change position. The first (top) figure shows the CWT result. The second figure is the binary mask indicating the part of the signal to be discarded. The third and the last (bottom) figures show respectively the Doppler signal and the belt reference. The latter was used since the Doppler signal consists mainly of the respiration contribution. In this figure, the parts of Doppler signal containing only the vital sign information (i.e., 0-9 s and 12-30 s) seem small in amplitude. However, this is only due to the normalization operation in a part of the signal containing a large artifact. The amplitude of the signal is sufficiently high and clear for an accurate detection.

V. Conclusion

A radar sensor and a signal processing algorithm have been proposed and *in vivo* demonstrated for remote in-bed monitoring of the vital signs (respiration rate and heart rate) of a single sleeping subject. They enable novel applications in the domain of ambient assisted living, telemedicine, healthcare, geriatric and quarantine medicine. Further works need to be done to confirm the presented finding involving more subjects and including further sleeping conditions and positions.

***Abstract*—Localized (targeted) therapies allow increasing the efficacy of treatments for several diseases, including cancer. Within this view, the BioMeld project aims at proposing a pipeline to guide the fabrication of an innovative intravascular steerable microcatheter, actuated on its tip by muscle cell contraction. A simulation framework streamlines the process of design quoting, manufacturing, verification, and reporting, thus significantly reducing error-prone manual steps and making the process more efficient. This new generation of steerable microcatheter, fostered by the unconventional kind of actuation provided by muscle cells, will be investigated throughout this project to target localized treatments of deeper and tortuous regions within the cardiovascular systems. In this work we report the overall project vision and we describe some preliminary results on the microcatheter design.**

***Keywords*—catheter, biohybrid actuation, drug release, cancer.**

I. Introduction

Cancer, or neoplasia, is a disease that is spreading more and more in recent years, to the point of being called the "disease of the century". The American Cancer Society has reported that over 1.9 million new cancer cases are expected to be diagnosed only in the US in 2023 [1].

Many therapies are currently available to fight cancers, and several efforts have been conducted by the scientific community to develop more sophisticated treatments to improve patient quality of life and extend life expectancy. Nowadays, chemotherapy, surgery and radiotherapy represent the gold standard. Among them, chemotherapy stands as a treatment based on the administration of drugs, typically injected through catheters by conventional accesses of the cardiovascular system (*e.g.*, in a vein residing in the hand or arm), to fight cancer cells with a cytotoxic action. However, the absorption of a drug at the blood circulation level can cause harmful effects due to the intrinsic toxicity of the chemotherapeutic drug, combined with a non-specific absorption by out-of-target cells, and consequently, a lower therapeutic index.

Alternatively, the use of microcatheters to release the drug locally at the site of interest may enable a local drug release, thus limiting the spread of the drug in healthy organs and tissues. One recent application of local chemotherapy is the hepatic artery infusion (HAI), in which the chemotherapeutic drug is released slowly and steadily into the hepatic artery through a catheter connected with a needle through the skin [2]. In the scientific state of the art, an example of a microcatheter able to locally release drugs has been developed by Sarker *et al.* [3]. Starting from a commercially available catheter, the authors provided a few lateral holes on the catheter wall, and closing the distal end to obtain a localized radial release of drug. The main challenge still remains the guidance of the commercial catheter at increased curvatures and pattern tortuosity.

For this purpose, catheters with a steerable tip have been proposed, recently. Steerable catheters are mainly classified into two groups: those with force generation in the tip and those with force transmitted to the tip [4]. Focusing on the first group, Gopesh *et. al*. developed a hydraulically steerable tip with an outer diameter of 900 µm provided with four channels of 50 µm diameters, filled with a saline solution, symmetrically arranged, and controlled remotely [5]. Regarding the second group, an interesting study was conducted by Kim *et al.* [6]: they developed a remotely-controllable steerable magnetic catheter featured with an outer diameter of 500 µm, remotely controlled, which can navigate through narrow and constrained environments. The magnetic navigation system can assist in approaching the *in vivo* target using magnetic responsive materials within the catheter. However, some restrictions lie on the generation of the torsion movement, which is necessary to facilitate the direction of the tip [7].

In recent years, many advances in manufacturing methods have allowed the production of intravascular catheters with diameters up to 1.8 Fr (500 µm). Such diameter size can potentially enable reaching deep districts, which are intrinsically characterized by a significant tortuosity, thus reaching different targets within the body. However, remotely controlling miniaturized microcatheters on such a small scale remain a challenge. Thus, precise drug release towards hard-to-reach *in vivo* targets still has large margins of improvement.

II. The BioMeld project

BioMeld is a European project funded in the Horizon Europe framework. It aims to develop an intravascular steerable microcatheter actuated by muscle cells to enable drug release in hard-to-reach areas. The development of the microcatheter would benefit from an artificial intelligence-guided modeling and simulation framework to optimize the search for the most efficient design, that will be validated within a validation framework (Figure 1).

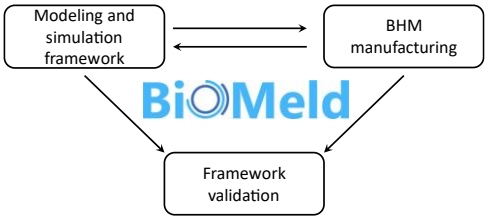

Figure 1: Scheme of a bio-intelligent manufacturing cell for design and production of the microcatheter within the BioMeld project. BHM = biohybrid microcatheter.

A biohybrid actuation paradigm, will be explored for controlling the microcatheter tip.

Biohybrid systems combine living organisms, such as contractile muscle cells, with engineered artificial structures [8]. Biohybrid actuators rely on their ability to convert the chemical energy of the environment into mechanical energy, thus there is no need to supply them when used in *in vivo* environments, avoiding the use of batteries.

One of the most significant challenges affecting current actuation technologies for in vivo applications is represented by the scalability of performance, especially for in vivo applications for which the requirement of biocompatibility is crucial.

Within the BioMeld project, we envisaged a reconfigurable and modular soft catheter bendable by the contractile force generated by the biohybrid actuator. The catheter will be composed of a magnetically-responsive catheter body and a catheter tip, equipped with: (i) a muscle cell-based actuator; (ii) a flexible electronic platform to trigger its activation and receive real-time feedback of catheter motion using flexible strain sensors; (iii) a bioreactor to keep it functional in the long-term.

The catheter body will include magnetically-responsive materials to allow its remote control. A good compromise towards guaranteeing a flexible body but magnetic responsiveness is represented by mixing polymeric materials (*e.g.*, silicones) with magnetic powder, such as NdFeB [9] and orienting them to maximize their responsiveness towards a specific magnetic field direction.

The catheter tip will be designed to host a biohybrid actuator based on skeletal muscle cells, which are controllable through electrical or optical stimuli to generate torque to the catheter tip. Muscle cell-based actuators, as the so-called bio-bots, can generate a relevant force (~100 µN) in the mm-size [10]. As mentioned, the biohybrid system also guarantees the maintenance of the contractile performance while keeping the actuation efficiency high with respect to other actuation technologies when scaled down.

Within the catheter tip, a flexible electronic platform will be integrated to provide muscle cells the electrical stimulation, and able to return the catheter deflection. This platform will exploit a low-voltage organic field-effect transistor fabricated on a polymeric substrate (*e.g.*, Parylene C) acting as a buffer through inkjet printing [11]. Such an electronic platform will also be provided with a deformation sensor to detect the curvature generated on the catheter tip by the muscle cells.

However, a disadvantage of using living materials as a source of actuation is the need to keep the environment parameters controlled with a bioreactor (pH and exchange of nutrients) to maintain muscle cells alive and functional over time [8].

All these components will be integrated inside the microcatheter, while maintaining the tip flexible and soft to be bent. Besides, the catheter will be provided with a hemocompatible coating, a crucial trait for all devices that encounter blood.

III. MATERIALS AND METHODS

A. Selection of the manufacturing techniques and material requirement

For the microcatheter fabrication, we considered molding, additive manufacturing, self-assembly techniques, and dip coating. Soft materials such as silicones (*e.g.*, PDMS, Dragonskin and Ecoflex) will be investigated at first instance. We do not exclude the use of thermoplastic polymers, such as polyurethane or Pebax®, and latex, since these materials represent suitable candidates already used for fabricating commercial devices. Our hypothesis assumes that the soft catheter will offer minimal mechanical resistance. For this purpose, we target materials with a Young's modulus lower than 1.5 MPa. Then, fabrication criteria will be directed to define geometrical parameters to decrease the catheter flexural rigidity.

B. Modeling and estimation of the flexural rigidity and deflection of the catheter

Apart from the magnitude of the force generated by the actuator, the catheter deflection is influenced by several parameters, such as internal and external diameter, wall thickness and elastic modulus [12].

Firstly, we analyzed the catheter mechanical properties in terms of flexural rigidity (*Fl*). For a catheter, such parameter can be calculated as follows:

$$Fl = E * I_0 \quad (1)$$

Where *E* is the Young's modulus of the material used to build the catheter, and *Io* is the moment of inertia that can be expressed for a hollow structure as:

$$I_0 = \frac{\pi(D^4 - d^4)}{64} \quad (2)$$

Where *D* is the external diameter and *d* is the internal diameter. We analyzed the variation of the external diameter *D* (from 2 mm to 10 mm) and, for a specific *D*, the variation of the Young's modulus up to 1.5 MPa.

Then, we estimated the deflection of the catheter by assuming the force generated by the biohybrid actuator equal to 100 µN [10]. According to the Euler-Bernoulli's beam theory [13], the deflection (δ) can be estimated as:

$$\delta = \frac{M * L^2}{2 * E * I_0} \quad (3)$$

Where *L* is the catheter tip length, set at 8 cm, while *M* is the torque generated by the biohybrid actuator, calculated as follows:

$$M = F * \frac{d}{2} \quad (4)$$

Where *F* is the force produced by the biohybrid actuator. Figure 2 shows a schematic representation of model parameters.

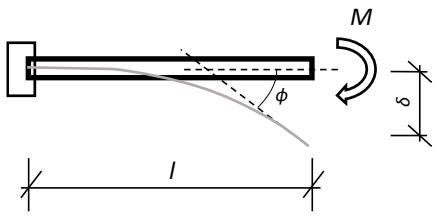

Figure 2: Depiction of the model applied to estimate the catheter deflection.

C. Analysis of the catheter kinking

When a catheter is curved under the application of a moment, the lumen may be occluded if the curvature radius becomes lower than a critical value ($R_{critical}$). This phenomenon is called kinking, and $R_{critical}$ is defined as:

$$R_{critical} = \frac{(1-\nu^2)*R^2}{K*t} \quad (5)$$

Where ν is the Poisson's ratio (set to 0.48, typical value for silicones), R is the external radius of the catheter, t is the wall thickness, and K is a constant (theoretically = 0.99; experimentally 0.72-1.14) [14].

IV. RESULTS AND DISCUSSION

A. Flexural rigidity

Figure 3 shows the influence of the catheter geometrical parameters in the estimation of the flexural rigidity.

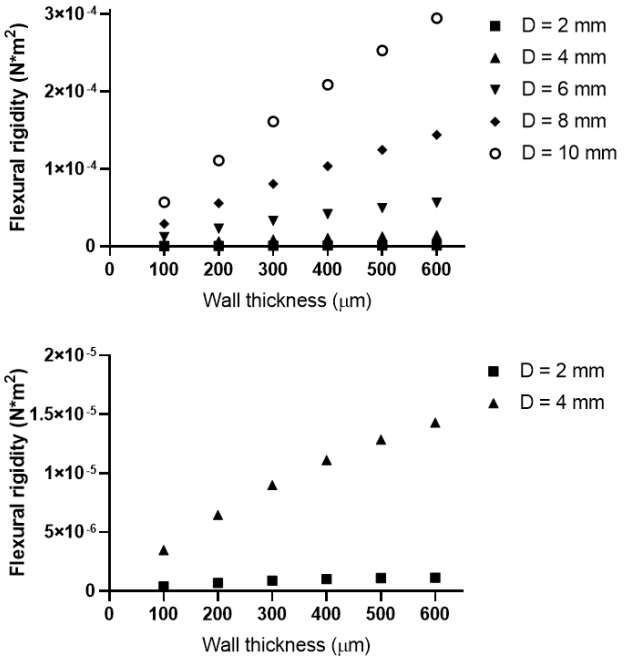

Figure 3: (top) Flexural rigidity estimated by varying the external diameter (D) from 10 to 2 mm, and the catheter wall thickness from 100 to 600 μm, and (bottom) a magnification for the cases D=2 and 4 mm. This estimation was performed by fixing the elastic modulus (E) of the catheter to 1.5 MPa.

Results showed a strong dependence of the flexural rigidity towards the geometrical parameters defined for the catheter, with a difference of two orders of magnitude between the larger (D = 10 mm) and the narrower case (D = 2 mm), for example, from $1.15*10^{-6}$ N*m^2 for D = 2 mm to $2.95*10^{-4}$ N*m^2 for D=10 mm, at a wall thickness of 600 μm. Typical values of flexural rigidity of catheters range from 1 to $50*10^{-4}$ N*m^2, mainly due to the stiffness of the material used to fabricate the catheter [15]. Here, the objective of designing a soft catheter for being actuated by muscle cells implicates the achievement of lower flexural rigidity for the catheter.

We also analyzed the influence of the elastic modulus for a specific case (D = 6 mm) The results are reported in Figure 4.

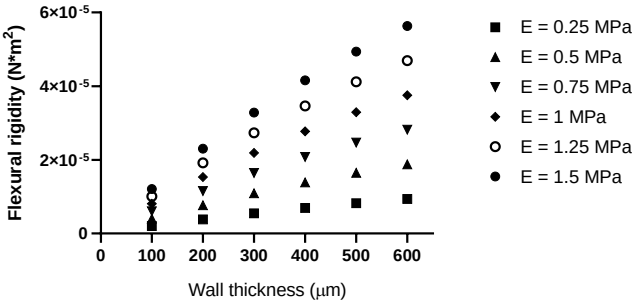

Figure 4: Flexural rigidity estimated by varying the elastic modulus (E) from 0.25 MPa to 1.5 MPa, and the catheter wall thickness from 100 to 600 um. This estimation was performed by fixing the external diameter (D) to 6 mm.

The graphs show that the wall thickness and the elastic modulus influence flexural rigidity. A non-linear trend can be observed with the variation of the external diameter, while a linear trend is noticeable while Young's modulus decreases. As a rule of thumb, flexural rigidity decreases by decreasing the external diameter, wall thickness, and elastic modulus.

B. Deflection

Figure 5 shows the influence of the catheter geometrical parameters in the estimation of the catheter deflection, according to the Euler-Bernoulli's beam theory.

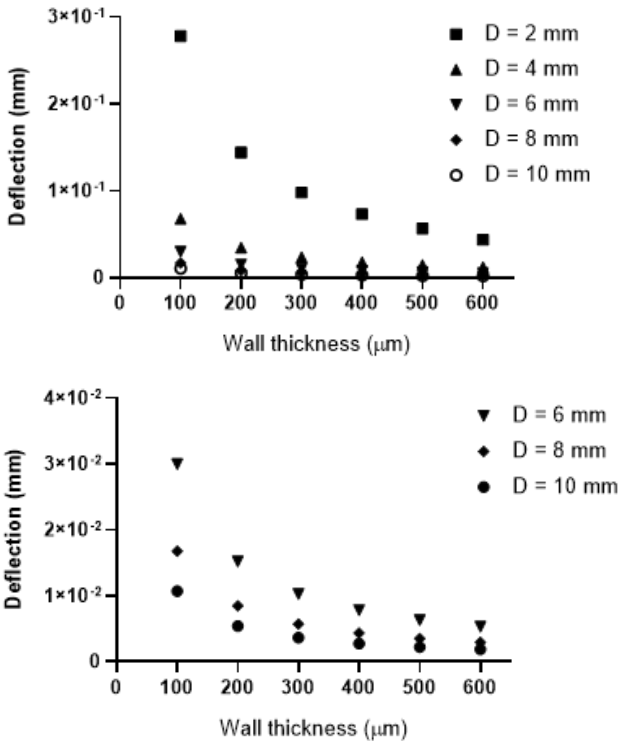

Figure 5: (top) Deflection estimated by varying the external diameter (D) from 10 to 2 mm, and the catheter wall thickness from 100 to 600 μm, and (bottom) a magnification for the cases D=6, 8 and 10 mm. This estimation was performed by fixing the elastic modulus (E) of the catheter to 1.5 MPa.

Results show a strong dependence of the flexural rigidity towards the geometrical parameters defined for the catheter, with a difference of one order of magnitude between the larger (D = 10 mm) and the narrower case (D = 2 mm). The deflection increases by decreasing the wall thickness. For example, for a diameter of 2 mm, and a wall thickness of 0.10 mm, the deflection will be 0.28 mm while for a higher thickness, such

as 600 µm, the deflection becomes less than 100 µm. These results are intuitive since an increase in the wall thickness means an increase in mass, therefore, a higher moment of inertia.

We also analyzed the influence of the elastic modulus for a specific case (D = 6 mm). Results are reported in Figure 6.

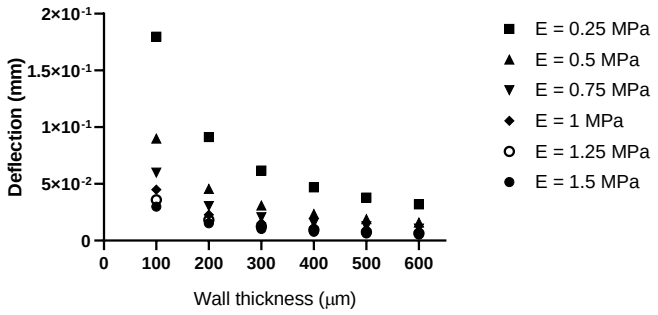

Figure 6: Flexural rigidity estimated by varying the elastic modulus (E) from 0.25 MPa to 1.5 MPa. This estimation was performed by fixing the external diameter to 6 mm.

Results show the effect of the elastic modulus decreasing in the increase of the expected deflection. Indeed, an increase in elastic modulus means a higher material rigidity, which reduces the expected deflection. Such deflections are relatively low and probably not sufficient to navigate vascular branches, and a process of parameter optimization will be necessary to provide a futuristic usage of biohybrid technology.

C. Kinking

Figure 7 shows the influence of the catheter geometrical parameters in the estimation of the critical radius.

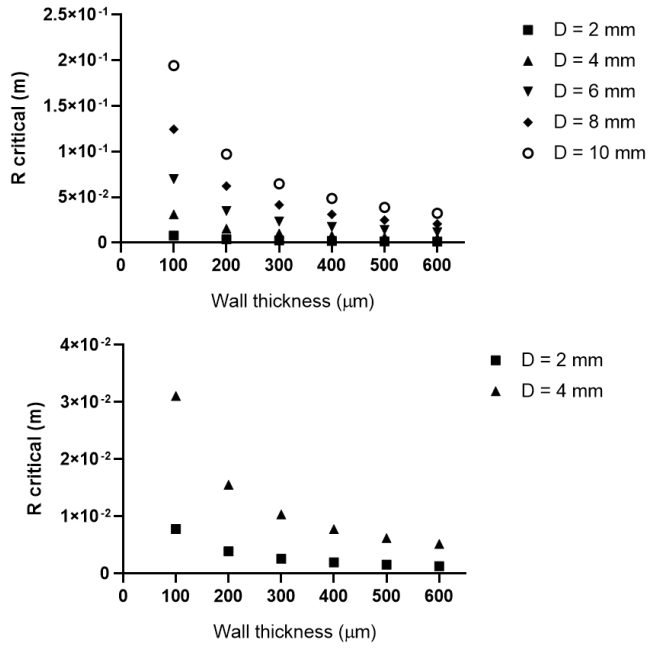

Figure 7: (top) Critical radius estimated by varying the external diameter (D) from 10 to 2 mm, and the catheter wall thickness from 100 to 600 µm, and (bottom) a magnification for the cases D=2 and 4 mm. This estimation was performed by fixing the elastic modulus (E) of the catheter to 1.5 MPa.

Results highlight that the $R_{critical}$ is strongly dependent on the geometrical features of the catheter. From the anatomical point of view, the angle of curvature expected to surpass the first branch of the hepatic artery is equal to ~45° [16], with a radius of curvature ranging between 1-4 cm. Catheter size and wall thickness will be chosen among the cases with the $R_{critical}$ lower than the targeted radius of curvature.

V. CONCLUSION

Within the framework of the BioMeld project, catheter design and manufacturing are encountering the technical challenges of integrating several components. Indeed, it must fit with the integration of an electronic platform and a bioreactor to enable the correct functioning of the biohybrid actuator, while maintaining good flexibility. Beyond the choice of materials and processing techniques, fabricating a soft catheter also involves the investigation of parameter designs. The next steps will be directed towards the definition of suitable geometrical parameters to target components integration, while maximizing the catheter flexibility.

***Abstract*— The design and optimization of cardiovascular devices must consider the hemolysis risk associated with their use since excessive hemolysis can lead to severe complications for the patient. Computational fluid dynamics (CFD) integrated with blood damage mathematical models is a powerful tool to evaluate the mechanically-induced hemolysis risk and highlight critical regions of blood contacting devices.**

In this work, a Lagrangian stress-based model is adopted to estimate the blood damage induced by hemodialysis catheters. CFD simulations were performed on two commercially available devices (the Palindrome™ Precision Symmetric Tip by Medtronic and the Arrow-Clark™ VectorFlow® by Teleflex). Technically, the shear stress histories along flow pathlines were computed and processed to quantify the mechanical blood damage associated with the use of the two devices. The computational results were consistent with the experimental findings obtained employing a set-up built in accordance with ASTM F1841, confirming the reliability of the developed hemolysis computational model as a tool supporting the design and optimization of hemodialysis catheters.

***Keywords*—Hemolysis, computational fluid dynamics, ASTM F1841, hemodialysis catheters.**

I. Introduction

An important aspect of the design of cardiovascular devices is the assessment of the mechanically-induced hemolysis risk associated with their use. Indeed, excessive mechanical blood damage can lead to anemia and tissue hypoxia, becoming dangerous to the patient's well-being [1]. Gaining knowledge regarding the hemolysis risk associated with the use of a cardiovascular device is crucial for its optimization and design improvement; therefore, accurate and trustworthy methods to estimate the hemolysis induced are needed.

Nowadays, the degree of mechanical blood damage is assessed experimentally by measuring the increase in the concentration of plasma free hemoglobin (pfHb) using a spectrophotometer, following the international standard ASTM F1841 [2]. Despite the efficacy of this method, it would be useful and cost-effective to be able to determine the hemolysis risk in a purely numerical manner using computational fluid dynamics (CFD) techniques. Various computational models were proposed over the years with this aim. However, there is not a universally accepted model for blood damage prediction yet. This is the consequence of a complex multiscale phenomenon, which is difficult to be simulated properly, and of a lack of a clear definition of the cause-effect relation leading to mechanical hemolysis. Moreover, approximations are needed, in order to reduce the problem complexity and obtain an acceptable computational cost [3].

The aim of this work is the development and the validation of a computational framework able to estimate the risk of mechanical hemolysis associated with cardiovascular devices, in particular with hemodialysis catheters.

II. Methods

The numerical model of hemolysis was implemented considering two central venous catheters for hemodialysis: the Palindrome™ Precision Symmetric Tip (Medtronic, Dublin, Ireland) and the Arrow-Clark™ VectorFlow® (Teleflex, Wayne, Pennsylvania). These are devices currently available on the market and in clinical use. The two devices present a symmetric tip with side openings and a dual-lumen configuration, with the presence of a venous and an arterial line.

In order to define a numerical model able to estimate the hemolysis risk associated with hemodialysis catheters, a geometric model was built for each device using SolidWorks (Dassault Systèmes, Vélizy-Villacoublay, France). Subsequently, the fluid domain was meshed in over 8 million cells employing the open-source software Vascular Modeling Toolkit. Figure 1 shows the geometric model and the mesh built for the Palindrome™ catheter; a similar geometry and mesh were also obtained for the VectorFlow® catheter [4].

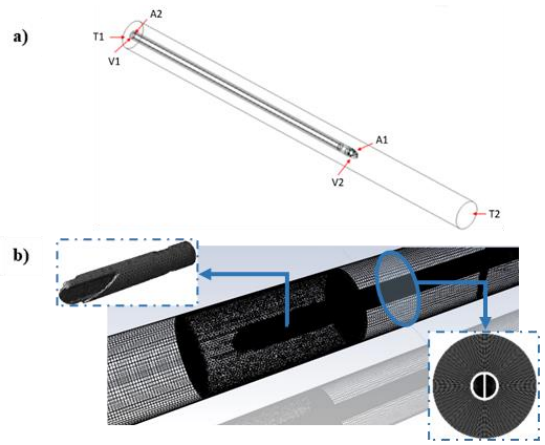

Fig. 1: a) Geometric model consisting of the Palindrome™ catheter coaxially placed into a cylinder representing the superior vena cava (SVC): T1) SVC inlet section, T2) SVC outlet section, V1) venous inlet section, V2) venous outlet section, A1) arterial inlet section, A2) arterial outlet section. **b)** Hybrid mesh created from the geometric model with tetrahedral and hexahedral elements.

The finite volume-based solver Ansys Fluent (ANSYS Inc., Canonsburg, Pennsylvania, USA) was used to solve the

governing equations of fluid motion in discretized form considering blood as a Newtonian fluid and imposing a reference pressure at the outlet of the superior vena cava (T2 in Figure 1). To mimic the working conditions of hemodialysis catheters, a flow rate of 3 L/min was imposed at the inlet section of the superior vena cava while 400 mL/min was imposed at the venous inlet section (T1 and V1 in Figure 1, respectively). Blood flow in the arterial lumen was set prescribing an outflow boundary condition of 400 mL/min in section A2 (Figure 1).

The mechanical hemolysis model adopted in this study employs a stress-based Lagrangian approach, considering the equivalent shear stress ($\bar{\tau}$) formulation proposed by Faghig and Sharp [5], which is based on the von Mises equivalent stress. The equivalent shear stress formulation used is presented in Equation 1, where σ_{xx}, σ_{yy}, σ_{zz} are the normal components of the Cauchy stress tensor and τ_{xy}, τ_{yz}, τ_{xz} are the shear components.

$$\bar{\tau} = \left\{ \frac{1}{3}\left[\sigma_{xx}^2+\sigma_{yy}^2+\sigma_{zz}^2\right] - \frac{1}{3}\left[\sigma_{xx}\sigma_{yy}+\sigma_{yy}\sigma_{zz}+\sigma_{xx}\sigma_{zz}\right] + \left[\tau_{xy}^2+\tau_{yz}^2+\tau_{xz}^2\right] \right\}^{\frac{1}{2}} \quad (1)$$

Equivalent shear stress values were extracted from the particle pathlines. These data, along with the time required by each particle to transit through the fluid domain (namely, the exposure time t), were then imported into MATLAB (MathWorks, Inc., Natick, Massachusetts, USA) to implement the Lagrangian hemolysis model by defining the mechanical damage index (DI in Equation 2). Following the formulation proposed by Grigioni *et al.* [6], the DI is quantified as a function of the magnitude of shear stress ($\bar{\tau}$), exposure time (t), shear history of the red blood cells, and the damage dose D. In Equation 2, χ, α and β are model parameters, firstly introduced by Giersiepen in 1990 [7].

$$DI = \int_{t_0}^{t} \chi\alpha \left[\int_{t_0}^{\phi} \bar{\tau}(\xi)^{\beta/\alpha}\, d\xi + D(t_0)\right]^{\alpha-1} \bar{\tau}(\phi)^{\beta/\alpha}\, d\phi \quad (2)$$

Model parameters are fundamental to the development of affordable models of blood damage; nevertheless, there are currently several sets available in literature, and there is not one universally used. In this work, four different sets were employed (see Table I) [3] – [8].

TABLE I: Parameters sets employed in the development of the hemolysis model [3] – [8].

Research group	χ	A	β
Giersiepen et al. (1990)	3.620 x 10^{-5}	0.7850	2.4610
Heuser and Opitz (1980)	1.800 x 10^{-6}	0.7650	1.9910
Zhang et al. (2011)	1.228 x 10^{-5}	0.6606	1.9918
Ding et al. (2015)	3.458 x 10^{-6}	0.2777	2.0639

The experimental set-up used to validate the hemolysis model was developed in accordance with the international standard F1841. The set-up is shown in Figure 2 and is composed by two volumetric roller pumps able to reproduce the catheter and the systemic flows, the catheter placed in a polymethylmethacrylat tube representing the superior vena cava, a reservoir and a thermostat bath. The test duration was 4 h and blood samples were withdrawn at specific time steps to assess the amount of pfHb.

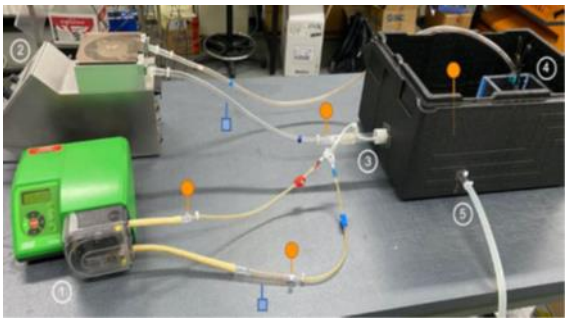

Fig. 2: Experimental set-up: 1) pump reproducing the catheter flow, 2) pump reproducing the systemic flow, 3) catheter, 4) reservoir and 5) thermostat bath. In blue and orange are reported the points where flow and pressure were measured, respectively.

III. Results

The trajectories of blood-like particles are presented in Figure 3, colored according to the value of equivalent shear stress $\bar{\tau}$ experienced along their path within the devices and in the vessel. Equivalent shear stress and velocity values are higher inside the catheters lumens. The hot spots of shear stress are the consequence of the flow disturbances induced in blood flow by the presence of the side holes of the devices, where pathlines undergo a marked deflection (Figure 3).

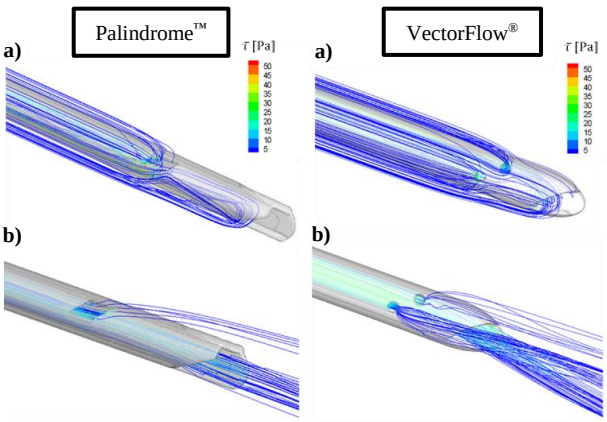

Fig. 3: Trajectories of the seeded particles entering the arterial lumen (**a**) and exiting the venous lumen (**b**) of the catheters.

The pathlines passing through the VectorFlow® catheter are affected by the helical-shaped geometry of its tip, which imparts a spiral motion to blood flowing out of the venous lumen. This feature deflects the flow away from the tip, in the opposite direction with respect to the blood withdrawn by the arterial lumen, theoretically reducing the recirculation and thus improving the device performance [9].

Nevertheless, this improvement is not evident when comparing the estimated mechanical-induced blood damage in the two hemodialysis catheters object of investigation.

Figure 4 shows the mechanical damage index DI (%) related to a passage of blood first into the arterial lumen and then into the venous one, computed by imposing the damage dose obtained at the arterial outlet as the initial damage dose $D(t_0)$ of the venous lumen.

These results highlight a hemolysis risk related to the VectorFlow® catheter double than the Palindrome™. The impact of model parameters on the hemolysis risk estimation is also presented in Figure 4: it emerges that the set of model parameters proposed by Giersiepen *et al.* [7] provides values of mechanical damage considerably higher than those obtained employing the other sets of model parameters available in the literature. This finding is consistent with other studies; in fact, it has been reported that the values of model parameters proposed in [7] tend to overestimate the risk of hemolysis associated with blood contacting devices, in part ascribable to the presence of secondary hemolysis affecting the experimental data used to fit the model [3].

The analysis of the estimated mechanical blood damage allowed also to compare the hemolysis risk related to the two identical lumens of the catheters. Table II shows the values of DI (%) obtained for each lumen of the hemodialysis catheters by employing the four sets of model parameters and considering a null initial damage dose $D(t_0)$. Regardless of the catheter or set of model parameters considered, the mechanical blood damage induced by blood transit into the arterial lumen is always higher than into the venous lumen. This observed difference can be ascribed to the abrupt change in flow direction and acceleration imparted to blood when it is withdrawn inside the arterial lumen. Contrarily, the blood flowing out of the venous side presents more regular trajectories.

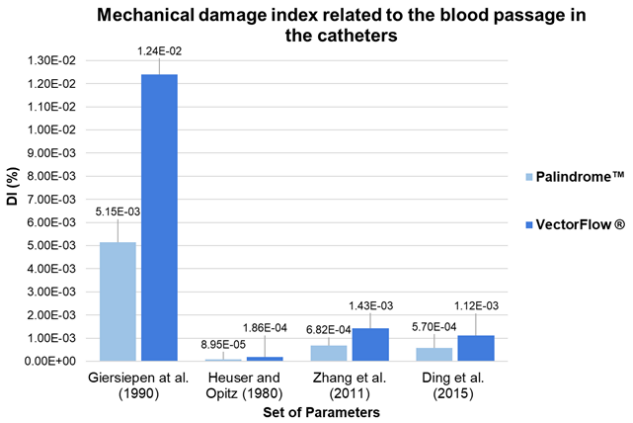

Fig. 4: Comparison of DI (%) related to the passage of blood first into the arterial lumen and then into the venous lumen of the Palindrome™ and the VectorFlow® catheters. DI (%) is reported for the four sets of parameters considered.

TABLE II: Values of DI (%) obtained by considering individually the venous and arterial lumen of the Palindrome™ and the VectorFlow® catheters.

Research Group	***Palindrome™***		***VectorFlow®***	
	DI (%) Venous	*DI (%) Arterial*	*DI (%) Venous*	*DI (%) Arterial*
Giersiepen at al. (1990)	1.77×10^{-3}	3.93×10^{-3}	4.86×10^{-3}	8.82×10^{-3}
Heuser and Opitz (1980)	3.50×10^{-5}	6.44×10^{-5}	7.86×10^{-5}	1.27×10^{-4}
Zhang et al. (2011)	2.46×10^{-4}	5.48×10^{-4}	5.11×10^{-4}	1.10×10^{-3}
Ding et al. (2015)	1.19×10^{-4}	5.68×10^{-4}	2.32×10^{-4}	1.12×10^{-3}

The experimental results are reported in Table III in terms of plasma free hemoglobin [mg/mL] at specific time instants of the in vitro tests. After the first hour, the VectorFlow® catheter presented consistently higher amounts of plasma free hemoglobin that the Palindrome™ and, at the end of the experimental tests a larger number of blood clots in its tip and side holes were observed. These observations are in line with the picture emerging from the CFD-based estimation of blood damage risk.

It must be clarified that the values of plasma free hemoglobin reported in Table III are related to the complete hydraulic circuit and might not accurately reflect the risk of mechanical hemolysis specifically associated with the tested catheter model. In fact, the in vitro tests performed with the set-up presented in Figure 2 did not generate significantly more plasma free hemoglobin than the hydraulic circuits where blood circulates without the presence of the catheters. Since both catheters produced sub-hemolytic blood damage, their specific contribution to the variation of plasma free hemoglobin in the hydraulic circuit is small when compared with other components, in particular the roller pumps, and is challenging to isolate. Therefore, a direct comparison with the numerical predictions is not feasible.

TABLE III: Difference between plasma free hemoglobin [mg/mL] at the various time instants of the in vitro tests and the plasma free hemoglobin of the sample taken before pumping for the Palindrome™ and the VectorFlow® catheters.

	5 min	***30 min***	***60 min***	***120 min***	***180 min***	***240 min***
Palindrome™ [mg/mL]	0*	0*	0	0.03	0.07	0.12
VectorFlow® [mg/mL]	0*	0*	0.01	0.05	0.11	0.16

*cases in which the plasma free hemoglobin before pumping was greater than the plasma free hemoglobin at the time considered.

IV. Conclusion

When used for comparative purposes, the Lagrangian stress-based model here adopted [6] is capable to discriminate among hemodialysis catheters in terms of associated risk of mechanical hemolysis. The findings of this study highlight the potential of the here adopted approach as a tool to improve the design and the optimization of catheters. Indeed, regardless of the set of blood damage model parameters employed, the model correctly predicts the higher degree of blood damage induced by the VectorFlow® catheter and allows the identification of regions characterized by high equivalent shear stresses. Furthermore, the analysis has allowed to discriminate between the intra-device blood damage risk related to the venous and the arterial line, the latter presenting a higher risk of blood damage as a consequence of the associated flow field. In particular, this finding is not affected by the adoption of different sets of model parameters and further supports the robustness and effectiveness of the proposed approach for the design and optimization of hemodialysis catheters.

Nevertheless, the set of model parameters used has great influence on the prediction of hemolysis risk and the results obtained cannot be directly compared with experimental

hemolysis values; therefore, there is a clear need to develop an experimental set-up capable of accurately validating the predictions. The validation of the developed hemolysis model would also pave the way for its application to the design and optimization phases of other cardiovascular devices.

Abstract— **Recently, the study toward the relationship between microbiota and metabolites is growing to try to understand the complex mechanisms that take place in the gut. Among the metabolites of greatest interest there are bile acids, synthesized in human liver, which interact with the microbial population that inhabits gut. Imbalances of these acids can result in numerous diseases and pathogenic infections. One possible solution to measure these molecules directly *in vivo* is to use synthetic biology techniques to engineer a biosensor into probiotic bacteria. An exploratory work on bile acid biosensors, which are promising tools for future medical and environmental diagnostic applications, is presented here.**

Keywords— **Synthetic biology, biosensor, probiotic bacteria, bile acids**.

I. Introduction

The scientific community interest in gut microbiota is constantly growing as it plays a fundamental role in human physiology due to mutual interactions between microbiota and host organism.

Changes in the microbiota composition lead to alterations in the intestinal metabolites and hence the health of the organism itself. Among the metabolites of greatest interest there are bile acids (BAs) [1], [2].

BAs are first synthesized in liver and, following each meal, released in gut to perform their primary action, i.e. the emulsification of fat-soluble molecules.

The output of cholesterol transformation is primary BAs, conjugated with an amino acid which can be a taurine (T) or a glycine (G). Consequently, in liver we find the conjugated species of the primary acids: taurocholic acid (TCA) and glycolic acid (GCA) are the conjugates of cholic acid (CA), while the taurochenodeoxycholic acid (TCDCA) and glycochenodeoxycholic acid (GCDCA) are those of chenodeoxycholic acid (CDCA) (*Fig. 1*).

When conjugated primary acids transit the gastrointestinal tract, the microbiota carries out a series of transformations that lead to the formation of more than 50 species of chemically different secondary BAs [3]. The predominant ones are deoxycholic acid (DCA) and lithocholic acid (LCA), reaction products from CA and CDCA respectively [3].

The BAs pool and the microbiota influence each other: the former exerts a controlling action on the growth of bacteria coexisting in the gut and the latter transform them into secondary BAs. The pool of BAs is thus the end product between the primary ones synthesized in liver and the secondary ones synthesized by gut microbiome.

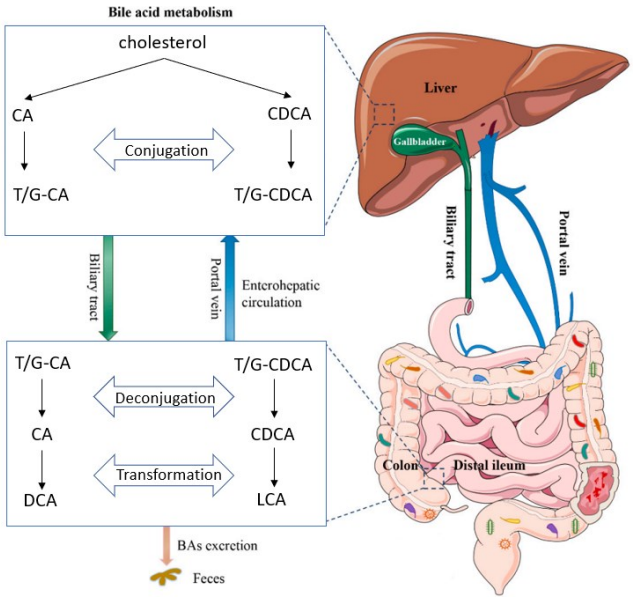

Fig. 1: Bile acid synthesis and metabolism and the major changes in the intestine. Figure adapted from [18].

It is evident how an unbalance of either component can cause a change in the available pool of BAs that results in a metabolic derangement. In fact, BAs are often correlated with numerous pathologies such as obesity, diabetes, colitis, bacterial infections and even colon carcinomas [1], [2].

Moreover, BAs play a fundamental role in the life cycle of *Clostridium difficile*, an enteropathogenic bacteria of considerable medical interest [4], [5]. Some BAs, in fact, inhibit the growth of *C. difficile*, while others promote it. Therefore BAs play a fundamental role in several physiological processes and being able to detect their unbalance is an important factor in recognizing pathologies and intervening with specific treatment [6], [7].

Bacterial biosensors, i.e., engineered bacteria capable of responding to external stimuli or to markers of disease by producing monitorable response signals, constitute promising systems for in vitro but also in vivo diagnostics [8].

In general, bacterial biosensors consist of a sensing module and a transcriptional element that produces a measurable output in response to an exogenous input.

The sensing module consists of a regulated promoter while the regulator is constitutively expressed within the biosensor's genetic circuitry. It is usually a receptor protein that ligates the input of interest and influences the associated promoter [8], [9]. The promoter, in turn, controls the transcriptional activity of the regulated gene, which may be a reporter gene that

translates to a fluorescent protein or an enzyme that performs some function on the input itself. Since model organisms are not always suitable for non-laboratory applications, the interest of the scientific community is shifting towards research and characterization of new engineerable microorganisms by seeking to optimize engineering protocols and the characterization of new parts for gene regulation.
Probiotic organisms, being able to survive in the gut together with the human microbiota, can be engineered with synthetic biology techniques for diagnostics and therapy directly in situ. *Escherichia coli Nissle 1917* (ECN), a Gram-negative bacterium, was chosen as the target probiotic which, compared to other *E. coli* strains, is non-pathogenic. Moreover, it is already used as a drug for the adjuvant treatment of various dysfunctions of the intestinal tract.

II. MATERIALS AND METHODS

ECN competent cells were prepared as described in [10].
A total of 4 different biosensors have been tested, each with its theorical specificity to different set of BAs, as reported in *Table 1*.
The first two tested biosensors, VtrAC and TcpPH, come from the work of Chang et al [11]. There is a regulatory promoter PcadBA, induced by a transcriptional regulator, CadC, and a receptor composed of assembling modules, i.e., the whole part composed of CadC and TcpP and TcpH. The regulated gene in this case encodes the superfolder green fluorescent protein (sfGFP). The other biosensor is identical except that it differs in the receptor modules, called VtrA and VtrC. These two biosensors were tested in the ECN probiotic organism, creating two strains of engineered bacteria inducible by BAs.
Another tested biosensor was *de novo* constructed using the operator sites of the transcriptional inhibitor VFA0359 (*Vibrio fischeri*) from the work of Taketani et al. [12] assembled within a constitutive *E. coli* promoter. The red fluorescent protein (RFP) has been chosen as the reporter gene.
This biosensor was tested in the model organism *Escherichia coli F'*. The last biosensor tested was the plasmid containing CmeR (*Campylobacter jejuni*) from the work of Nasr et al., which was tested by the authors on numerous BAs [13], [14]. The regulated gene encodes the enhanced green fluorescent protein (eGFP). Instead, this biosensor was tested in *E. coli TOP10*.

TABLE I: MAIN CHARACTERISTICS OF THE FOUR BIOSENSORS.

	Regulated promoter	*Transcriptional regulator*	*Reporter gene*
TcpPH	PcadBA	CadC (TcpP+TcpH)	sfGFP
VtrAC	PcadBA	CadC (VtrA+VtrC)	sfGFP
VFA0359	Plac	VFA0359	RFP
CmeR	Ptac	CmeR	eGFP

Biosensors were characterized with the Tecan Infinite F200 Pro instrument, used to incubate bacterial cultures in 96-well plates.
This instrument allows the simultaneous reading of the optical density at 600 nm called OD600, which is a proportional measure of cell growth, and the fluorescence, proportional to the expressed reporter protein.
Collected data are processed by first computing the GFP/OD ratio and then normalizing it by calculating relative promoter unit (RPU). The RPU measurement, shown in Eq. (1), is obtained by normalizing the intensities of fluorescence with those of a reference construct [15].

$$RPU = \frac{GFP/OD(biosensor)}{GFP/OD(reference)} \qquad (1)$$

Each biosensor has been tested at five different concentrations of each BA by measuring the RPU as a quantification of the relative strength of an inducible promoter.
The reference construct is a plasmid containing the same fluorescence protein under the control of a constitutive promoter of known strength. For this reason, the reference construct used for the calculation of RPU of biosensors TcpPH and VtrAC, has a GFP, while for the other two biosensor containing VFA0359 and CmeR, it was used a construct expressing a RFP.

III. RESULTS

Nissle was made competent, i.e. able to be engineered by means of a specially designed and optimized protocol. After establishing that none of the used BAs was toxic to ECN growth, the experimental set-up for the characterization of the four biosensors was defined. The four recombinant strains with the four biosensors were created. The BAs chosen for biosensor characterization have been CA, TCA, CDCA, GCDCA, TCDCA, DCA, GDCA, TDCA and LCA.
While as for concentrations, 10 µM, 40 µM, 80 µM, 120 µM and 200 µM were selected in accordance with physiological levels in the intestine, and at least three replicates were performed for each strain, unless differently indicated.
As mentioned above, the RPU was calculated from the data from the microplate reader, and was fitted to the Hill equation model, shown in Eq. (2), in order to obtain the characteristic parameters; where V_{max} represents the maximum RPU value reached and K_m represents the sensor activation switch point, i.e. the concentration at which it is activated.

$$RPU(V_{max}, K_m, n, C) = V_{max} * \frac{C^n}{K_m^n + C^n} \qquad (2)$$

Overall, the strain engineered with TcpPH senses the expected acids, which were supposed to be all conjugated primaries, i.e., TCA GCA GCDCA and TCDCA [11] although it is actually sensitive to conjugated secondaries as well (Fig. 2A).
The strain engineered with VtrAC senses the same expected acids, i.e., conjugated secondaries GDCA and TDCA, just like previously shown in [11] (Fig. 2B).
The new biosensor containing VFA0359 tested in *Escherichia coli F'* appeared to be insensitive to the selected BAs. Only two replicas were performed for this biosensor (Fig. 2C). Additional promoter engineering will be carried out to address the inducible behavior of this component.
Lastly, the biosensor containing CmeR tested in *Escherichia coli TOP10* also turned out to be not insensitive to the selected BAs (Fig. 2D).

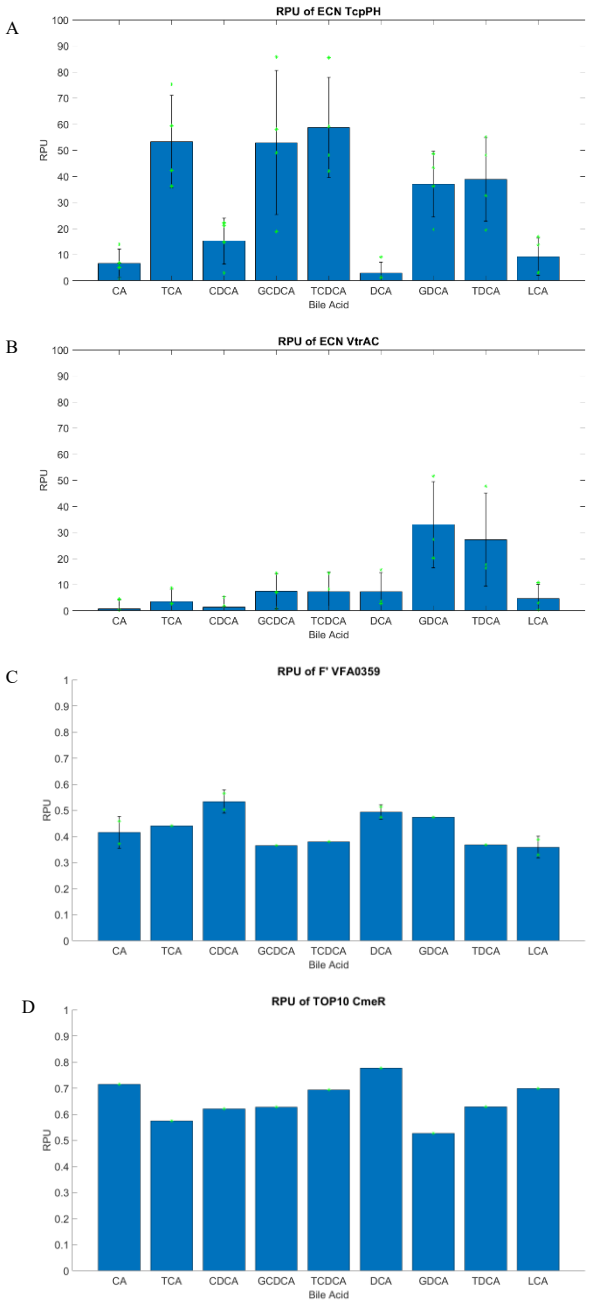

Fig. 2: Bar graphs of mean RPU values related to the four tested biosensors for each BA at the concentration of 80 µM are shown in blue. Individual replicates are shown as green dots. A) TcpPH sensor in ECN. B) VtrAC sensor in ECN. C) VFA0359 sensor in *Escherichia coli F'*. D) CmeR sensor in *Escherichia coli TOP10.*

Another measure for comparing the four different biosensors is Fold Change (FC), calculated as the ratio of two measures of gene expression. In this particular case, the RPU measure was used because it is representative of how much a particular BA activates the expression of the fluorescent protein. Two groups of BAs were distinguished in the 80 µM bar graphs; those that activate the biosensor are identified as on-group, and those that do not activate it are called off-group. The FC measure was calculated as the lowest RPU of the on-group divided by the highest RPU of the off-group. Accordingly, a FC was calculated for every replicate of each biosensor and then averaged across replicates.

The TcpPH and VtrAC biosensors show a FC of 3.49 and 9.05, respectively, while CFA0359 and CmeR exhibit a FC of 0.97 and 0.84, respectively. The latter two have FCs close to 1, which means there are no particular BAs that seem to activate the biosensors. Appropriate tuning of the biosensors, such as changing RBS or promoter strength, can be done to improve these measurements.

As mentioned before, a Hill-type equation model was used to fit the data for biosensors TcpPH and VtrAC since they are the ones sensitive to BAs.

Fig. 3A and 3B shows two fitting examples from which the characteristic parameters V_{max} and K_m can be derived. Fig. 3A shows a fitting example related to TCA, one of those that most activates the TcpPH sensor. Fig. 3B shows a fitting example related to GDCA, one of those that most activates the VtrAC sensor, in this case it looks more like a Michaelis-Menten equation because of the n=1.

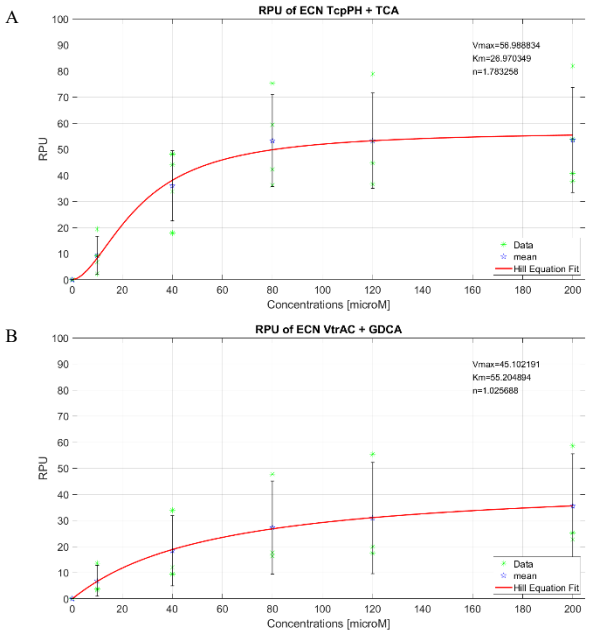

Fig. 3: Fitting of the Hill model to the RPU data from the biosensors. In red it is shown the curve obtained from the model, in blue the averages of the data, and in green dots the data for individual replicates. The characteristic parameters are shown in top left. A) TcpPH sensor in ECN with TCA. B) VtrAC sensor in Escherichia coli Nissle with GDCA.

IV. CONCLUSION

In this study, the TcpPH and VtrAC biosensors are the most suitable to be used for diagnostic purposes, since they are found to be sensitive to different combinations of BAs. As for VFA0359 and CmeR, new studies will be carried out to optimize the response of the biosensors since they currently would not seem to be inducible by BAs. Developments in the short term will include an attempt to expand the number of biosensors available and characterize them in ECN to enrich the number of sensed acids. Although neither biosensor turns out to be specific to a particular BA, a possible approach will be finding combinations of the biosensors that can detect physiological situations of interest. In addition to expanding

the pool of available biosensors, a possible future development is the implementation of a BAs controller in a probiotic organism: for this purpose, in addition to sensors, it will be necessary to develop and couple molecular actuators to them.
An actuator can be a gene that translates for a BA-transforming biosynthetic enzyme(s), exerting control over the target variable, i.e. BA concentration. Assembling a controller means measuring a concentration of a BA by means of a sensor and, if necessary, returning it to an equilibrium state by means of an actuator. It can be done by exploiting genes that implement transformations on BAs, namely bsh gene [16], which deconjugates BAs from amino acids, and bai operon [17], which transforms unconjugated primary conjugated into unconjugated secondaries.
For example, possible scenarios could be:
-sensor of conjugated primary BAs, and sensor of deconjugated primary BAs, with the bsh gene going to inhibit the deconjugation of conjugated BAs;
- deconjugated primary BAs sensor and secondary BAs sensor, with the bai operon going to inhibit the transformation of primary BAs into secondary BAs.
Overall, these platforms can be combined to customize systems able to sense the level of different BAs classes *in vivo*, or interconnecting controller circuits to implement robust regulation tasks, paving the way to for new therapies to interact with microbiota imbalances and restore BAs to normal concentrations.

***Abstract*—Chronic lymphocytic leukemia (CLL) and diffuse large B-cell lymphoma (DLBCL) are two common lymphoid neoplasms, characterized by high heterogeneity among their subtypes. A murine model presenting features of human CLL revealed the existence of two distinct leukemic presentations that differ for their transcriptomic profile. In this study, we used gene expression data from two DLBCL datasets to identify human subjects analogous to the murine and characterize their behaviour in terms of prognosis and microenvironment properties. The results revealed that, despite showing molecular features related to poor prognosis in solid cancers, such as extracellular matrix remodeling and epithelial-mesenchymal transition, group 1 leukemia patients have a significantly better overall and progression-free survival outcome.**

***Keywords*—lymphoid malignancies, tumor microenvironment, gene expression, bioinformatics**

I. Introduction

LYMPHOID neoplasms are a heterogeneous group of diseases arising from the malignant transformation of lymphoid cells. Two common classes of lymphoid malignancies are chronic lymphocytic leukemia (CLL) and diffuse large B-cell lymphoma (DLBCL) [1].

CLL is the most common leukemia among adults in Western countries. The main characteristic of the disease is the progressive accumulation of B lymphocytes in blood, bone marrow, spleen and lymph nodes [2]. The incidence increases with age, with a mean age at diagnosis of 72 years; however, CLL cases in younger subjects are on the rise. Survival times after diagnosis vary greatly, spanning between a few months and decades. The clinical presentation is also extremely heterogeneous: about a third of the patients needs immediate treatment after the diagnosis due to their heavy symptoms, while a similar proportion of subjects are asymptomatic and never require any treatment [2], [3]. DLBCL is the most common lymphoid malignancy in adults and shares some molecular characteristics with CLL, such as the cell of origin [4]. Moreover, it can arise from histologic transformation of CLL in a process called Richter's transformation [5]. It is more frequently observed in elderly patients, but it can also occur in younger subjects and, rarely, in pediatric cases. The majority of patients show a rapidly expanding tumor mass located in one or more lymph nodes and extranodal sites [6].

Similarly to other solid cancers and hematological malignancies, an essential role in survival and proliferation of tumoral B cells is played by the tumor microenvironment, an entity composed by stromal cells that act as an active component of the disease [7], [8]. Within some specialized niches located inside the bone marrow, mesenchymal stromal cells interact with leukemic cells via contact-dependent and soluble factor-dependent mechanisms. This mutual interaction favors cell proliferation, influences their migratory activity and can protect B-cells from cytotoxic agents [9], [10]. For instance, studies conducted in vitro on chronic lymphocytic leukemia (CLL) B-cells demonstrated that direct contact between bone marrow-derived stromal cells and leukemic B-cells is able to protect tumoral cells from apoptosis [11], [12]. As proposed by recent studies regarding tumor microenvironment in lymphomas, its features also play a role in determining the prognostic outcome [13], [14].

In this work, we wanted to analyze the characteristics of two distinct presentations of murine lymphoid neoplasia identified in the Eμ-TCL1 murine model, a mouse model that displays some of the features of human CLL. We utilized gene expression data to investigate the presence of similar transcriptomic profiles in human samples and to examine their properties, in order to investigate molecular mechanisms that could be related to the heterogeneous presentation of the disease. Given their importance in hematological malignancies and their suggested influence on prognosis, we especially focused on molecular mechanisms related to the tumor microenvironment.

II. Materials and Methods

A. Mouse gene expression data

RNA-seq technology was used to measure gene expression in leukemic B-cells samples from the spleen of transgenic mice displaying two distinct transcriptomic profiles. Data were available in 4 replicates for each neoplastic subtype.

B. Human gene expression data

Human microarray gene expression data were downloaded from Gene Expression Omnibus (GEO) [15] for datasets GSE117556 and GSE32918, that include 928 and 172 DLBCL samples, respectively.

C. Mouse data analysis

Gene expression data obtained from mouse models were employed to define a characteristic transcriptomic signature representing the two distinct lymphoid presentations. To this aim, a differential analysis was performed to identify the most distinctive genes for each subtype. The characterizing signature was defined as the 200 genes most upregulated in one subtype with respect to the other.

D. *Human samples classification*

To map the two presentations of leukemia identified in mice to human samples and evaluate their molecular differences, each subject from the selected DLBCL datasets was assigned to group 1 or group 2 according to their expression profile. First, mouse genes included in the signatures representing each type were assigned to their human homologs using the correspondence retrieved from the Mouse Genome Database [16]. After the conversion, the rank-based single sample scoring method Singscore [17] was used to test the enrichment of both signatures in the expression profile of each human sample. Specifically, genes were ranked based on their expression level in the tested sample, then, the mean rank of genes in the signature was calculated and normalized against the theoretical minimum and maximum values. Associated p-values were obtained using a permutation test.

Each sample was assigned to one of the two groups if the corresponding signature had reached the significance level in enrichment analysis ($p<0.05$), otherwise it was considered unclassified.

E. *Characterization of distinct lymphoid presentations*

We performed a log-rank test on follow-up data available for GSE117556 and GSE32918 samples to compare the prognostic outcomes in different lymphoid groups. Both overall survival (OS) and progression-free survival (PFS) were tested.

As for functional characterization of the two subtypes, we tested for differences in enrichment of gene sets representing molecular processes related to tumor microenvironment. Specifically, we selected the signature *Epithelial Mesenchymal Transition* from the Hallmark collection of MSigDB [18] and the signature *STROMAL-1* from Lenz et al. [14]. The enrichment scores were computed using Singscore [17], and the statistical significance of the difference between enrichment scores in group 1 and group 2 was verified using the Mann-Whitney U test.

III. Results

A. *Human samples classification*

To investigate the differences in the molecular presentation of the microenvironment in the two murine preparations in human patients, we assigned each human sample to different groups according to their molecular similarity with murine transcriptomic profiles. Using a single sample enrichment approach, we were able to assign to one of the two classes 34,6% of samples for GSE117556 and 26.2% of samples for GSE32918. In dataset GSE117556, 83 samples were assigned to group 1 and 23 to group 2; for GSE32918, 13 samples were assigned to group 1 and 34 to group 2 (Figure 1).

B. *Survival analysis*

Survival data from patients assigned to one of the two classes were used to test differences in OS times and PFS times between different lymphoid groups (Figure 2). The results showed a significantly better prognosis for group 1 patients, with longer OS times in both datasets (GSE117556: p=0.0168; GSE32918: p=0.0279) and longer PFS times in GSE117556 (p=0.0020). DLBCL patients that were not assigned to any of the groups showed a prognostic outcome intermediate between the two groups (GSE32918, data not shown) or more similar to group 2 (GSE117556, data not shown).

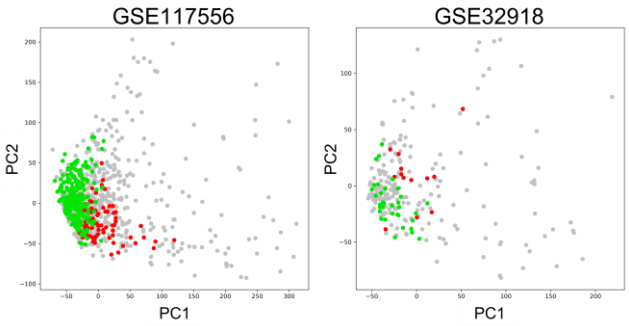

Figure 1: PCA displaying the results of the classification of human samples from GSE117556 and GSE32918. Group 1 samples are shown in red, group 2 samples are shown in green.

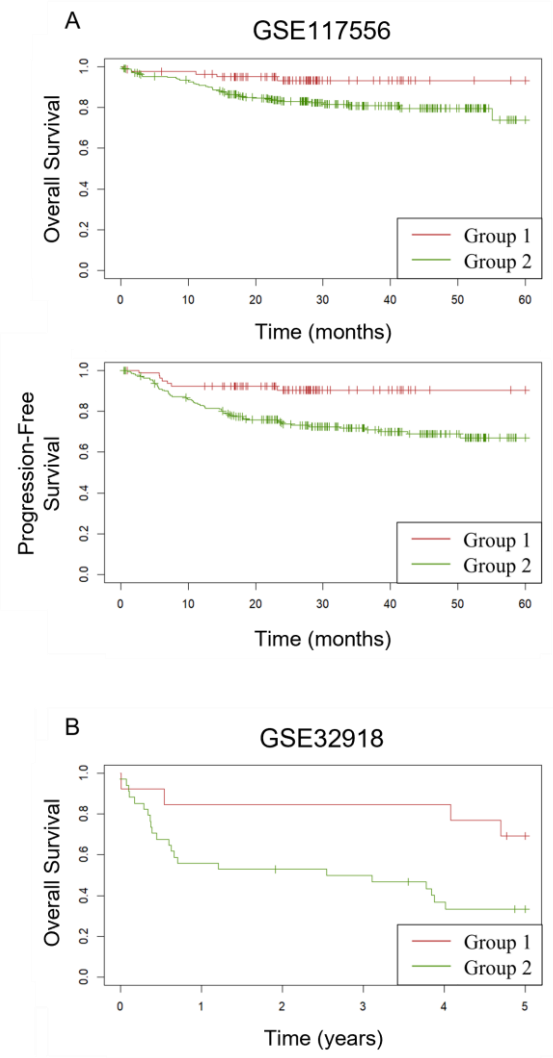

Figure 2: Kaplan-Meier curves comparing OS and PFS times of group 1 and group 2 patients from GSE117556 (A) and GSE32918 (B).

C. *Molecular characterization*

The differences in tumor microenvironment features between patient groups were investigated by evaluating the enrichment of specific gene signatures in each classified sample. The first signature considered included genes involved in epithelial-mesenchymal transition (EMT), a process that disrupts cell adhesion. The signature showed significantly higher enrichment scores in group 1 samples, according to the Mann-Whitney U test (GSE117556: $p=1.12x10^{-17}$, GSE32918: $p=9.30x10^{-7}$).

The second signature tested was defined as *STROMAL-1* in [14] and included genes responsible for the deposition and remodeling of the extracellular matrix. Again, group 1 samples showed significantly higher enrichment scores in both datasets (GSE117556: $p=1.36x10^{-12}$, GSE32918: $p=1.09x10^{-7}$).

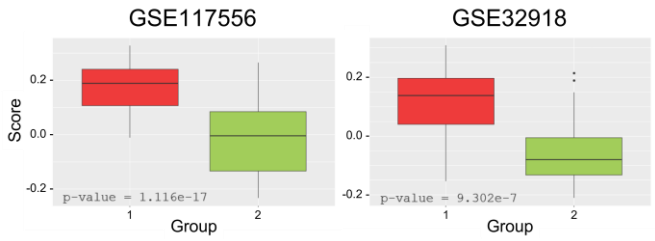

Figure 3: Enrichment scores for the signature *Epithelial-Mesenchymal Transition* in group 1 and group 2 samples.

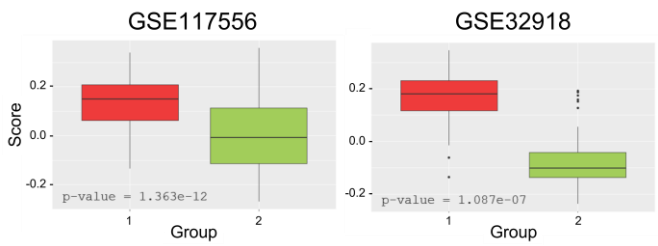

Figure 4: Enrichment scores for the signature *STROMAL-1* in group 1 and group 2 samples.

IV. DISCUSSION

The aim of this study was to explore the molecular characteristics of two subtypes of leukemias identified in the Eμ-TCL1 murine model and showing a different transcriptomic profile. We employed gene expression data from publicly available DLBCL datasets to identify human samples matching murine expression profiles. Then, we used survival data and gene signatures derived from literature to explore the properties of the two leukemias in human patients, with a particular focus on tumor microenvironment.

The mapping of human samples to the two murine lymphoid groups revealed that about one third of the total number of human samples had similar expression profiles to one of the two leukemias, suggesting that the same classes could be translated to humans. Following classification, a survival analysis was conducted to highlight possible differences in patients' prognostic outcome. The results indicated that patients assigned to group 1 had a significantly better prognosis in both datasets. In addition, progression-free survival times were significantly longer in group 1 patients in the largest dataset.

With regard to molecular characterization, we chose to focus on the features of tumor microenvironment, given the increasing amount of evidence demonstrating its vital role in promoting the survival and proliferation of leukemic B-cells [9]–[13]. In solid cancers, extracellular matrix (ECM) remodeling and other processes related to tumor microenvironment are associated to increased aggressiveness and poor prognosis [19]. However, a recent study has proposed the hypothesis that processes traditionally considered as unfavorable in solid tumors could be associated to better survival outcomes in lymphoid neoplasms [14]. There, the authors defined a signature that included components of the extracellular matrix, together with modifiers of collagen synthesis, proteins involved in ECM remodeling and connective-tissue growth factors. In order to comprehend the behavior of these processes within the two distinct lymphoid groups examined in this work, we evaluated the enrichment of the signature proposed by [14], named *STROMAL-1*, in each human sample, together with a signature including only genes related to EMT. The enrichment analysis showed significantly higher expression values in group 1 patients for genes associated to ECM remodeling and EMT.

To summarize, there is a clear distinction in the molecular characteristics of the microenvironment between human samples mirroring murine transcriptomic profiles. Group 1 samples are characterized by the activation of EMT-like programs and an active production and processing of ECM components. Notably, our analysis has further confirmed an unexpected correlation between these features, typical indicators of aggressiveness in solid tumors, and a more favorable outcome of lymphoid neoplasms, with group 1 patients displaying significantly better prognosis with respect to group 2.

Modeling metabolic overload effects in bacterial growth rate in synthetic biology

E. Gaetan[1], C. Cimolato[1], L. Schenato[1], and M. Bellato[1]
[1] *Department of Information Engineering, University of Padova, Padova - Italy*

***Abstract*—Modeling growth in bacterial cells is a major issue in systems and synthetic biology. Despite several growth rate functions are proposed in literature, most of them focus on nutrients composition, without explicitly counting for possible perturbation provided by the expression of recombinant genes, an effect called metabolic load or burden. In this work, some already published growth functions are evaluated, highlighting possible disagreements with the biological knowledge, which allow to reject some of them. Furthermore, some alternative functions based on biological evidences are proposed and tested as well, specifically oriented on metabolic load effects. The final aim is to identify a growth rate function that can be applied to models with different levels of complexity, leading to coherent results, which also account for the addition of metabolic burden, decoupled from nutrient composition.**

***Keywords*—Molecular systems biology, metabolic burden, bacterial ribosomes, control systems.**

I. INTRODUCTION

In Synthetic Biology, engineers modify bacterial cells to create novel biological systems with potential therapeutic or biotechnologically-relevant effects. Genetic circuits, realized following a model-driven rational design approach, are added to engineered cells, leading to the production of different proteins than the ones normally synthesized, in a mathematically-predictable manner.

Due to the finite nature of the cells, the limitation in resource availability harness the whole engineering process, often leading to unpredictable outcomes in engineered cells behaviour [1],[2], to the point that extra demand for protein synthesis necessarily affects the cell growth.

While the *growth rate* of the bacterium *Escherichia coli* in its exponential growth phase is typically assumed to be conserved (cells can double every ~ 20 min at $37\,\mathrm{deg}$), it has been observed that this time can be severely reduced [3] or either increased [8] by several factors, such as the amount of available nutrients in the surrounding environment.

While several examples of growth rate functions including temperature or nutrient starvation can be found in literature, unfortunately they do not include metabolic load perturbations, being mostly related to non-engineered systems. Nevertheless, all of them agree that the growth rate function should depend on the ribosomal component.

In [3], [5], the proposed model for the cell growth is a function dependent on the total number of ribosomes: in the first case, the function is linear, while in the second one it is a first order Hill function. In [4], growth rate is a linear function as in [3], but it now depends on the difference between the total active and inactive number of ribosomes and on the total protein mass. Additionally, in [6], the linearity is maintained, but on the ribosome complexes (i.e., a ribosome bound with a mRNA.). Lastly, one more example can be found in [7] where, while a growth rate function was not explicitly defined, the authors provided the ratios of free ribosomes over the total amount of them. Accordingly to this information, the growth rate has been analytically drawn by fitting a Hill function on the available points.

As already stated, all these growth rate functions do not account for the inclusion of metabolic load and therefore they can not be directly applied. Thus, a test phase is needed in order to verify that the chosen growth rate function produces coherent results with the biological evidences.

The following Section 2 describes our mathematical modeling approach to describe the cell system to overcome the existing limitations, Section 3 shows the simulation results and Section 4 resumes the conclusions.

II. MATHEMATICAL MODELING

A. Biological hypothesis and mathematical assumptions

The first assumption to be performed is that RNAP can be considered constant [7]. Consequently, the chemical reaction for the transcription process can be approximated by:

$$\mathrm{D} \xrightarrow{\omega} \mathrm{D} + \mathrm{m} \tag{1}$$

where D is the DNA, ω is the transcription rate and m is the mRNA. In order to limit the number of parameters, assuming equal order of magnitude and over time, the spontaneous decay is considered equal for proteins, ribosomes and ribosomal complexes (regardless of the species) and indicated with δ; analogously, mRNA and rRNA decay is indicated with γ.

Another assumption regards the degradation rate μ. It is defined as the sum between the spontaneous decay γ and the growth rate λ. From [7], it is known that γ is faster than λ for mRNA and rRNA. This leads to the approximation: $\mu_{mRNA,rRNA} = \gamma + \lambda \approx \gamma$. Thus, the degradation rate of mRNA and rRNA can be considered constant.

The last assumption concerns the synthesis of ribosomes R. Indeed the process of formation should involve both rRNA and R-Protein. To simplify further the model structure, the ribosomes are assumed to be derived directly from the DNA with rate β_r:

$$\mathrm{D}_r \xrightarrow{\beta_r} \mathrm{D}_r + \mathrm{R} \tag{2}$$

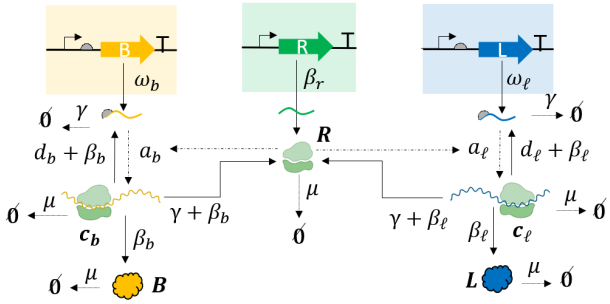

Fig. 1: Model of the cell system.

Additionally, it is possible to identify two different ribosomal species (i.e., components involving free ribosomes in their characteristic chemical reactions): the basal species b, which represents all the components that are fundamental for the survival of the cell and the load species ℓ, which corresponds to extra demand of protein to be synthesized, thus to metabolic burden.

B. Model implementation

The derived model can be represented as in Fig. 1. The structure involves three different types of ribosomal species: the free ribosomes R, the basal c_b and load c_ℓ complexes. Together, they form the total amount of ribosomes of the cell R^{TOT}. Starting from the DNA, the transcription produces the mRNA with RBS (*Ribosome Binding Site*). This can bind the ribosome with rate a_i (where i indicates the species, namely $i = b, \ell$). However, this link can be broken with dissociation rate d_i. In the building phase of the model, an hypothesis is assumed: c_i can release the free ribosome with rate γ. Furthermore, the translation process synthesizes the protein with rate β_i from the ribosomal complex c_i, but also returns the mRNA and the free ribosome used for the bound.This model structure accounts also for the degradation rates (γ for mRNA and μ for ribosomes, ribosomal complexes and protein). Hence, this model is characterized by the following set of chemical reactions (with $i = b, \ell$):

$$\mathrm{D}_i \xrightarrow{\omega_i} \mathrm{D}_i + \mathrm{m}_i \quad (3)$$

$$\mathrm{D}_r \xrightarrow{\beta_r} \mathrm{D}_r + \mathrm{R} \quad (4)$$

$$\mathrm{m}_b + \mathrm{R} \underset{\mathrm{d}_b}{\overset{\mathrm{a}_b}{\rightleftharpoons}} \mathrm{c}_b \xrightarrow{\beta_b} \mathrm{m}_b + \mathrm{R} + \mathrm{B} \quad (5)$$

$$\mathrm{m}_\ell + \mathrm{R} \underset{\mathrm{d}_\ell}{\overset{\mathrm{a}_\ell}{\rightleftharpoons}} \mathrm{c}_\ell \xrightarrow{\beta_\ell} \mathrm{m}_\ell + \mathrm{R} + \mathrm{L} \quad (6)$$

$$\mathrm{m}_i \xrightarrow{\gamma} 0 \quad (7)$$

$$\mathrm{c}_i \xrightarrow{\gamma} \mathrm{R} \quad (8)$$

$$\mathrm{R}, \mathrm{c}_i, \mathrm{B}, \mathrm{L} \xrightarrow{\mu} 0 \quad (9)$$

and mass conservation laws:

$$R^{TOT} = R + c_b + c_\ell \quad (10)$$

$$m_i^{TOT} = m_i + c_i \quad (11)$$

The reactions 3-9 can be translated into a system of differential equations, as it follows (with $i = b, \ell$):

$$\dot{m}_i = \omega_i D_i - a_i m_i R + d_i c_i + \beta_i c_i - \gamma m_i \quad (12)$$

$$\dot{c}_i = a_i m_i R - d_i c_i - \beta_i c_i - \gamma c_i - \mu c_i \quad (13)$$

$$\dot{R} = \beta_r D_r - \sum_i a_i m_i R + \sum_i d_i c_i + \sum_i \beta_i c_i + \gamma \sum_i c_i - \mu R \quad (14)$$

$$\dot{B} = \beta_b c_b - \mu B \quad (15)$$

$$\dot{L} = \beta_\ell c_\ell - \mu L \quad (16)$$

$$\dot{R}^{TOT} = \beta_r D_r - \mu R^{TOT} \quad (17)$$

$$\dot{m}_i^{TOT} = \omega_i D_i - \gamma m_i^{TOT} - \mu c_i \quad (18)$$

A further approximation can be performed. By considering the relation between γ and μ ($\gamma >> \mu$, from [7]) and knowing that $m_i^{TOT} \geq c_i$ (easily derived from Eq. 11), then Eq. 18 become:

$$\dot{m}_i^{TOT} \approx \omega_i D_i - \gamma m_i^{TOT} \quad (19)$$

In the following analysis, this approximated version will be considered. The set of Eqs. 12-17, 19 can be studied in steady state condition. In particular, while Eq. 19 have a closed form solution, namely:

$$m_i^{TOT} = \frac{\omega_i D_i}{\gamma} \quad (20)$$

the others must be solved numerically. However, by exploiting the speed of the reactions, it is possible to find an approximated solution also for the Eqs. 12-14 (and thus for Eq. 17).

Considering the set of differential equations: the fast dynamics are represented by Eqs. 12 and 13, while the slow dynamics is described by 18. Rewriting them by replacing a_i as $\frac{d_i}{K_i}$ (K_i is the dissociation constant) and d_i as $\frac{1}{\epsilon}$:

$$\dot{m}_i = \frac{1}{\epsilon}(-m_i \frac{R}{K_i} + c_i) + \omega_i D_i + \beta_b c_i - \gamma m_i \quad (21)$$

Due to the condition of fast dynamics, $\epsilon \longrightarrow 0$. Consequently, the obtained manifold is:

$$c_i = \frac{R}{K_i} m_i \quad (22)$$

Replacing c_i from Eq. 22 in Eq. 11, one obtains:

$$c_i = \frac{R}{R + K_i} m_i^{TOT} \quad (23)$$

$$m_i = \frac{K_i}{R + K_i} m_b^{TOT} \quad (24)$$

This shows how the evolution of c_i and m_i uniquely depends on the total amount of mRNA and the strength of the bound mRNA-ribosome. Since it is proved that m_i^{TOT} depends on the transcription rate ω_i (by Eq. 20), the only factor which does not influence the mRNA and complex concentration is the translation rate β_i. By replacing Eq. 23 in Eq. 10, one obtains:

$$R^{TOT} = R + \frac{R}{R + K_b} m_b^{TOT} + \frac{R}{R + K_\ell} m_\ell^{TOT} \quad (25)$$

It is worth to notice that this formulation is independent on the growth rate function. Eq. 25 must be solved numerically. However, it is possible to find a closed form solution if the manifolds of c_i (which are Hill functions, according to Eq. 23) are approximated by piece-wise linear functions. Without loss of generality, assuming that $K_b < K_\ell$, then the approximated functions are:

$$c_i \approx \begin{cases} \frac{m_i^{TOT}}{K_i} R & , R \leq K_i \\ m_i^{TOT} & , R > K_i \end{cases} \quad \text{where } i = b, \ell \tag{26}$$

Because of the mass conservation law Eq. 10 and by exploiting Eq. 26, the approximated function of R^{TOT} is:

$$R^{TOT} = \begin{cases} \left(1 + \frac{m_b^{TOT}}{K_b} + \frac{m_\ell^{TOT}}{K_\ell}\right) R & , 0 \leq R \leq K_b \\ \left(1 + \frac{m_\ell^{TOT}}{K_\ell}\right) R + m_b^{TOT} & , K_b < R \leq K_\ell \\ R + m_b^{TOT} + m_\ell^{TOT} & , R > K_\ell \end{cases} \tag{27}$$

Now it is possible to reverse the equations to obtain R as function of R^{TOT}:

$$R = \begin{cases} \frac{1}{\left(1 + \frac{m_b^{TOT}}{K_b} + \frac{m_\ell^{TOT}}{K_\ell}\right)} R^{TOT} & , 0 \leq R^{TOT} \leq \tilde{R}_1^{TOT} \\ \frac{R^{TOT} - m_b^{TOT}}{\left(1 + \frac{m_\ell^{TOT}}{K_\ell}\right)} & , \tilde{R}_1^{TOT} < R^{TOT} \leq \tilde{R}_2^{TOT} \\ R^{TOT} - m_b^{TOT} - m_\ell^{TOT} & , R^{TOT} > \tilde{R}_2^{TOT} \end{cases} \tag{28}$$

where accordingly to the conditions in Eq. 27:

$$\tilde{R}_1^{TOT} = \left(1 + \frac{m_b^{TOT}}{K_b} + \frac{m_\ell^{TOT}}{K_\ell}\right) K_b \tag{29}$$

$$\tilde{R}_2^{TOT} = \left(1 + \frac{m_\ell^{TOT}}{K_\ell}\right) K_\ell + m_b^{TOT} \tag{30}$$

C. Growth Law

Before performing any simulations with the designed ribosomes synthesis model, a growth rate function must be stated. As already explained in the introduction, none of the literature examples can be directly applied, since none of them accounts for the metabolic load. Consequently, one possible strategy is to exploit some of them and verify if they still produce coherent results even with the addition of a burden. The table below resumes all the performed tests.

TABLE I: TESTED GROWTH RATE FUNCTIONS

Growth function	*Variable*	*Data reference*
Linear	c_b	[3]
Linear	$R^{active} = c_b + c_\ell$	[3]
$Hill_{DV}$	c_b	[7]
Hill	c_b	[3]

Furthermore, it is necessary to estimate the initial configuration, which must be the same throughout the tests to perform valid analyses, in which the bacterial cell is before the metabolic burden is applied. We suppose that the cell is in the condition of maximal growth. However, the point of maximal growth varies based on the chosen growth rate function. By assumption, the growth rate formulation in [7] is pursued. As claimed in it, the partition of the ribosomes (in maximal growth) is the following:

$$c_b = \frac{2}{3} R_{max}^{TOT}, \quad R = \frac{1}{3} R_{max}^{TOT} \tag{31}$$

From Eq. 17 at the steady state, the value of $\beta_r D_r$ can be derived simply by substituting R_{max}^{TOT} and μ_{max}. To obtain $\omega_b D_b$, m_b^{TOT} in Eq. 18 at the steady state must be replaced with its value derived from Eq. 23:

$$0 = \omega_b D_b - \gamma \frac{R + K_b}{R} c_b - \mu c_b \tag{32}$$

By replacing c_b and R in Eq. 32 with their values in Eq. 31, the value of $\omega_b D_b$ in the maximal growth condition is obtained:

$$\omega_b D_b = \frac{2}{3} R_{max}^{TOT} (\gamma + \mu_{max}) + 2\gamma K_b \approx 2\gamma \left(\frac{R_{max}^{TOT}}{3} + K_b\right) \tag{33}$$

where the approximation is possible since $\gamma >> \mu_{max}$.

Assuming that the association rate between the ribosome and the mRNA is stronger than the dissociation due to the importance of basal proteins committed to the fundamental processes of the cell, a further approximation is possible, namely:

$$\omega_b D_b \approx 2\gamma \left(\frac{R_{max}^{TOT}}{3} + K_b\right) \approx \frac{2}{3} R_{max}^{TOT} \gamma \tag{34}$$

III. RESULTS

A. Analysis of Total Ribosomes variation

Before studying the load effect, a prior analysis on the distribution of the total amount of ribosomes R^{TOT} among the different ribosomal species (R, c_b and c_ℓ) is required.

The concentration of R^{TOT} is limited in the cell. Because of that, the species must compete for obtaining the needed ribosomes for their reactions. Thus, it is fundamental to understand which parameters regulate the competition for the ribosomes between different species. In Fig. 2, the evolution

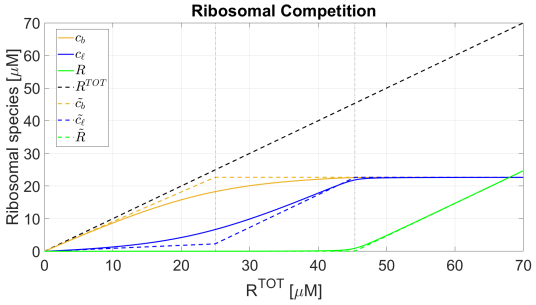

Fig. 2: Competition between species ($K_b < K_\ell$, $m_b^{TOT} = m_\ell^{TOT}$).

of different components is plotted as function of R^{TOT}. The approximate functions are used to predict the behavior of the ribosomal components. Indeed, the study of the breaking points gives information regarding the rise of the complexes. From Eq. 26, it is straightforward that the first complex to reach its maximum value has the smallest K. Thus the order of rising is just regulated by the dissociation constants.

This is consistent with biological knowledge. At the beginning, the amount of available ribosomes is limited; when the species start to compete, only the one with the strongest association rate (which implies the smallest K) can rise, while the others do not have enough strength to bind the needed ribosomes. Furthermore, they are not even able to steal the ribosomes from the already synthesized complex. Thus, when the first complex reaches its maximal value, which means that it does not need other ribosomes, the species with the second smallest dissociation constant can increase.

Moreover, Eqs. 29 and 30 show that the breaking points depend from both the dissociation constants and the total amount of *mRNA*. This is reasonable because, as already explained, the species j starts increasing when the previous one i (with $K_i < K_j$) reaches its maximal value m_i^{TOT}.

B. Analysis of Load effect

Afterwards, it is interesting to extend the analysis in order to better understand the load effects on the system, in particular on the cell growth, starting from the dynamics described by Eqs. 12-17, 19.

Equilibria are studied as function of the burden. This is characterized by three parameters: the dissociation constant K_ℓ, the transcription rate ω_ℓ and the translation rate β_ℓ. From a biochemical point of view, the easiest to adjust is ω_ℓ. Thus, the assumed choice is to vary the transcriptional rate, while the other parameters are kept constant. In particular, the evolution of c_b, c_ℓ, R and R^{TOT} is considered. Despite the concentrations of *mRNAs* and the proteins are changing as well, they do not directly affect the cell growth (indeed, all the growth rate functions in Tab. I depend uniquely on the ribosomal components). Therefore, the study of the evolution of these elements is not fundamental for the aim of the analysis. However, differently from the previous case, the degradation μ is now involved in the equations. In fact, even though the evolution of the complexes can be still derived from the manifolds equations, Eq. 17 at the steady state depends on the growth rate function λ. This means that the results are strongly influenced by the chosen type of growth rate function.

Following the order in Table I, all the growth rate functions were tested. Among all the formulations, the more consistent with the biological evidences is the linear growth rate function dependent on R^{active} (Fig. 3). All the other simulations showed the same critical aspect: the stronger the load, the higher the amount of total ribosomes in the cell. This evidence is used to rule out these growth rate functions, indeed, it is not reasonable to have a potentially infinite concentration of ribosomes in the cell. It is also possible to appreciate the competition between species, which is coherent with the results in Fig. 2. In fact, at first the load species takes the needed ribosomes from the free ribosomes compartment. Once this is empty, it starts stealing them from the basal complex.

IV. Conclusion

In this work, the cell growth was studied, testing different type of functions from literature and it was possible to state

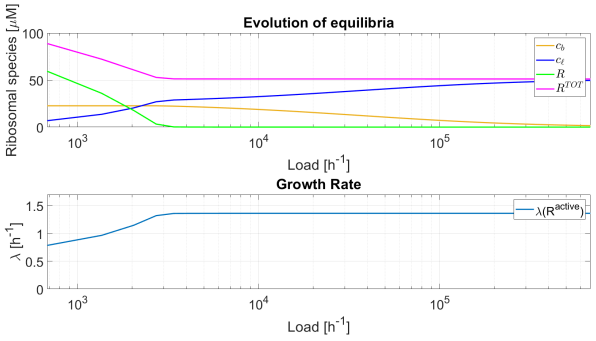

Fig. 3: Evolution of the equilibrium points and the growth rate varying the metabolic load.

that the best growth rate function is the *Linear* dependent on R^{active}. Possible improvements to this work can be performed, especially regarding the model. Its complexity can be increased, reaching a better level of description: in particular, it is possible to add a new species R-Protein, responsible for the synthesis of the ribosomes ([11],[13]), and some biological feedbacks, which are reported in literature ([9]-[12]).

Network-based integration of clinical, imaging and molecular biomarkers of dementia

C. Alfano[1], L. Farina[2], and M. Petti[2]

***Abstract*—Biomarkers are measurable characteristics used as indicators for diagnosis, prognosis and therapy-response: they can be of different nature (e.g., clinical, imaging and molecular) and each type captures and describes one or few specific aspects of disease development and progression. However, a single biomarker is rarely enough to operate the high-level characterization needed in a precision medicine scenario. Still, it is not a common practice to study different biomarkers of the same disease at the same time, focusing on their inter-relationships and role in the disease. The common practice is to evaluate pairwise relations. Thus, the definition of comprehensive and integrative biomarkers is an open challenge especially in complex diseases, such as in dementia. Dementia is in fact a multi-factorial condition, with factors related to different domains and whose interactions are not well known. In this study, we applied simple and partial correlation to data of patients and healthy subjects related to a set of relevant features of dementia. Network representation and analysis showed that both approaches provide a clear pattern of interactions among different heterogeneous biomarkers. We found that, even if the two tested methods agree on the strongest edges, partial correlation graphical LASSO can detect more connections and is more sensible to negative correlations providing a more complete description of biomarkers interactions. Comparing the biomarker networks of patients and control cases we also highlighted the changes that can be seen with the development of the disease.**

***Keywords*—Network medicine, biomarker network, partial correlation, dementia**

I. INTRODUCTION

A biomarker is defined as a measurable characteristic that serves as an indicator of normal biological processes, pathogenic processes or responses to an exposure or intervention; there can be many types of biomarkers, depending on what they are derived from (molecular, histological or physiological characteristics) [1]. Molecular biomarkers have recently received particular interest, due to their usefulness in patient stratification, understanding disease etiology, assessing risks, assisting with disease prevention and early detection, and in predicting therapy-response [2]. However, complex diseases are often caused by an intricate network of alterations involving different elements and the way they interact with one another [3], and a single biomarker is not able to capture this complexity. Medical practitioners are stressing the need for more precise and at the same time comprehensive biomarkers, but approaching a disease by considering a multitude of molecular interactions and comprehensively understanding complex biological systems and their link with clinical features is a hard task. However, by using network-based methods is now possible to provide a holistic view to the study of disease complexity, by focusing on more components of the disease at the same time; this is why network-based approaches are successfully used in precision medicine research, for example in disease gene prediction [5] and for the investigation of side effects [6], [7]. Still, common networks analysis approaches rarely include different types of data at the same time [8] and are mostly focused only on gene expression or protein-protein interactions. By creating a biomaker network we are able to integrate different omics and clinical data, and therefore consider the underlying relationships between biomarkers of different nature. In fact, elucidating the inter-dependency and inter-connectivity among different biomarkers and pathways may provide a more comprehensive view of and insight into the pathogenic process [2].

The importance of considering the relationships between different relevant features of a disease has even led to the idea of using a network as a biomarker [3], [4]: this means considering the whole set of disease features and their interaction as a comprehensive biomarker to characterize the patients. This is particularly useful in a dynamic network scenario, where the changes of the biomarkers' network through time can be measured and studied.

Given the fact that this approach is not yet commonly used, no go-to practice has yet been established in the literature. In this work we compare the use of Spearman correlation [9] and partial correlation Graphical Lasso (Glasso) [8], to build a network of different dementia-related biomarkers. Dementia is in fact a multi-factorial condition, that is a major cause of disability and dependency among older people. Nonetheless, risk factors have mainly been researched in isolation. Previous research has identified many factors potentially related to cognitive decline and dementia, some more studied than others. These factors include genetic preconditions, life-style related factors, medical conditions, environmental and social health factors [10].

In this study we will create network biomarkers for both dementia patients and control cases, to describe how the relationships between different dementia-related features changes with the disease development.

II. MATERIALS AND METHODS

A. Data

The data used in this project was taken from the Aging, Dementia and TBI Study, which is available on the Allen Brain

Map webiste [11][12]. This dataset contains neuropathologic and transcriptomic information as well as quantitative image metrics from both people affected by dementia and control cases. All the donors were over 78 years old, but not all of them had suffered traumatic brain injuries (TBIs) before. The available information is of various nature:

- Clinical data (e.g. age, past TBIs, sex, diagnosis etc.)
- RNA sequencing data for temporal cortex, parietal cortex, cortical white matter, and hippocampus isolated by macrodissection
- Protein quantification of neuropathological and immune system targets
- Gas chromatography mass spectrometry (GC/MS) quantitation of isoprostanes
- Histology and immunohistochemistry (IHC) quantitative image metrics

In this study, for each donor more samples were taken from different areas of the brain, depending on analyzed features; for example, quantification of isoprostanoids was only performed on parietal and temporal cortex. We decided to focus on the hippocampus. As for the donors, we only considered the ones that did not present the mutation of the APOE gene, to reduce the differences among the considered cohort.
Among the data available for the chosen region, we selected a group of biomarkers, making sure to avoid both linear dependence between them (tested with the "findLinearCombos" from the caret R package. [13]) and missing values, as well as maintaining a good ratio of cases and control cases. Our final dataset consisted of 50 donors (29 cases and 21 controls) and 20 biomarkers (reported in Table I).

B. Methods

We used and compared two different ways to infer biomarker networks: Spearman correlation and Graphical Lasso (Glasso). Spearman is a non-parametric measure of rank correlation that assesses how well the relationship between two variables can be described using a monotonic function. The Glasso algorithm uses instead partial correlations to infer the connection between each pair of variables, and it estimates sparse graphs through a lasso penalty applied to the inverse covariance matrix.
We created a total of 4 networks: healthy donors with Spearman, dementia patients with Spearman, healthy donors with Glasso and dementia patients with Glasso. For the first ones we used Spearman pairwise correlation and considered only results with an adjusted pvalue (FDR adjustment) lower than 0.05. For the other two we used the "estimateNetwork" function from the bootnet package [14], set on "EBICglasso" with the tuning equal to use regular BIC
Additionally, we performed a pairwise Wilcoxon test with fdr adjustment to check if and which of our variables was significantly different in the two categories of patients.

TABLE I: CONSIDERED BIOMARKERS

Name	*Description*
Age	Age of the donor. Linear for 72-89, binned at 90-94, 95-99, and 100+
Braak	Staging of neurofibrillary tangles (NFTs) from 0 to 6 based on Braak method of staging
ihc_tau2_ffpe	Phospho-tau (mature) immunohistochemistry (formalin fixed, paraffin embedded; labeled by Tau2): areal density
ihc_at8_ffpe	Phospho-tau (immature and mature) immunohistochemistry (formalin fixed, paraffin embedded; labeled by AT8): areal density
ihc_at8	Phospho-tau (immature and mature) immunohistochemistry (fresh frozen tissue; labeled by AT8): areal density
ihc_a_beta	Beta-amyloid immunohistochemistry (fresh frozen tissue): areal density
ihc_a_syn	Alpha-synuclein immunohistochemistry (fresh frozen tissue): areal density
il_10	IL-10 protein quant. by Luminex
ptau	pTau-181 protein quant. by Luminex
tau	Tau protein quant. by Luminex
ab40	Aβ40 protein quant. by Luminex
il_6	IL-6 protein quant. by Luminex
vegf	VEGF protein quant. by Luminex
rantes	RANTES protein quant. by Luminex
mip_1a	MIP-1α protein quant. by Luminex
SLC6A1	Gene expression
MOBP	Gene expression
GFAP	Gene expression
AQP4	Gene expression
SLC17A7	Gene expression

III. Results and Discussion

As a first result, we identified which biomarkers were significantly different among the two groups of donors. We found that braak, ihc_tau2_ffpe, ihc_at8, ptau and GFAP showed a significant increase in people affected by dementia. As far as the first four variables are concerned, this increase

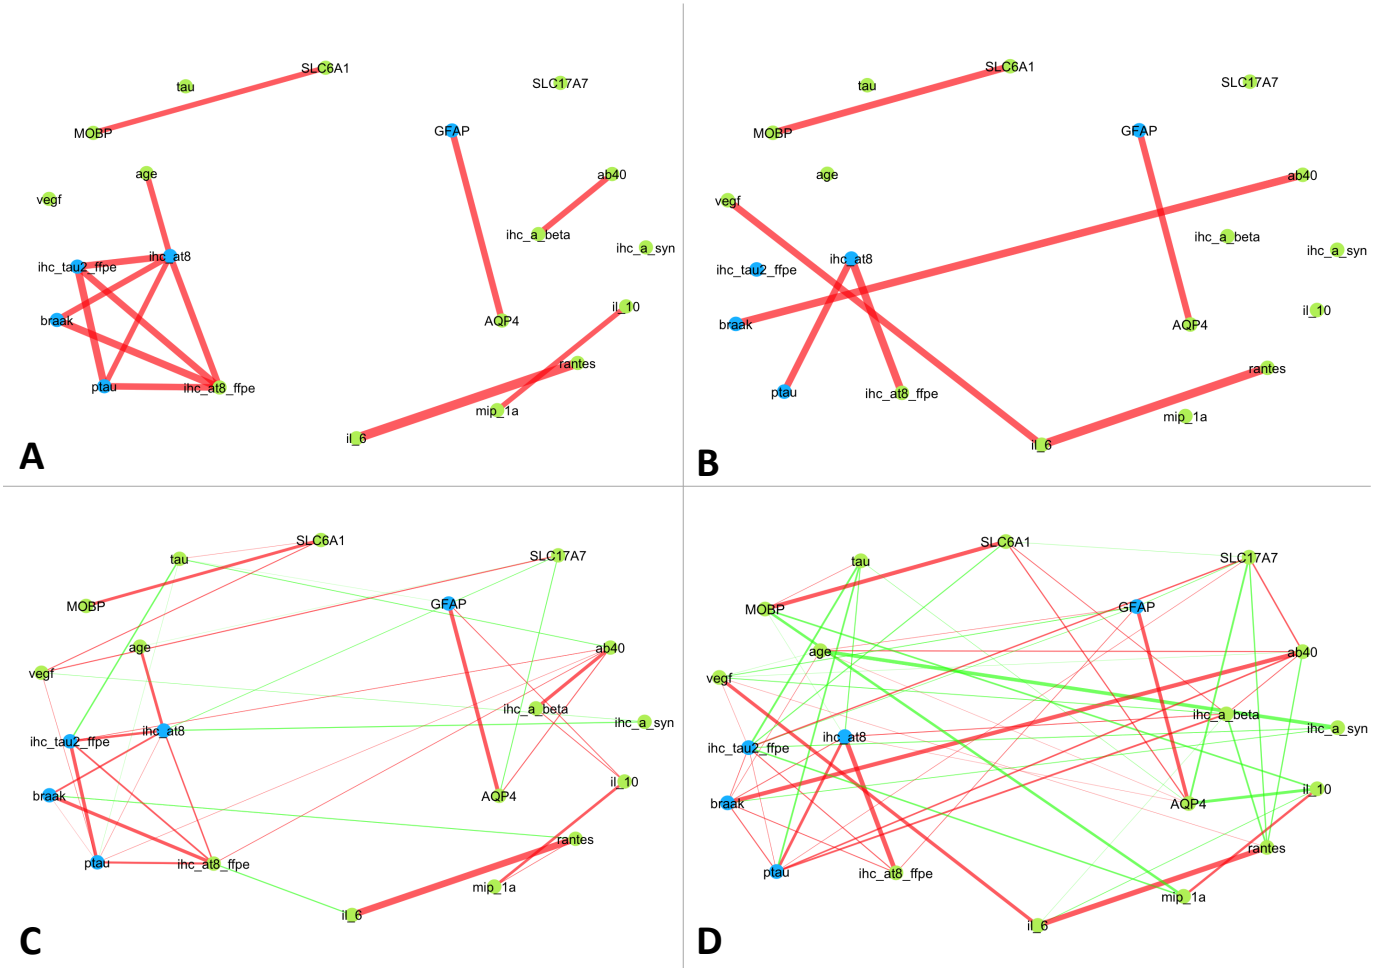

Fig. 1: The four biomarker networks obtained: A) control cases with Spearman correlation, B) dementia patients with Spearman correlations, C) control cases with Glasso, D) dementia patients with Glasso. The biomarkers significantly different in the two conditions (patients vs healthy donors) are displayed with blue nodes. Red edges represent positive correlations, while green ones represent negative correlations. Bigger edges code for bigger weights.

is consistent with the fact that they are all measures linked to brain tangles, which increase with dementia. This result is also consistent with what found by Miller et al. [12] in their first analysis of the dataset.

To carry out the rest of the analyses we used and compared the two methods more commonly used in similar studies: Spearman correlation and Graphical Lasso. Doing so, we obtained four weighted networks: two based on healthy donors and two based on dementia patients (Fig. 1). We found that overall there is a good degree of agreement on the strongest edges between the two methods. However, the Glasso method seems to be better at uncovering more complex underlying interconnections between the biomarkers. Moreover, only the networks created with the Glasso method contain negative correlations.
The general weights of the edges are also smaller in Glasso networks. However, we do find most of the edges detected by Spearman to be among the stronger edges in Glasso networks too (e.g. il-6 and rantes).
Looking at both networks of healthy donors we can find an expected correlation between $A\beta$ IHC density and $A\beta 40$ protein quantification, as well as a correlation between the gene expression of GFAP and AQP4 (both canonical marker genes for astrocytes), SLC6A1 and MOBP, MIP-1α and interleukin10, rantes and interleukin6. However, the Glasso network is also able to detect some interesting negative correlations, like the one between braak and rantes or ihc_tau2_ffpe and tau protein quantification.
Both networks of healthy donors also confirm, as found by Miller et al. [12], a relationship between age and ptau pathology, seen via the at8 immunoistochemistry. Moreover, in the Glasso network we found a negative correlation between age and SCL17A and a positive one between ab40 and APQ4. This caught our attention because Miller et al. [12] searched, without any luck, for module eigengenes (MEs) significantly associated with age, Aβ or α-synuclein pathology. Most of these relationships change when we look

at the network of dementia patients: in this case we found a positive correlation between SCL17A and ab40 as well as between ihc_a_beta and SCL6A1; we also found a positive correlation between GFAP and age.

Depending of the chosen method, we can notice other changes when comparing the relationships between biomarkers in healthy donors and dementia patients. Firstly, we saw a strong correlation between ab40 and braak score, as well as the one between vegf and il-6. Secondly, while the Spearman network mostly highlighted different relationships between metrics of tau pathology (tau, tau2, at8 etc.), Glasso was able to represent a more complex network of correlations, showcasing many interesting negative correlations, like the one between age and α_synuclein or APQ4 and il-10.

IV. Conclusion

We tested and compared two different methods to infer networks of disease biomarkers, and used the results to compare how these networks differ between healthy subjects and dementia patients. By doing so we saw that, in our application, the network obtained with Spearman and Glasso are similar as far as heavier weights are concerned, but that Glasso is better suited to detect negative edges. Through the networks inferred on the chosen dataset were able to confirm some of the findings of the dataset's authors and to extend those information by providing an holistic view of interrelationship between biomarkers of different nature (e.g., ihc_a_beta and rantes in Fig. 1 D) , and how these relationships change once a person has developed dementia. In particular, with Glasso we found correlations between genes of interest and both age and Aβ pathology. This had not been possible with the methodology proposed by Miller et al. [12] or by constructing networks based on Spearman correlations.
A more extensive analysis could reinforce the results illustrated here. Further improvements could include the selection of more biomakers, as well performing test on simulated data or on biomarkers of more varied nature.

***Abstract*— *In vitro* models lack quantitative criteria to determine their extent of physiological relevance. Such criteria could be defined through a bio-inspired methodology, based on the study of how closely *in vitro* models imitate the natural intelligence inherent in biological systems.**

In this work, Genetic Algorithms are used to identify the fittest and hence most physiologically relevant shape and size of 3D constructs, leveraging on fundamental biophysical laws. Preliminary results suggest the feasibility of this approach for providing a predictive tool for identifying robust design criteria for 3D cell aggregates.

***Keywords*—cell cultures, genetic algorithms, optimization, *in-silico* models.**

I. INTRODUCTION

Physiological relevance is defined as the resemblance of a model to its *in vivo* counterpart. Advanced *in vitro* models have been developed for mimicking the functionality, biomechanics and architecture of human tissues. Although they are widely considered a promising technology for different biomedical applications [1,2], quantitative design criteria for determining their physiological relevance and thus their translational potential as functional replicates of their *in vivo* counterpart are still lacking. In this sense, physiological relevance can be considered as the coherence of a construct with biological and biophysical rules. Specifically, it is important to ensure that all the cells within thick constructs have an adequate nutrient supply, due to the lack of vascularisation *in vitro* [14]. Moreover, thermodynamic laws governing energy and mass distribution must be also considered, since all living organisms reach an equilibrium configuration characterised by minimal surface energy [4].

In silico methods have been already exploited as cost-effective and fast tools for guiding the design of more predictive and physiologically relevant *in vitro* models, providing an effective alternative to animals in research [1,2,3,8]. In this scenario, to define biomimetic design criteria, one could rely on the rules governing 'natural selection', *i.e.*, the process through which living organisms adapt to external changes. Mathematically speaking, this process could be described as a global optimization. *Genetic Algorithms (GAs)* [7] have been successfully used in designing reconfigurable organisms with the goal of optimizing cellular characteristics under specific constraints, providing a powerful paradigm for connecting *in silico* and *in vitro* applications [8]. This approach furnishes a starting point to predict the optimal combination of cellular features enabling the emergence of experimentally observable biophysical behaviour.

In this work, we investigated the feasibility of using GAs as an optimization tool for designing physiologically relevant *in silico* cell-laden spheroids, *i.e.*, identifying the optimal biophysical parameters for generating 3D *in vitro* constructs with enhanced predictive and translational power.

II. EXPERIMENTAL PROTOCOL

A. Algorithm overview

The GA workflow (*Figure 1*) is implemented via the COMSOL LiveLink™ for Matlab, which extends the COMSOL modelling environment with an interface between the two platforms. Briefly, a population of individuals is generated. All the individuals are scored through the Fitness Function (FF). The FF allows the identification of the optimal individuals (*Section C*). From this point, all the next generations are obtained through gene recombination, using crossover and mutation operators (*Section D*). The loop of evolution ends once the maximum number of generations is reached, and thus the best score fitting construct is identified. The GA parameters are listed in Table I.

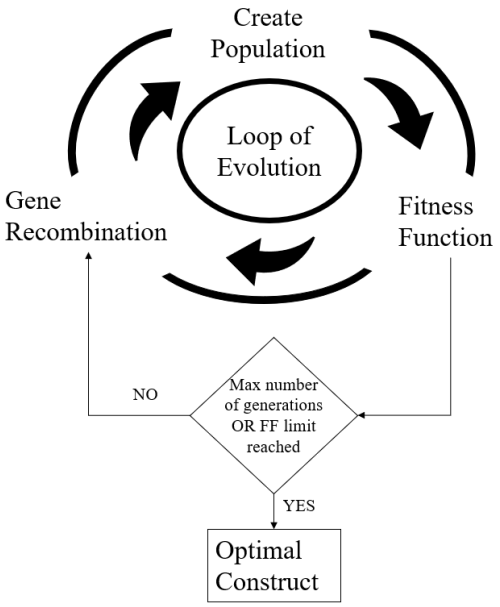

Figure 1 Loop of evolution of the Genetic Algorithm (GAs)

TABLE I: CUSTOMIZED PARAMETER OF THE GA FUNCTION

Parameter	*Description*	*Value*
Crossover fraction	The fraction of the population at the next generation, not including elite children	Γ(γ=4.94) [12]
Elite count	Number of individuals in the current generation	0.05*Population Size

	guaranteed to survive to the next generation.	
Population size	Number of individuals considered	10 – 100
Max Generations	Maximum number of iterations.	3 – 100

B. Generation of the population

A population is a group of individuals, all characterized by a genome, whose genes are described as an array of *morphological* and *biophysical* constraints. While *morphological genes* carry information on shape and dimension of the constructs, the *biophysical* ones deal with surface tension and volume of hypoxic core.

As regards the morphological genes, each individual is modelled as a spheroid with several identical hemispherical protrusions on its surface in order to increase the surface to volume ratio. The different masses so-obtained have an impact on both nutrient supply and surface energy.

Three input parameters are introduced:

i) the *number of protrusions n*, whose formulation is derived according to *Circle Packing Problem* [9] to obtain a maximum number of protrusions uniformly covering the spheroid surface;

ii) the *dimension of the protrusion f*, is defined as the ratio between the radius of the protrusion (r) and that of the central core (R) (*Figure 2*);

iii) the *volume of the whole construct* V_{constr}, a function of R, n and f (Eq. (1)).

$$V_{constr} = \frac{4}{3}\pi R^3 + \frac{n}{2}\frac{4}{3}\pi r^3 = \frac{4}{3}\pi R^3\left(1 + \frac{n}{2}f^3\right) \quad (1)$$

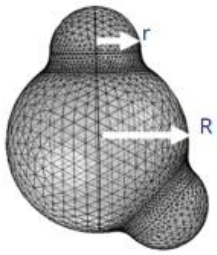

Figure 2 Protrusions' dimension f is the ratio between the protrusions' radius r and the central cores' radius R

The algorithm starts randomly defining the *morphological genes*: the value of *f* and consequently *n*. The first generation of individuals is created from volumes with a lognormal distribution, with means and variances as in [5]. *Morphological genes* are randomly assigned to each construct. and used as input parameters for drawing the computational model geometry.

To determine the oxygen concentration field at the steady state for all the geometries obtained, oxygen transport is modelled via the *Transport of Diluted Species* module in COMSOL Multiphysics (version 6.0, Stockholm, Sweden). The system can be described through the reaction-diffusion equation:

$$\frac{\partial C}{\partial t} = D\nabla^2 C + R \quad (2)$$

Where C $\left[\frac{mol}{m^3}\right]$ is the oxygen concentration field, D $[\frac{m^2}{s}]$ is the diffusion coefficient of oxygen in water and R $[\frac{mol}{m^3 s}]$ describes the cells' oxygen consumption modelled using the Michaelis-Menten (MM) kinetics:

$$R(x,y,z,t) = -\frac{OCR * \rho_{cell} * c(x,y,z,t)}{k_m + c(x,y,z,t)} \quad (3)$$

where ρ_{cell} $[\frac{cell}{m^3}]$ is the volumetric cell density, while OCR $[\frac{mol}{cell\ s}]$ and k_m $\left[\frac{mol}{m^3}\right]$ are the maximum oxygen consumption rate and the MM constant, respectively. All parameters and boundary conditions are listed in Table II.

The 3D models are implemented and solved numerically using the UMFPACK direct solver with a *finer* mesh size. A skewness scale between 0.5 and 0.8 is used to maintain the mesh as regular as possible.

At the end of each computation, the oxygen concentration field is obtained, together with the following derived values:

i) The *fraction of necrotic core NCF*: the percentage of the construct volume in which the oxygen concentration is below the critical threshold for cell viability ($c(x,y,z,t) \leq 0.04$ $[\frac{mol}{m^3}]$)[10];

ii) The *surface area of the construct* S_{constr}*;*

iii) The *sphericity* φ of the construct, defined as:

$$\varphi = \frac{S_{constr}}{S_{sph}} \quad (4)$$

where S_{sph} is the surface area of a sphere with the same volume as the construct considered.

At this point, the whole genome - comprising both *morphological* and *biophysical information* - is determined for each individual.

TABLE II: COMSOL SIMULATION PARAMETERS

Parameter	*Description*	*Value*
k_m	Michaelis-Menten constant	0.201 [mol/m^3] [3]
C_0	Boundary condition oxygen concentration	0.2 [mol/m^3] [10]
OCR	Oxygen Consumption Rate	2.73e^{-17} [mol/s][3]
T_{cell}	Temperature	310.15 [K]
ρ_{cell}	Physiological cell density	5.14e^{14} [1/m^3] [11]
R	Central core radius	R [m]
r	Protrusion radius	f*R [m]
f	Ratio of radii	r / R [∗]
n	Number of protrusions	(π / f) – 2 * π [∗]
D	Diffusion coefficient of oxygen in water	3e^{-9} [m^2/s] [3]

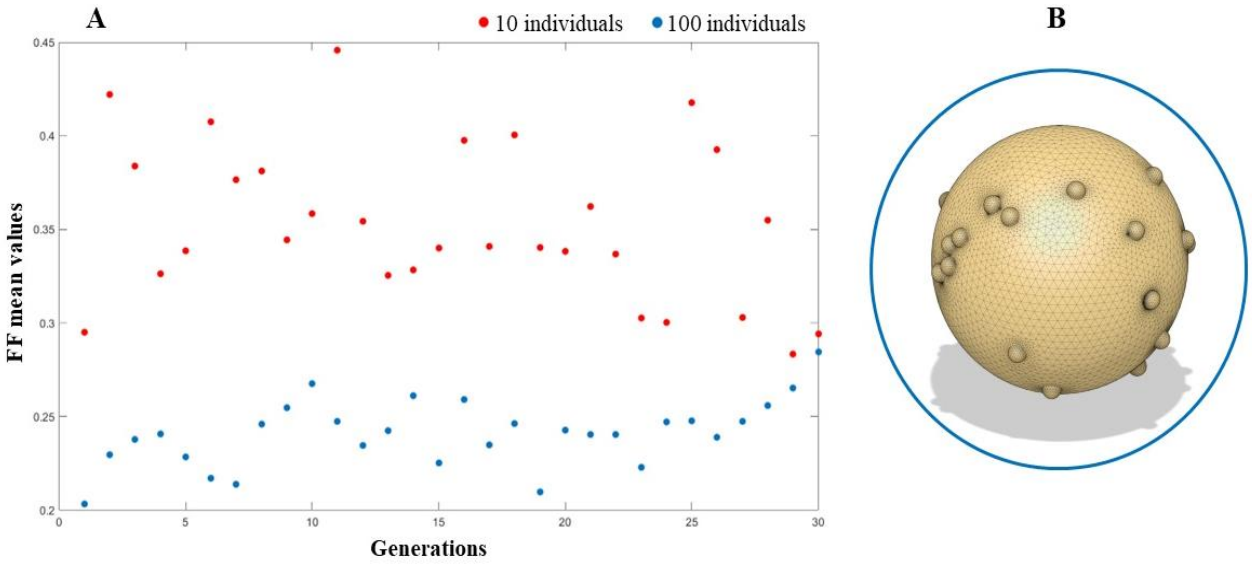

Figure 3 A) Points are the value of the mean fitness function at a given iteration of the algorithm. Blue points represent the GA with 100 individuals per iteration and the red points are that for the GA with 10 individual per iteration. B) The geometrical 3D model of the optimal construct obtained from the convergence of the GA with 100 individuals per iteration

D. *Fitness Function*

The FF scores individuals in every step of creation, crossover and/or mutation. In this work, the FF takes into account both the fraction of necrotic core and sphericity (φ), which are equally weighted ($w_{NCF} = w_{\varphi} = 0.5$) as expressed in Eq. (5):

$$FF = w_{NCF} * NCF + w_{\varphi} * \varphi (5)$$

In such formulation, the FF returns information about how a given morphological arrangement maximizes the cellular viability – a crucial problem in non-vascularized 3D cellular construct – also considering the thermodynamic constraints, i.e., the minimization of the surface tension, which is universally observed in physical systems. Indeed, the FF represents a balance between the number and dimension of the protrusions and the whole constructs' volume.

E. Gene Recombination: Crossover and Mutation Operator

From the second generation onwards, individuals are obtained using gene recombination, which involves only the morphological genes (n, f and V_{constr}). This process takes individuals of the previous generation, called parents, and randomly modifies their morphological genes, obtaining individuals called children.

Gene recombination consists of two operators, namely crossover and mutation. The crossover takes two parents, selects their morphological genes and combines them obtaining the crossover children (*crossover* in Eq. (6)). On the other hand, mutation takes only one parent, randomly selects genes to be changed and modifies their values, obtaining the mutation children (*mutation* in Eq. (6)).

The portion of individuals from the previous generation scored with the highest FF is considered as the elite (*elite* in Eq. (6)). They are not recombined but are directly promoted in the subsequent generation. Its fraction is defined using the *Elite Count* parameter (Table I).

Thus, the total number of children in the next generation is defined by Eq. (6):

$$children = elite + crossover + mutation (6)$$

For better mimicking the stochasticity of natural gene recombination [12], the *Crossover Fraction* of individuals is determined with a Gamma distribution (Table I). The Mutation fraction is automatically defined following the same Gamma distribution. Once these fractions are detected, the algorithm proceeds in varying the genes of individuals. A uniform distribution is used for determining the number of genes (*i.e.*, *n*, *f* and V_{constr}) and which of them are recombined. Once the genes (or the gene) to be recombined have (has) been chosen, their (its) values change according to the principles reported in *Section B*.

At the end, to complete the child's genetic information, the biophysical parameters pertaining to oxygen metabolism are computed. A new offspring population is created, and a new FF ranking is performed. The algorithm proceeds iteratively until the maximum number of generations is reached.

III. RESULTS

Running the GA with a different number of individuals, we noticed that the higher their number, the lower the dispersion of the mean FF against the number of generations (*Figure 3A*), obtained as in [13]. It is worth noting that the two curves appear to converge at the highest number of generations investigated. Thus, optimal biophysical features can hold for different combination of morphological genes.

In *Figure 3B*, the optimal construct geometry (n = 22, f = 0.07444, V_{constr} = 1.8e^{-12} [m^3]) from the GA run with 100 individuals is reported. These "genes" ensure the absence of necrotic core; moreover, since the protrusions are very small, the sphericity is anyway close to 1, so the minimization of surface tension is also respected.

IV. DISCUSSION AND CONCLUSIONS

In this work, GAs were used for identifying the optimal shape and size of cellular aggregates which respect thermodynamic and biophysical criteria for physiological relevance. Having an *in-silico* protocol that automatically predicts the optimal morphology of 3D constructs (based on the evaluation of biophysical parameters) could allow the improvement of experimental protocols for generating engineered tissues. It may also enable the development of high-fidelity computational models, which could, in the future, augment or even substitute costly in vitro models.

Our preliminary results suggest the feasibility of this approach. Further refinements of the algorithm are ongoing, in particular concerning the definition of the FF. Specifically, we are introducing different weighting factors for NCF and φ in Eq. (5) as well as asymmetry which is known to be important in morphogenesis. We will also introduce biological fluctuations as in our previous study [6] and external perturbations for evaluating how the shapes and sizes of optimal constructs adapt to their environment.

In addition, we are currently performing experimental studies to validate the *in-silico* outcomes. As far as we know, this is the first application of genetic algorithms to the study of 3D construct design.

***Abstract*—Pluripotent stem cells are undifferentiated cells with the extraordinary capability to differentiate into all cellular types. Based on these characteristics, human induced pluripotent cells (hiPSCs), produced in the laboratory, represent the new frontier of regenerative medicine as an innovative platform for partial or complete regeneration of injured tissues. The metabolic analysis of hiPSCs is fundamental in understanding the mechanisms underlying their functioning and ability to respond to particular environmental conditions, as well as how to develop better strategies for their production. In this context, genome-scale metabolic models (GEMs) offer a powerful tool to model and investigate the metabolism of hiPSCs. In this work, we present hiPSCGEM01, the first version of the context-specific genome-scale metabolic model (GEM) for the hiPSCs, extracted from RECON 3D, [1], as well as a first analysis of the pathways and essential genes reconstructed in the iPSCs specific model. Future developments will focus on the metabolic analysis of the phenotypes resulting from the knockout of the identified essential genes and on the possibility of exploiting the devised metabolic model to design new optimal culture media.**

***Keywords*—genome-scale metabolic model, flux-balance analysis, induced-pluripotent stem cells, reconstruction**

I. INTRODUCTION

Cellular therapies represent the new and promising frontiers for the treatment of several debilitating and degenerative disorders, which result in the gradual deterioration of the involved tissue. These advanced therapies consist of the implantation of selected and laboratory-treated cells into the patient to repair and restore the proper function of the injured organ or tissue. The ideal candidate cells involved in such therapies are pluripotent stem cells (PSCs) due to their proliferation and differentiation capabilities. Every tissue and organ in the human body contains stem cells. During cell division, stem cells originate two types of cells one of which retains the stemness feature while the other becomes committed to a specific cell lineage.

Among the several types of stem cells, the more fascinating ones from a therapeutic standpoint are pluripotent stem cells (PSCs). These cells derive from the early stages of an embryo (ESCs), and they can differentiate into all types of body cells. Ethical issues and the possible post-implantation rejection limit the isolation from embryos and the use of ESCs. To overcome these issues, several studies look for the generation of pluripotent stem cells from differentiated ones. These kinds of induced pluripotent stem cells (iPSCs) are artificially generated in the laboratory from the differentiated cells of the patients by forced expression of a specific set of genes such as Oct3/4, c-Myc, Klf4, and Sox2 (known as Yamanaka factors), [2]. In addition, since iPSCs derived from patient cells, they have the same genotype and hence do not cause rejection issues during cell therapy. For all these reasons, understanding the metabolism of the iPSCs is essential for optimizing their therapeutic efficacy. In this respect, it is critical to look into several issues, including the relevance of particular genes and their effects on metabolic pathways, as well as the potential to enhance the generation of iPSCs in the laboratory by, for example, developing new growth conditions. Despite of the classical mathematical approach to investigate and analyse the behavior of single metabolic pathways, [3], [4], Genome-scale metabolic models (GEMs) represent an easy and attractive systems biology framework able to capture the comprehensive metabolism of different types of cells under different experimental conditions. GEMs consist of a collection of reactions and active enzymes exclusive to a given cellular contest or cellular line. Several strategies have been developed to extract these GEMs from omics data, including transcriptome and proteome data, as well as from all of the literature's accessible knowledge.

In this work, we provide a first version of a dedicated genome-scale metabolic model for the iPSCs. In particular, we focus our attention on the reconstruction, the assessment, and the validation of the model, reported in Section II, as well as, on the analysis of the main reconstructed pathways, and the essential genes, presented in Section III.

II. Materials & Methods

A. Constraint-based model & Flux-Balance Analysis (FBA)

Ordinary differential equations (ODEs) are commonly employed to model the variation of concentration of each metabolite of the observed network, as reported below

$$\frac{dS}{dt} = N \times \nu \tag{1}$$

where $S = (S_1, S_2, ..., S_n)^T$ is the vector of the metabolites of the model, N is $n \times m$ the stoichiometric matrix, composed by n rows (metabolites), and m columns (reactions), and $\nu = (\nu_1, \nu_2, ..., \nu_m)^T$ represents the vector of the reactions rates. The components of a stoichiometric matrix are the stoichiometric coefficients, which represent the ratio of molecules, both substrate, and product, involved in a specific reaction. Stoichiometric coefficient signs assume positive or negative values based on whether a particular metabolite is produced or consumed by a specific reaction. Assuming that the cellular systems can reach their steady-state very quickly (i.e., the metabolic concentrations do not change but reach constant values), we can reduce the complexity of the model (2) by setting $N \times \nu = 0$. In this regard, constraint-based modeling represents the best mathematical framework to describe, in an easy way and with a low computational cost, complex metabolic networks. Since generally, we have more reactions than metabolites, [5], to obtain a unique solution from the devised system, it will be necessary to introduce all the known chemical-physical, spatial or topological constraints useful to determine the metabolic phenotype of the modeled network. These constraints are expressed through the definition of appropriate lower and upper bounds, which are set for each model reaction and allow for the construction of an acceptable range of solutions. Flux-Balance Analysis (FBA), [6], and its variants, are effective methods for determining the best point that maximizes an objective function within a confined space. However, to obtain reliable results, FBA requires the consistency of the model, which can be ensured through several techniques, [7].

B. Experimental Data

To derive the context-specific network for human induced pluripotent stem cells (hiPSCs), we have exploited genome expression data properly selected from Gene Expression Omnibus (GEO). The genome expression dataset used to create the model is shown in Table (I), and it consists of 10 samples acquired using the Affymetrix HG-U133 2 Plus platform. Then, we proceeded with the classification of the processed data by performing detection calls for gene expression: the hybridization of each spot is evaluated by assigning a label Present (P), Absent (A), or Marginal (M), based on the hybridization level, [8]. Before proceeding with the reconstruction of the model, the *ubiquity score*, [11], indicating the frequency with which a gene is expressed in a collection of relevant samples was calculated for each gene. This index was obtained by binarization of the different classes of gene expression levels (1 for the Present call, and 0 otherwise), and, then, by applying to binarized data the following function:

TABLE I: Genome-expression dataset selected from GEO data bank, and employed to reconstruct the iPSC model.

GEO ID	Authors	Description	Series

GSE9865	W. E. Lowry et al., 2008, [10]	Dermal fibroblasts are used to generate hiPSCs through different reprogramming and differentiation methods.	GSM249028 GSM249095 GSM249137

$$U_g = \frac{\sum_{n \in N} X_{g_n}}{N} \tag{2}$$

where X represents the binary value associated to the gene *g* in the experiment *n*, while N is the total number of samples. The pre-processing phase, including the labels evaluation, and the computation of the ubiquity score were performed in R by using the Bioconductor package, [12], and in Matlab environment.

C. Reconstruction of the hiPSCGEM01

We obtained the specific GEM for the iPSCs cells by exploiting both the mCADRE (metabolic Context-specificity Assessed by Deterministic Reaction Evaluation), [11], and the COBRA toolbox functions, [13]. Especially, mCADRE requires as input to reconstruct a specific metabolic model i) the gene expression data and ii) the entire metabolic model, RECON 3D, i.e. the most comprehensive and accessible model of the human metabolic network, [1]. The first possible metabolic network for the human iPSCs, hiPSCGEM01, contains 4038 metabolites, 6024 reactions, and 2773 genes. To make the devised hiPSCGEM01 suitable for the FBA, we proceeded to add the metabolites and all the exchange reactions and their constraints necessary to simulate the growth medium for the iPSCs: after this first phase of hiPSCGEM01 refinement, we added to the model 46 new reactions, and 5 new metabolites, for a total of 6070 reactions and 4313 metabolites. Then, we performed the assessment of the model following the protocol reported in [14]. In particular, we proceeded with:

i) the removal of all genes not involved in any reaction;
ii) the analysis of the consistency of the model, evaluated in terms of both flux and stoichiometric matrix, [15];
iii) the analysis of the mass and charge balance;
iv) the removal of all the duplicate reactions in the hiPSCGEM01, and the insertion of transport reactions needed to connect the added metabolites to the remaining model. In this regard, all the missing metabolites, reactions, and charge formulas were added by searching online databases, such as, e.g., Kegg, Reactome, and MetaCyc.

All the analyses performed and described by the protocol previously mentioned, allow us to ensure the consistency of

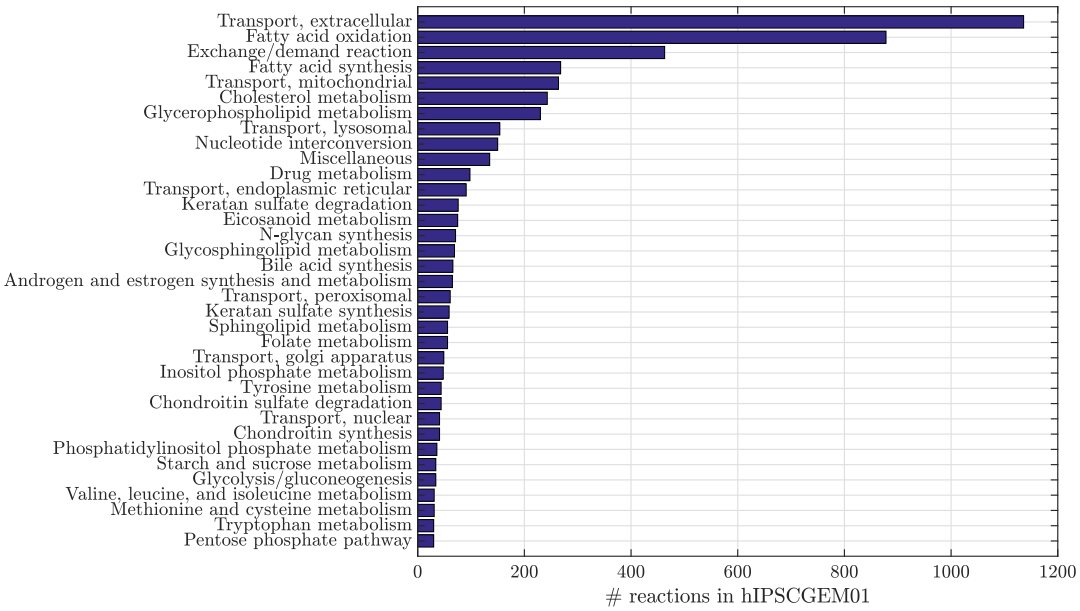

Fig. 1: Distribution of the main pathway reconstructed in hiPSCGEM01 ordered by the number of reactions.

our hiPSCGEM01, as well as make it ready for the FBA. The final hiPSCGEM01 model is composed of 5991 reactions, 4291 metabolites, and 2773 genes.

III. Results & Discussion

Before moving forward with future applications of the hiPSCGEM01 model, we investigated and validated the major pathways and genes involved in the reconstructed network using all the information available in the literature.

A. Analysis of the reconstructed pathways

The hiPSCGEM01 model consists of a total number of 101 pathways. In Figure 1 are reported the first 35 pathways ordered by the number of modeled reactions in hiPSCGEM01. Leaving aside the pathways involved in the transport of metabolites across the several cellular compartments, as well as all the exchange reactions, it is clear from Figure 1 how the most well-modeled seems to be the one related to the oxidation of the fatty acids. In this regard, Lin et al., [16], discovered carnitine palmitoyltransferase (CPT)1B as a regulator of reprogramming mediated by changes in fatty acid oxidation, and identified two of its products, palmitoylcarnitine (PC) and acetyl-CoA, as excellent reprogramming enhancers. Fatty acid synthesis is another fascinating metabolic pathway. A recent study, [17], conducted on the hiPSC-derived differentiated cardiomyocytes (hiPSC-CMs), shows as high levels of enzymes of fatty acid synthesis are expressed in the hiPSCs. In particular, Tanosaki et al. observed a correlation between the inhibition of the fatty acid synthesis pathway and the premature death of these cells following a significant reduction of the PC levels. As outlined in [18], all the pathways involved in energy metabolism are significant during the nuclear reprogramming of differentiated cells into iPSCs, and correctly modeled in hiPSCGEM01, as shown in Figure 1.

B. Analysis of the essential genes

Finally, we focused on the analysis of the essential genes involved in the hiPSCGEM01. Through FBA and knock-out of every single gene of the model, we found 592 different essential genes. Among these genes, we examined those whose removal affected the greatest number of reactions (> 35) in the hiPSCGEM01 model, resulting in a total of 14 selected essential genes. Figure 2 reports the results of the gene ontology enrichment analysis conducted on the set of 14 genes previously selected, for biological process (BP), cellular component (CC), and molecular function (MF). GO enrichment analysis allows screening among the genes identified as essential, those candidates for future in-depth studies. Furthermore, as seen in Figure 2, these genes are also those engaged in the fatty acids metabolic pathways, which, as previously mentioned, are essential to preserving the pluripotency of hiPSC.

IV. Conclusion

Genome-scale metabolic modeling is a powerful tool for studying the metabolism of human induced pluripotent stem cells (hiPSCs). Despite significant advancements in this field, as well as the discovery of the inevitable involvement of cellular metabolism in the expression and maintenance of the pluripotency characteristic, many aspects have not yet been investigated or remain incompletely understood. In this paper, we have presented the reconstruction and assessment phases of the first version of the genome-scale metabolic model specific to the hiPSCs (hiPSCGEM01). Preliminary analyses

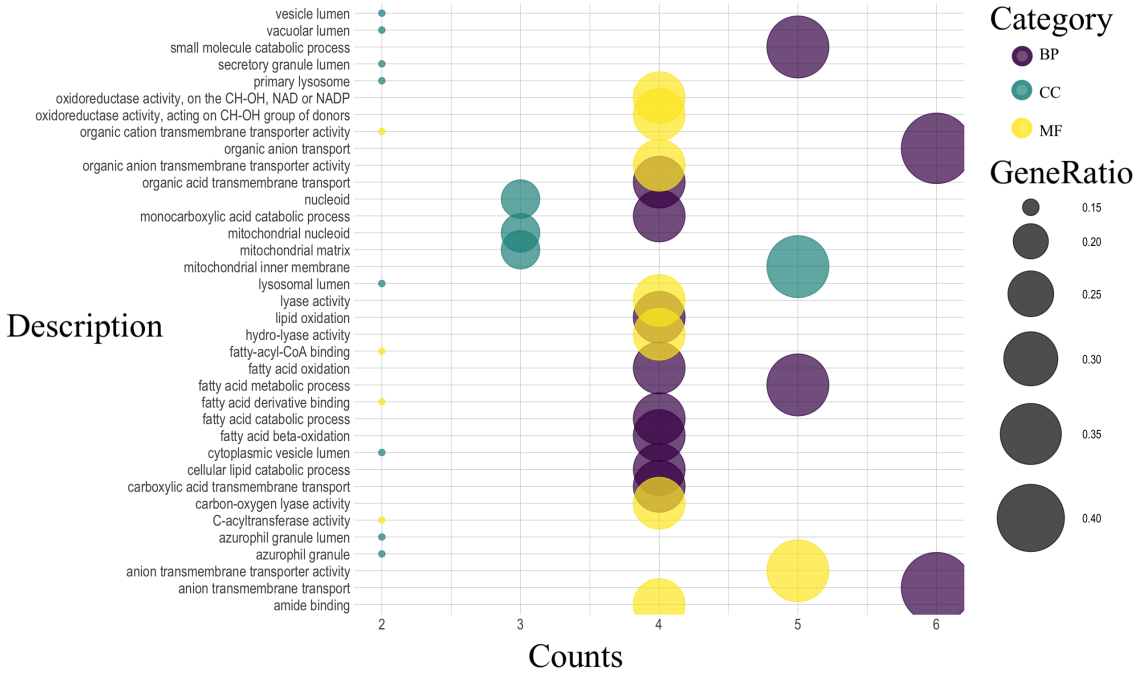

Fig. 2: Gene Ontology (GO) analysis conducted on the 14 most important essential genes, where *Gene Ratio* represents the percentage of total differentially expressed genes (DEGs) in the given GO term, and *Counts* is the number of the annotated genes in the subset of interest.

conducted on the hiPSCGEM0, especially on its pathways and essential genes, allow us to identify a set of genes interesting for future studies. Future studies are focused on investigating the metabolic phenotypes resulting from the knockout of the previously identified set of essential genes. Furthermore, we are interested in studying possible novel and optimal culture media by exploiting the devised model.

[1] *Biomolecular Engineering Lab, Dipartimento DEIB, Politecnico di Milano, Milan, Italy*
[2] *Università degli Studi di Modena e Reggio Emilia, Modena, Italy*

***Abstract*—Chitin is a recalcitrant, crystalline polysaccharide composed of chained sugar rings of N-acetyl-glucosamine (NAG). This polymer is an unexploited waste product in global seafood industry, a sugar-based waste that could be utilized as an energy resource for a plethora of destinations, from bioplastics to biofuels production. Lytic Polysaccharide Mono-Oxygenases (LPMOs) are newly discovered enzymes with the ability of efficiently degrading molecules like chitin or cellulose, thanks to a redox mechanism. In this study, we predicted and engineered the 3D structure of an LPMO, named PpAA10, acting on the protein sequence and enhancing its stability while preserving its catalytic activity. Studies were carried via molecular dynamics (MD) simulations, selecting the best outcomes for further *in vitro* production and assessment. The best mutants were produced on a lab scale, for *in* vitro testing. Obtaining an operative and stable mutant of PpAA10 could lead to the optimization of a green, sustainable, degradation process to obtain sugars from unutilized chitin waste.**

***Keywords*—LPMO, chitin, molecular dynamics, enzyme engineering.**

I. Introduction

CRUSTACEAN production, in the picture of global seafood economy, has registered up to a 2-3% annual growth rate, reaching 13.7 million metric tons (mmt) in 2015; this resulted in a total of 6 to 8 mmt of lobster, crab and shrimp shells waste [1]. In this framework, chitin represents a widely distributed structural polymer of technological interest, as it can be found unutilized and composing more than 40% in weight of seafood waste materials [2]; more generally, chitin is the most abundant aminopolysaccharide occurring in nature, also being the main structural element for insects (exoskeleton) and fungi (cell walls) [3]. However, its degradation is still a work in progress, as a green and effective process is yet to be found. Lytic Polysaccharide Mono-Oxygenases (LPMOs) are enzymes of recent discovery, now populated by several subfamilies isolated from bacteria, fungi, and insects [4]. The main target of LPMOs are recalcitrant polysaccharides, mostly cellulose or chitin, as the producing organism exploits the activity for nutritional or physiological purposes [5]. LPMOs degrade their target polymer with an oxidative mechanism, based on a copper ion in the active site; this makes them a promising substitute of classic enzymatic cocktails of hydrolytic nature (generally referred as chitinases) [6]. In this work we aim to engineer an LPMO to improve its yield, stability and activity and ultimately improve their usability in waste reconversion. The protein of interest, PpAA10 (UniProtKB – B1J2U9), was isolated from bacterium *Pseudomonas putida* W619, and belongs to the LPMO subfamily named AA10 (Auxiliary Activity 10) on CAZy database [4], [7]. The protein sequence was provided by prof. Giulia Di Rocco's lab (Università degli Studi di Modena e Reggio Emilia) [8].

II. Materials and Methods

A. PpAA10 structure prediction

For the protein of interest there are no experimental structures. Therefore, based on the aminoacidic sequence, structural studies were made via computational modelling. The first step included the prediction of the protein three-dimensional folding. SwissModel online tool was exploited to perform a sequence-based prediction [9]; being able to identify a PDB-deposited protein with a high sequence identity, a chitin-binding domain from *Burkholderia pseudomallei*, we adopted that as a template to perform a structure prediction of PpAA10's folding. RoseTTAFold was also exploited to predict *Pseudomonas putida* LPMO's 3D structure with a different approach, a deep learning-based method for *de novo* structure-from-sequence prediction [10]. Coordinates obtained by both methods (4 structures from SwissModel, 5 from RoseTTAFold) were structurally aligned via PyMOL software to highlight possible differences.

B. Copper ion introduction

Given that the structure prediction was based on the sequence alone, a copper ion had to be included in the PDB file generated. To create a reliable initial structure to use in molecular dynamics simulations, the model proposed by Liao et al. [11] was chosen. This model consisted in a central copper ion surrounded by six so-called "dummy atoms". These dummy atoms, partially charged (+) and covalently bonded to the ion itself, were placed to better simulate its interactions with surrounding atoms. To place the ion and relative dummy atoms in the right place, an alignment was performed between PpAA10 RoseTTAFold predicted structure and *Burkholderia pseudomallei* LPMO, which PDB deposited structure (PDB code: 3UAM) is complete of the copper ion. At this point, PpAA10 and copper coordinates were merged in a separate PDB, hence providing a complete coordinates file for the subject protein.

C. Structure preparation

The complete structure of PpAA10 underwent NAMD simulations to minimize the structure and assess the correct placement and behavior of the metallic ion. To generate the system topology, CHARMM force field was used. Water and counter-ions were added to neutralize the charge of the periodic box.

D. Enzyme equilibration

Starting from the ionized solvation box, three sets of equilibrations were performed. Before the equilibration, 2'000 minimization steps were performed to settle properly the structure. The first equilibration stage was performed at 310 K temperature. 25000 steps were run with a 1 fs timestep, producing a 25 ps simulation. Periodic Boundary Conditions (PBC) and Particle Mesh Ewald (PME) were applied, along with constant pressure (1 atm), applying NPT conditions. For the first equilibration, protein backbone and copper ion were fixed into their original position, with only the residues free to move. In the second equilibration stage, restrains with a 1.0 elastic constant were applied only to backbone and Cu (II) ion. The second equilibration lasted 25000 steps with a 2 fs timestep, producing a 50 ps simulation. In the third equilibration, all parameters were maintained as above, except that the NVT ensemble was used and no restrains were applied. The simulation was run for 1.5 ns. The main target was to produce a functioning model of a structurally unknown protein, to use in further simulations.

E. Chitin model

To replicate chitin fibrils' 3D structure, a VMD tool was exploited, named *Chitin Builder* [12]. The result was a fiber composed by 24 α-chitin chains, organized in 6 parallel columns of 4 layers (Fig. 1). The chains were 24 N-acetyl-glucosamine (NAG) rings each [13] [14] [15].

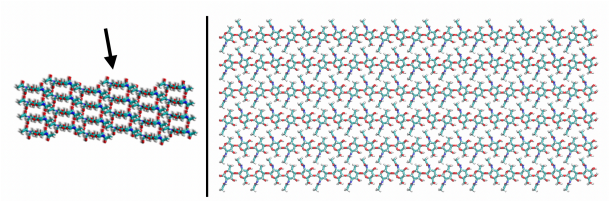

Fig. 1: Front-side and upper view of the small fibril reproduced with *Chitin Builder*. The 24 chains organized in 6 columns of 4 layers each can be seen on the left; the 24-ringed chains can be visualized on the right.

Black arrow represents the most suitable place for PpAA10's structure, in order to simulate the binding on an exposed chitin layer.

This chitin crystal was merged with the LPMO-copper complex previously created. Protein-chitin distance was set at 6 Å, to avoid bad contacts that would crash the simulation. To explore all possible binding geometries, the ion was placed right onto the glycosidic bond's oxygen, without choosing neither C1 nor C4 of the involved NAG rings. Two main systems were generated, distinguished by the 180° rotated orientation of the protein's active planar face. After preparing the crystal with the LPMO on top, the system was equilibrated following a protocol similar to the enzyme alone. Three equilibrations were performed for both orientations of the protein onto the crystal. Subsequently, 100 ns of MD simulation were performed in a water box with 150 mM NaCl. The bottom layer of chitin molecules was restrained (by fixing the positions of C1 atoms).

F. Production MD simulations

Production simulations of 100 ns were performed for the enzyme alone. In the production simulations, no restrains are applied except for three *extrabonds*. *Extrabonds* are additional chemical bonds that were used to prevent copper ion wandering by linking it to its coordination shell: the N terminal free amine (His1) and the two nitrogen atoms of His1 and His100 side chains. *Extrabonds* had distances and energies coherent to the values found in nature [16]. Production simulations were carried in triplicate at two different temperatures (310K and 350 K), to test the enzyme structure in term of stability.

G. PpAA10 mutants library generation

PpAA10 was submitted to two major online tools for designing coupled- or multiple-residue mutations to improve protein stability. PROSS (Protein Repair One-Stop Shop) [17] is an online tool that generates stable mutants based on multi-sequence alignment on known structures (to exclude well conserved regions), followed by filling hydrophobic pockets, pairing H-bonds donors and acceptors, and exposing polar or charged residues on the surface. DbD (Disulfide by Design) [18] is the second online tool that was used for producing the pool of stabilized mutants. DbD introduces coupled mutations, assessing the pairs in terms of distance and geometry coherent to the formation of a disulfide bond (assuming they were mutated into cysteines).

H. MD simulations of engineered enzymes

Molecular Dynamics simulations were performed following the same protocol used for the wild-type protein. Following the equilibrations, a 100 ns, protein-only simulation was performed for each mutant, either at 310 K or at 350 K temperatures. Results were analyzed in terms of Root Mean Square Deviation (RMSD) and Root Mean Square Fluctuation (RMSF).

I. In vitro *production of wild type and mutants*

E. coli BL21 (DE3) was used as a vessel for the lab expression of the studied mutants. Cells were transformed with plasmids containing one of the different variants, and cultures were scaled up to 4 L batches. Proteins were purified and prepared for activity and stability experiments, regarding attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) for activity (after incubation on crystalline chitin), and circular dichroism (CD) and differential scan calorimetry (DSC) for stability.

III. Results and Discussion

A. PpAA10 structure prediction

After the alignment performed in PyMOL, RMSD values (measuring spatial distance between the atoms, along the chain, belonging to different structures) showed that the prediction was reliable. The average value among all nine structures (4 by SwissModel, 5 by RoseTTAFold) was 0.8 Å, indicating a strong correspondence in the coordinates of the respective atoms in the molecule.

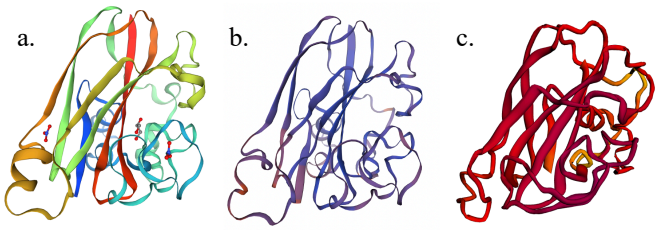

Fig. 2: a) SwissModel 3D representation of *Burkholderia pseudomallei*'s AA10 deposited structure. Color scheme by spectrum. b) SwissModel prediction of Pseudomonas putida AA10 via homology modelling. Colour scheme (purple to orange) based on confidence gradient (high to low). c) RoseTTAFold structure prediction based on a deep learning-based method, working on the sole aminoacidic sequence. Colour scheme (red to yellow) based on confidence gradient (high to low).

B. Chiti-binding residues

Thanks to the previous preparation of a 3D model for chitin layers, we performed production MD simulations of interaction between PpAA10 and chitin, placed in two different, 180°-twisted positions around the vertical axis. This was set to explore possible important residues' behavior, like Glu21, Tyr140 and Trp141 horizontal axis on the planar face (Fig. 2).

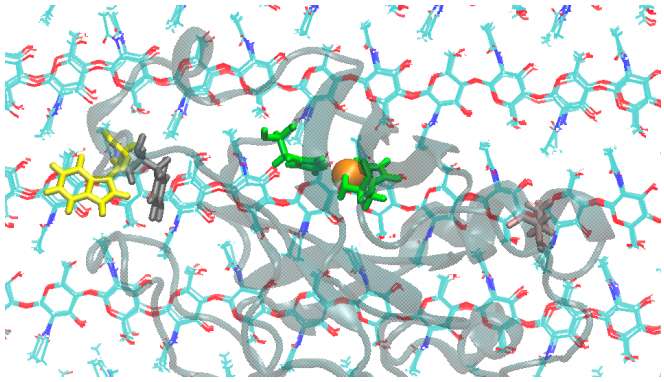

Fig. 3: Detail of the most interesting aminoacids regarding the active planar face of the enzyme: His1 and His100 (green, with copper in orange), Glu21 (pink, on the right), Tyr140 (grey, left) and Trp141 (yellow, left), all in *licorice* visualization. Protein backbone is represented in grey *glassy* cartoon, chitin crystal in *lines* (internally misaligned after equilibration).

From MD runs, aminoacid-chitin distances were calculated, identifying the close contacts as those which remained closer than 6 Å from chitin for at least 33% of the simulation time. Following this criterion, a list of putative positions more likely to be interacting with the substrate was drafted. The interacting aminoacids were excluded during the search of stabilizing mutations. The list of excluded aminoacids comprehended the following positions: 1 (active site), 21-24, 26, 40, 47, 53, 54, 66-68, 99, 100 (active site), 139-142, 143-145, 177-180.

C. *Enzyme mutants libraries*

PROSS and DbD were exploited to produce, via different approaches, stabilized mutants of the query 3D structure. PROSS generates a total of nine protein designs, with a process of cumulative stabilizing mutations (e.g., the second generated structure keeps all the mutations of the first, adding more, and so on). Interactive aminoacids were excluded as an input. From the outputs, six designs were extracted for further evaluation, as the stabilizing mutational process had produced redundant sequences. DbD has a simpler approach (mainly based on distances) and proposed 15 structures with compatible aminoacidic couples substituted into cysteines. Excluding the mutations involving interactive residues (see Section B.), 12 designs were extracted, each with a unique couple of mutated positions.

D. Mutants selection

With a total of 18 designs selected from mutation tools and simulated in the same conditions of the *wild type* protein, RMSD and RMSF data were evaluated. While RMSD certificated the overall stability of the structures, with no critical or terminal anomalies, RMSF was the main indicator for assessing stability along the chain. RMSF is graphed on the *y* axis, with aminoacidic positions on the *x* axis. Its value indicates the average deviation relative to the average position of amino acid during the time of the simulation: the higher the value, the more mobile atoms are, enhancing the probability of misfolding and undermining the overall stability. Three mutants showed significant results after the simulations, that highlighted an improved stability in 350 K high temperature

runs, probably due to the higher stress enhancing differences. Those mutants (1 from PROSS, 2 from DbD) were selected for further *in vitro* production and purification, and named "1", "2", and "3".

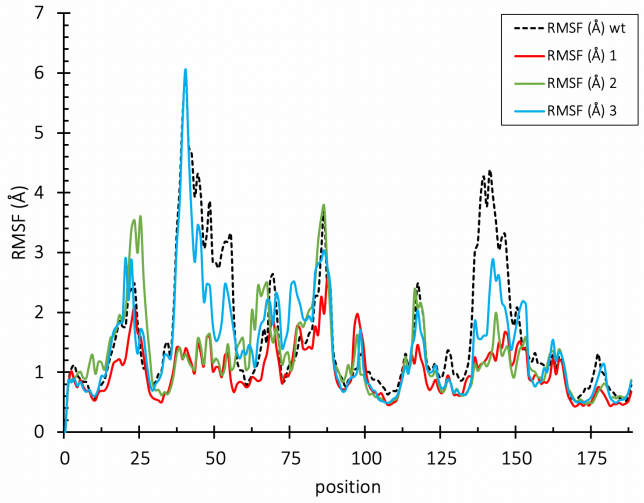

Fig. 4: RMSF (*y* axis) summary comparison between wild type (black, dotted), and mutants 1 (red), 2 (green) and 3 (blue). Aminoacidic positions along the chain are placed on *x* axis. It can be seen how values are mainly under or matching the black dotted line of the wt enzyme, indicating that the stability is always higher (or equal at least). Local matching peaks, in particular, indicate regions of the protein that aren't influenced by mutations.

IV. Conclusion

Starting from the aminoacidic sequence of the LPMO enzyme PpAA10, we predicted its folding with two different computational methods, which converged to a likely structure. Such model was the basis for the production and characterization of possible, more stable mutants, via computational engineering. After determining the best three candidate mutants, the next steps have already included the *in vitro* production and purification, to experimentally assess their effective improvement in stability. These experiments will help the design of an effective, industrial process involving LPMOs and living organisms to efficiently degrade chitin in an environmentally-friendly way. The success of this project could lead to a relevant valorisation of industrial waste-to-resource material, in a true circular economy perspective.

[2] *Department of Information Engineering, University of Pisa, Pisa, Italy*

***Abstract* — Modelling down-scaled replicates of biological communities using bioengineering approaches is of interest in life sciences, as it facilitates the investigation of metabolic patterns driven by inter-individual crosstalk across scales. To explore this concept, in this study computational models were used to probe whether multi-spheroid systems can constitute reliable models of coexistence *in vitro* (or *in vitro* ecosystems).**

The results in terms of oxygen metabolism and size-related scaling are consistent with initial predictions, indicating the feasibility of the approach. These models could be employed to better understand cell-cell or organoid-organoid crosstalk and even extended to ecological sciences to assess the impact of resource sharing in the presence of heterogeneities and environmental disturbances.

***Keywords* — coexistence, community dynamics, oxygen metabolism, cell-laden constructs, finite element modelling.**

I. Introduction

COEXISTENCE and resource sharing have been extensively documented to shape individual behaviours across scales, underpinning metabolic patterns which emerge throughout biological communities [1]–[6]. Properly rescaled, these concepts are also likely to hold in cellular systems - such as tissues and organs *in vivo* or corresponding replicates *in vitro* - and should be taken into consideration in the design of human-relevant models. In turn, creating a population of coexisting cell-based constructs might furnish insights into the metabolic behaviour of real communities in biology, providing tractable down-scaled models of ecosystems.

To date, no attempts in quantitatively investigating to what extent the degree of specific inter-individual interaction affects metabolic dynamics at the cellular level have been reported. Recent studies propose allometric scaling [7] as a criterion to assess the physiological relevance of cell-based models [8], [9]. The reasoning is that physiologically relevant *in vitro* systems should obey the Kleiber's law (KL) [10] - which states that the metabolic rate of an organism scales with mass as a power law and holds for over 20 orders of magnitude of size. However, they probe metabolic scaling in isolated cell aggregates but do not investigate whether the presence of multiple consuming individuals modulates cell metabolism. The ability to assess collective metabolic behaviours using *in silico* and *in vitro* models could open up new perspectives, paving the way towards applications to more biologically relevant scenarios. For instance, multi-construct systems containing randomly distributed cell aggregates characterized by variable size and metabolic features or exposed to fluctuating/perturbed environmental conditions could be used to establish a predictive and translational framework for the assessment of mechanisms of coexistence which drive resource management in living systems. Such mechanisms might also play a role in determining scaling coefficients and the size range of cellular models in which KL holds.

This work reports a study designed to evaluate whether and how the oxygen (O_2) metabolism of cell aggregates and the emergence of KL-like behaviours and associated scaling coefficients vary as a function of their coexistence with neighbouring constructs. More in detail, the feasibility of designing, modelling and realizing an *ecosystem* (*i.e.*, a multi-construct model where the crosstalk among cell aggregates coexisting in a shared environment drives metabolic dynamics according to their number and spatial arrangement) was investigated *in silico*. The potential of the approach as down-scaled modelling of community behaviours was tested in simple geometries and ideal conditions, to verify whether computational predictions match expected results. In practice, the influence of community abundance and spatial distribution of coexisting individuals (*i.e.*, cell-laden spheroids) on O_2 uptake and associated scaling characteristics was evaluated in multi-spheroid systems, combining finite element (FE) and statistical analysis.

Albeit preliminary and derived from a simplified model of non-competitive coexistence, the outcome of this work represents a first step towards understanding how multiple cell constructs can interact *in vitro* in terms of resource consumption, with potential applications in diverse fields, such as biomedical sciences and ecology.

II. Materials and Methods

The impact of coexistence on O_2 metabolism and mass-related scaling (*i.e.*, allometric as opposed to isometric mass dependency) was assessed using FE models implemented in Comsol Multiphysics (version 5.6, COMSOL AB, Stockholm, Sweden). O_2 transport and consumption of a population of *in silico* cell-laden spheroids sharing a common resource were simulated to evaluate how metabolic scaling is affected by varying size, abundance and spatial distribution of constructs.

A. Definition of the geometry

For determining how the O_2 metabolism of cellular constructs varies with their number and density, all of them have to be exposed to the same conditions of resource supply, irrespective of their size. To this end, the geometry shown in Fig. 1 was implemented, since it ensures that all spheroids are exposed to the same boundary condition. Spheroids are contained in a toroid, filled with aqueous medium and surrounded by an O_2-saturated environment. Constructs are placed such that their centres constitute the vertices of a regular polygon (Tab. 1) inscribed within a circumference concentric to the toroid (thus, symmetrically distributed with respect to its axis) and having radius $R_{av} = (R_{ext} + R_{int})/2$,

where R_{ext} and R_{int} are the external and internal radii of the toroid, respectively (Fig. 1A).

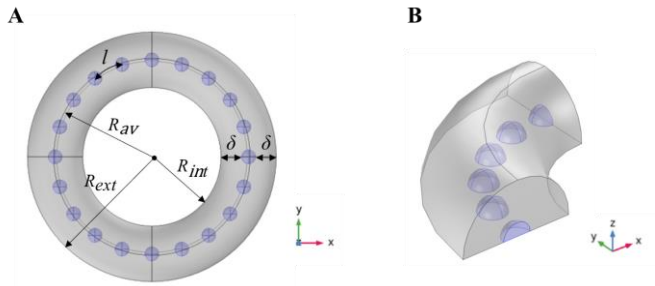

Fig. 1: The toroidal multi-spheroid system in the case of 20 coexisting spheroids. **A)** Top view of the whole designed geometry. **B)** Isometric view of the effectively simulated geometry, accounting for symmetries which hold for the system.

TAB. I: REGULAR POLYGONS USED AS REFERENCES FOR SYMMETRICALLY POSITIONING SPHEROIDS WITHIN THE TOROIDAL ENVIRONMENT ACCORDING TO THEIR ABUNDANCE.

Spheroid abundance (N)	*Regular polygon*
1	-
3	Equilateral triangle
4	Square
6	Hexagon
8	Octagon
12	Dodecagon
20	Icosagon

Hence, spheroid centres are coplanar, and l – intended as the length of the arch joining centres of two adjacent aggregates – is indirectly set through R_{av} depending on the number (or *abundance*, N) of coexisting spheroids. To avoid constructs getting closer to each other while increasing their radius (r_{sph}) and hence decouple coexistence from spheroid size, R_{av} is in turn parametrized as proportional to r_{sph} by means of a constant k, ultimately rendering the expression of l as below.

$$l = \frac{2\pi}{N}\left(k r_{sph} + 2\delta\right) \quad (1)$$

In Eq. (1), δ represents the difference between r_{sph} and the radius of the toroid cross-section (Fig. 1A). Together with the value of k, it determines the relationship between R_{ext} and R_{int}. δ is kept constant and equal to 3 mm, which is in the range of typical thicknesses of hydrogel shells used for organoid cultures [9], [11], [12], to match the requirement of a homogeneous diffusive O_2 supply at the aggregate boundary across sizes. As a result, spheroid cores are increasingly further from the source (and, thus, potentially depleted of O_2) as they increase in radius (r_{sph}), as for studies reported in [8], [9]. As a control, the case of a single construct was also implemented, in which the above-described constraints were maintained by placing the spheroid in the centre of a sphere with radius $R_{ext} = r_{sph} + \delta$.

Regardless of specific values of r_{sph}, N and k, the spatial distribution of constructs results in a geometry with three orthogonal symmetry planes, intersecting each other in the toroid centre. Thus, only the upper (or, equivalently, the lower) half of a toroidal sector corresponding to a 90° angle on the x-y plane (Fig. 1B) needed to be simulated. The parametric sweep on r_{sph}, N and k was performed according to ranges reported in Tab. 2.

B. Simulated biophysical processes and model implementation

The O_2 concentration field c (mol m^{-3}) in the generalized diffusion-reaction equation was solved at the steady state (Eq. (2)), assuming consumption according to the Michaelis-Menten's (MM) kinetics within spheroid domains [8], [9], [13] (then, $D\nabla^2 c = 0$ was the governing equation in the toroid domain).

$$D\nabla^2 c = \frac{\rho_{cell}\, sOCR\, c}{k_M + c} \quad (2)$$

In Eq. (2), D (m^2 s^{-1}) is the O_2 diffusion coefficient in water at 37 °C, ρ_{cell} (cells m^{-3}) the cell density in each construct, while $sOCR$ (mol cells^{-1} s^{-1}) and k_M (mol m^{-3}) denote the maximum rate of single-cell consumption and the MM constant, respectively.

A concentration equal to c_0 (Tab. 2) was set as both the initial and boundary condition on the outer surface of the toroid, while continuity of transport properties and O_2 flux field was assumed on spheroid surfaces. Symmetry held at all the other boundaries. Relevant parameters set for the FE models are listed in Tab. 2. As stem cells are the starting point for organoid generation [14], [15], the consumption parameters are those reported for human mesenchymal stem cells (MSCs) [9], [16]. Each geometry was discretized using a predefined *fine* mesh size.

TAB. II: PARAMETERS USED FOR SIMULATING O_2 DYNAMICS IN THE MULTI-SPHEROID SYSTEM.

Parameter	*Range/Value*	*Description/Reference(s)*
N	[1, 3, 4, 6, 8, 12, 20]	Parametric sweep range
r_{sph}	[31; 5000] µm	Parametric sweep range (log-spaced) [8], [9]
k	[1, 2, 4, 8, 16, 32]	Parametric sweep range
δ	3 mm	[9], [11], [12]
D	3×10^{-9} m^2 s^{-1}	In both culture medium and spheroids [11]
c_0	0.2 mol m^{-3}	O_2 saturation [13]
ρ_{cell}	5×10^{14} cell m^{-3}	*In vivo*-like [9], [19]
$sOCR$	2.75×10^{-17} mol cell^{-1} s^{-1}	Value for human MSCs [9], [16]
k_M	0.201 mol m^{-3}	Value for human MSCs [9], [16]

C. *Post-processing and statistical analysis*

Once convergence was reached, the parametric solution obtained for each possible combination of r_{sph}, N and k was post-processed to estimate the metabolic rate B (mol s^{-1}) of single constructs according to Eq. (3):

$$B = -\oiint \boldsymbol{J}(r_{sph}, t \to \infty) \cdot d\boldsymbol{S} \qquad (3)$$

where $\boldsymbol{J}(r_{sph}, t \to \infty)$ (mol m^{-2} s^{-1}) is the stationary flux field of O_2 through the spheroid surface. Since spheroids are symmetrically distributed in the environment, they all have the same B.

Then, size-related scaling exponents of single-spheroid B were identified as a function of N and k to assess whether these parameters affect metabolic scaling of cell aggregates. Linear fittings were performed in Matlab (The Mathworks Inc., Boston, Massachusetts, USA) on log-log data of construct size (*i.e.*, r_{sph}^3 or, equivalently, mass) and B, applying an approach similar to that proposed by Magliaro *et al.* [9] across the size range studied. However, in this work, the fitting algorithm did not look for a predefined slope (*i.e.*, 3/4 in [9], according to the classical formulation of KL) but determined the optimal stepwise regression of each log-log curve. The best fit was then identified as that in which each size sub-range of the obtained partition covers the most datapoints and displays the highest R^2. Corresponding slopes of regression lines were then extracted, representing the size-related scaling coefficient. Finally, correlation analyses were carried out in GraphPad Prism (version 7, GraphPad Prism Software, California, USA).

III. Results

The results are summarized as interpolated surface plots, to visualize the metabolic rate of single constructs and associated scaling exponents as multivariate functions of r_{sph}, N and k.

Fig. 2A shows values of individual B computed for a single spheroid with respect to r_{sph} and k for the minimum abundance (N = 3). B remains constant with r_{sph} independent of the inter-spheroid distance (*i.e.*, the value of k). Increasing the abundance of the community up to N = 20, B starts depending on k if the construct size increases; a positive correlation is indeed observed for $r_{sph} \geq 466.12$ µm (Spearman coefficient r = 1, significantly different from 0 with p = 0.0028), as evidently shown in the upper-left corner of Fig. 2B. In this region, the spheroids are large (high r_{sph}) and closely packed (since k is small and N equals its maximum). Hence, they are forced to share resources, and the individual B substantially decreases. Overall, this is an expected behaviour. In fact, given that the toroidal configuration avoids the formation of diffusion-limited regions with low O_2 concentration, each spheroid in the system is exposed to near-saturation conditions for high values of k. Then, as k decreases, the constructs are forced to cooperate for resource uptake.

These results suggest that the cooperative coexistence of cell aggregates may also have implications on their size-related scaling. Therefore, for each combination of values of N and k, the power-law behaviour of B versus r_{sph}^3 was analyzed through the stepwise regression procedure described in the previous section. In all cases, three size sub-ranges were identified: *i*) small radii, characterized by isometric scaling behaviour; *ii*) intermediate sizes, where the scaling exponent starts being significantly different from 1 (*i.e.*, *non-isometric* or *allometric* scaling); *iii*) large radii, with a geometry-driven metabolic scaling set by diffusion limitations depending on the system design (*i.e.*, geometric scaling). Construct radii corresponding to the isometric to non-isometric transition as a function of N and k are plotted in Fig. 2C. Irrespective of N, the positive correlation between the transition size and k (Spearman coefficient r = 0.8452, significantly different from 0 with p = 0.0467) indicates that the closer the spheroids are, the smaller their radius triggering non-isometric scaling (Fig. 2C). This result is reasonable for the chosen configuration, since O_2 concentration gradients leading to adaptive and cooperative metabolic behaviour emerge for smaller radii in densely packed constructs, because of limited O_2 availability due to resource sharing. Although the regression coefficients were not constrained, scaling exponents of spheroids in the non-isometric size sub-range were shown to be gathered around the typical value of 3/4 (Fig. 2D), with a coherent decrease when a high number of constructs coexist at low distances. In fact, for $k \leq 8$, correlation analysis between the exponent value and N results in a Spearman coefficient $r \leq$ -0.9429, significantly different from 0 with $p \leq 0.0167$.

IV. Discussion

In this work, a preliminary investigation on the impact of coexistence on O_2 metabolism and the associated size-related scaling of cell aggregates is presented. The aim was to probe the potential of cellular models as down-scaled replicates of ecosystems, to be used for predicting population behaviours in cooperating biological communities.

Metabolic rates (B) of single constructs were computed for MSC-laden spheroids in different configurations, maintaining the same boundary levels of energetic resource for each

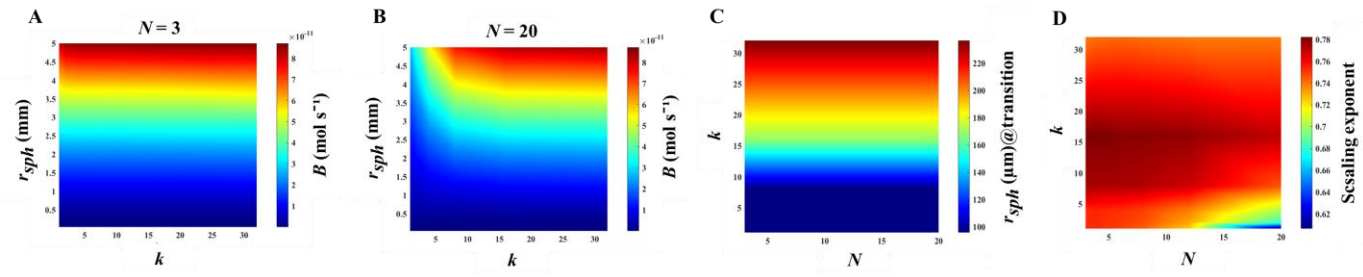

Fig. 2: Impact of coexistence on O_2 metabolism and its size-related scaling in *in silico* cell-laden spheroids. Single-spheroid B estimated as a multivariate function of k and r_{sph} for a toroidal environment hosting **A)** 3 or **B)** 20 constructs. **C)** The spheroid radius corresponding to the isometric to non-isometric transition and **D)** the scaling exponent in the non-isometric size sub-range as multivariate functions of N and k.

population. The *in silico* models show that, for large constructs ($r_{sph} \geq 466.12$ μm), individual *B* decreases when community abundance is high and the inter-spheroid distance small (Fig. 2B). This is in line with the expected behaviour: when coexisting and induced to share resources, cell aggregates tend to adapt their O_2 utilization, giving rise to a metabolic cooperation. Additionally, for widely spaced spheroids (*i.e.*, *k* = 32), the non-isometric size range (Fig. 2C) and associated scaling exponents (Fig. 2D) are similar to those reported in Magliaro *et al*. for single spheroids embedded within a hydrogel shell of thickness comparable to δ [9], even though values for the exponents were not assumed *a priori* in this work. However, when *k* decreases, the isometric to non-isometric transition occurs at smaller size ranges (Fig. 2C). This is because the spheroids approach each other and need to cooperate to share energetic resources. Sharing the same environment also leads – not surprisingly - to the reduction of scaling exponent values in the non-isometric size range when a high number of constructs are densely packed (Fig. 2D).

Even though most of the results reported here are expected, they serve to highlight that computer-based models have the potential for studying cooperative coexistence *in vitro*. In fact, the observed dynamics are analogous to those emerging in cells in both monolayer cultures and 3D spheroids, which have been reported to modulate their individual metabolism as a function of cell density [17]. Although based on specific and simple configurations, these results suggest metabolic adaptation as an inherent feature of any biological system, occurring across scales when multiple biological "units" – be they cells, simple cell aggregates or interconnected organ models – share a finite amount of a fundamental resource (*e.g.*, O_2) within the same environment.

Currently, further analyses on more sophisticated and biologically relevant multi-spheroid systems are being performed. Specifically, we are introducing stochasticity in terms of both construct size - as discussed by our group in [18] - and spatial distribution, accounting for coexisting aggregates laden with different cell phenotypes (*e.g.*, relevant to the composition of a biological tissue or organ). The aim is to identify configurations able to replicate key ensemble behaviours observable among individuals of real non-competitive biological communities. Moreover, experimental tests are ongoing to reproduce and validate the computational models.

To conclude, the outcome of this work is novel, since it represents the first attempt of exploiting coexisting cell aggregates as a down-scaled predictive model of natural cooperative ecosystems. The impacts span from multi-tissue or multi-organ systems in the biomedical field up to heterogeneous communities at the macroscale, which may be of ecological relevance. Taken together with properly designed experimental cell models, the *in silico* tools discussed here could constitute a cost-effective, easy-to-use and sustainable platform to investigate a broad spectrum of coexistence configurations, with a specific focus on how populations adapt to environmental changes.

***Abstract*—Promoters are short regions of DNA where RNA polymerase and transcription factor bind to initiate the transcription of target gene sequences. Currently, there is no validated scientific method to predict the total set of promoters within a bacterial genome, especially for non-model chassis. The purpose of this work is the development of an algorithm to support the prediction of bacterial promoters with the desired characteristics, based on genomic and transcriptomic data. The pipeline can allow to expand the toolkit of biological parts implemented in synthetic genetic circuits to enable reliable engineering and gene expression control in model and non-model bacteria. Genome-scale identification of promoters with stable activity in *Escherichia coli* is herein provided as pipeline application.**

***Keywords*—Bioinformatic pipeline, synthetic biology, bacterial promoter, gene expression.**

I. INTRODUCTION

IN bacteria, expression levels are extremely variable between genes. The expression of many genes is subject to variation in response to environmental changes. This regulation is essential for the overall fitness of the bacterial cell. The key regulatory step that modulates gene expression is promoter recognition and transcription initiation which takes place via the enzymatic complex formed by RNA polymerase- *σ-factor* [1]. Different families of *σ-factors* exist. Generally, only one of them (e.g., σ^{70} in *Escherichia coli*) promotes constant transcription of genes in any condition, possibly in combination with specific transcriptional regulators. In contrast, promoters regulated by others are generally modulated by stress and other environmental stimuli [2].

Bacterial promoters are characterized of three elements: Transcription Start Site (TSS), i.e., the position where transcription begins, and two short DNA sequences called "-10" and "-35" because they are located at about 10 and 35 bases upstream TSS, respectively. The nucleotide composition of these two regions mainly determines the strength of the binding between RNA polymerase and DNA [3]. Each sigma factor recognises a specific consensus sequence on the promoter to be regulated. The consensus sequence can be different as a function of the bacterial species.

Inducible promoters alter their transcriptional rate because of external stimuli represented by a physical agent, such as temperature, or a chemical agent, such as a molecule [4]. The quantitative characterization of inducible promoters is a key task in synthetic biology. They are adopted in synthetic circuits as user-controlled transcription initiators. However, some problems can arise using inducible promoters such as hypersensitivity to inducer, the range of activity may be unsuitable to ensure efficient activation or repression of downstream gene expression, the high cost of the inducer may also make the system unusable, and, finally, the levels of expression achieved fluctuate significantly within the population, leading to a large heterogeneity of the transcript. Therefore, in different applications it is preferred to use constitutive promoters with known strength in the construction of synthetic circuits to be inserted inside the host microorganism [5]. Different environments could affect promoter activity unpredictably, due to regulations that are not previously characterized. This motivates further efforts in identifying promoters with robust activity across genomes.

One method that can be used to discriminate between constitutive and regulated promoters is to analyse transcriptomic data. Genes whose transcription is regulated by constitutive promoters have stable level of expression in different experimental conditions. Blount et al. conducted a study to identify a constitutive promoter *in Saccharomyces cerevisiae* and re-engineer it to create a library of promoters by changing the basis of the found promoter sequence [6]. A large data set of microarray experiments in yeast databases was used to identify the promoter whose downstream gene has the least variability under different test conditions.

The identification of the location and function of the promoter regions is challenging as they very often do not reflect certain patterns of sequences and are therefore difficult to determine by analysing the genome with traditional methods of exact research. This becomes an even more difficult test if the objective is to identify promoters in poorly studied species. Most bioinformatic algorithms for promoter identification use research of conserved motives in the regions upstream of genes [7]-[10]. Recently, two bioinformatic tools have been developed using differential RNA sequencing (dRNA-seq) data for the high-throughput screening to examine the precise position of TSS [11],[12].

Here, we present a bioinformatic pipeline, developed in R, to support the prediction of bacterial promoters with desired characteristics, based on genomic and transcriptomic public data. The pipeline is divided into two procedures: the first one analyses transcriptomic data (microarray and RNA-sequencing experiments) to obtain a list of genes with stable transcription level (non-differentially expressed - NDE); the second one predicts TSS upstream of NDE genes from RNA-sequencing (RNA-seq) data. Using expression values from both technologies increases the reliability of the result about NDE genes as many more experimental conditions are considered. The algorithm can be used for any bacteria with

annotated genome and available data from microarray and RNA-seq experiments.

II. METHODS

A. *Identification of NDE genes*

The analysis of transcriptomic data is split up according to the chip technology, RNA-seq vs microarray, and the latter is divided in turn based on the construction of the chip (Affymetrix – one or two channel by other manufacturers). In Fig.1, the overall schema of the procedure is reported.

The experiments, identified by a GSE code, are analysed separately: data are downloaded from the NCBI Gene Expression Omnibus (GEO) database [13]. While for microarray experiments raw expression data are available, for RNA-seq they must be reconstructed through the alignment of the reads along the reference genome and counting how many reads have mapped to each gene. We align along the reference genome because not all the species under study have a well annotated genome.

Then, expression data are processed also making an evaluation of data quality, through standard indices (for microarray Affymetrix data), or evaluating the correlation of expression values among pairs of experiments and removing background noise. If experiments, or some samples, do not pass quality tests, they are discarded from the analysis.

In RNA-seq analysis, *Rockhopper*, i.e., a tool for the identification of operons, is integrated [14]. The information derived from the prediction of operon architecture is stored to eventually eliminate the genes that are not first gene in operon because they are not expected to have specific promoters immediately upstream.

Then, an appropriate *intra-experiment* normalization is applied to remove bias among samples in the same batch (e.g., Robust Multiarray Averaging (RMA) for Affymetrix data, quantile normalization for other microarray data and normalization with DESeq2 for RNA-seq data).

NDE genes are identified using a statistical test with a Bonferroni correction to filter out the genes showing significant differences among the experimental conditions.

For microarray data, the information about the genome of the strain on which the experiment has been performed is not always available. Often therefore the notations, i.e., the locus tag, with which the genes are uniquely identified are not consistent or easily traceable among experiments. As a result, the mapping of all annotated genomes of the species concerned to the reference genome is necessary. A tool implemented in python, *OrthoFinder* [15], is integrated in the procedure: it deals with identifying orthogroups, i.e., groups of orthologous genes, between pairs of genomes, based on the comparison between proteins. A post processing of the *OrthoFinder* output must be done to obtain unique correspondences between pairs of genes of the two compared strains. At the end of the process, all the names by which a gene is annotated in all the strains of the considered species are known.

After the identification of NDE genes commons to all the considered experiments, we proceed with an *inter-experiment* normalization of the expression values using *ComBat* [16], an R function which corrects data to remove *batch-effect*, specifying how many and which batch are present. We considered each experiment as a batch. A sub list of NDE genes of interest can be selected using a threshold on Standard Deviation (SD) or coefficient of variation (CV) of expression. CV is considered equal to SD on the used data because expression values are assumed log-normally distributed, and the data are log-transformed to carry out the analysis.

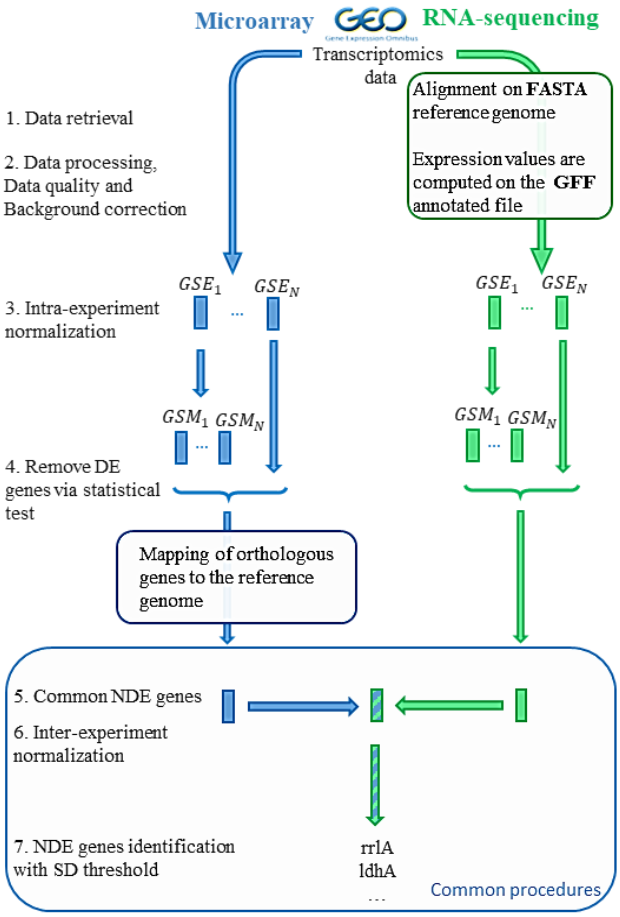

Fig.1: Overall representation of the procedure for NDE genes identification. It has been adapted to handle microarray (blue) and RNA-seq (green) data with different procedures due to the different nature of the transcriptomics data, based on a shared rationale reported in the enumerate list on the left part of the graph. GSE indicates the code of an experiment, while GSM code identifies samples.

B. *Identification of Transcription Start Site*

Coverage is the number of unique reads that include a given nucleotide in the sequence reconstructed during alignment.

This procedure requires the following inputs: files reporting the distribution of reads along the reference genome (coverage and number of reads that starts aligning in each genomic position) for each RNA-seq experiment; a GFF file containing genomic information; a file reporting the level of mean expression, percentiles, and CV of expression of NDE genes identified by the first procedure.

Coverage profiles of every experimental condition are analysed and the TSSs predicted positions are merged to identify the most likely ones (Fig. 2).

For each gene, the genomic region extending from 300 bp upstream starting codon to 300 bp after the gene is extracted. TSS position is searched in the 300 bp upstream of the gene.

First, it is necessary to apply a mathematical transformation to the values of coverage to limit sharp variations in the profiles of genes due to noise. Subsequently, a limitation of the search area is implemented to exclude areas larger than the

length of the reads where there are no pairings between reads and transcripts.

Despite the applied mathematical transformations, coverage profiles are still very noisy: a filter to remove high and low frequency noise must be applied. Coverage values before and after the gene start codon have been differentiated to distinguish the area where the probability to find a TSS position (before the gene start codon) is higher compared to the area where the probability is much smaller (after the gene start codon). The differences of coverage values between one base and the next are calculated and the growth fronts of coverage value are identified both in the area upstream and within the gene. In each sample, each position in the region before gene is selected as a TSS if the probability of belonging to the within-gene distribution of differences is lower than 5%. The probability is computed by comparing each before-gene coverage excursion with the distribution of the within-gene values. At the end of the analysis of all samples, for each gene we get the possible positions of the TSS associated with it.

A post-processing phase of the results is needed to limit the number of false positive TSS due to noisy graphs. Starting from the most identified TSS, called *TSS mode*, we look for the TSS belonging to a range of N bases on the right and left. These are part of the distribution centred in *TSS mode*. It iteratively extends the research area of TSS in the same population by enlarging the same region of N bases starting from extremes. This operation is repeated until in the region under observation there are no more TSS. Once a population is completed, mode is sought among the excluded TSS, and the corresponding population is built. Eventually, a certain number of populations is obtained and each of them is associated to a metric equal to the number of times the population is found multiplied by the number of times the *TSS mode* is found. The *TSS mode* with top metric is considered as the final TSS identified by the pipeline. Putative promoter sequences are the 50 bp upstream the predicted TSSs.

C. Data set

All microarray and RNA-seq experiments have been downloaded from GEO. The organism selected for the analysis is *Escherichia coli* (*E. coli*). It has more than 3000 chassis or version of annotation downloaded from Assembly summary NCBI [17]. Its reference genome is *E. coli str. K12 substr. MG1655* (taxid 511145).

The number of microarrays experiments available on GEO is ~500. A large number has been removed from the analysis because more than one organism was tested, or because there were experimental conditions with single replicate, or because there were problems during the reading of the files. Therefore, only 50 experiments passed this check.

The number of RNA-seq experiment available on GEO is ~170. 16 experiments were excluded because the number of aligned reads on the reference genome was too low.

For the identification of NDE genes were used 206 GSE, i.e., 206 different experimental studies.

Datasets of promoter sequences of *E. coli* have been retrieved from the EcoCyc database [18]. In EcoCyc, 1700 promoter sequences with their relative sigma factors and TSS were present.

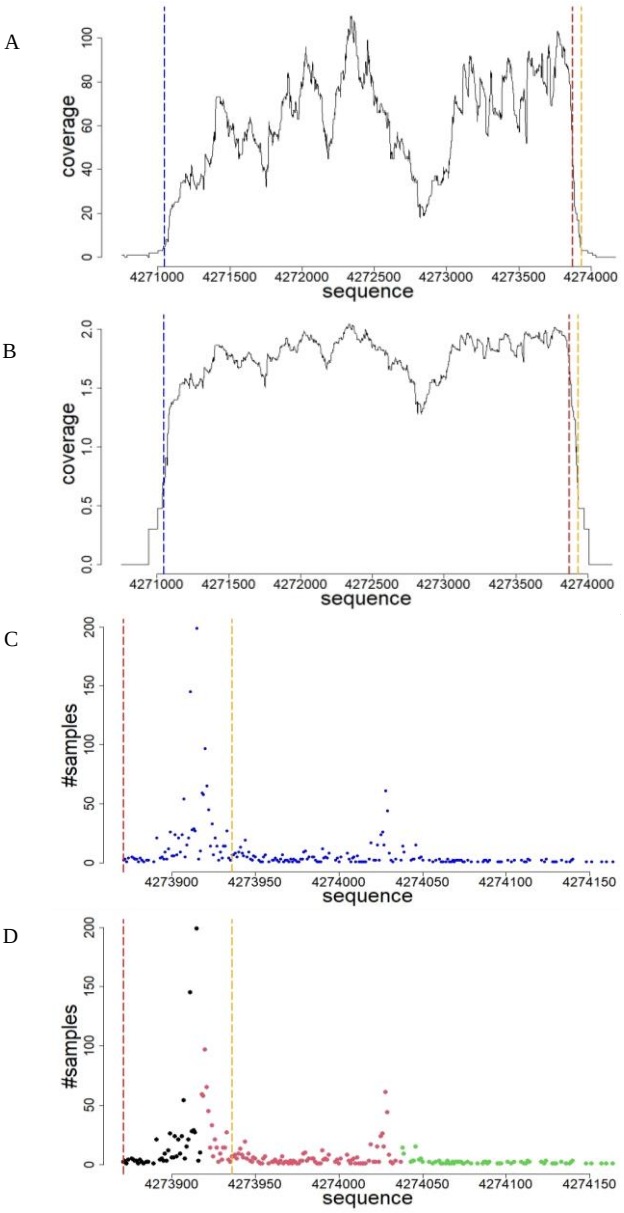

Fig.2: Overall representation of the procedure for the identification of TSS. A. The coverage profile of a gene in the genomic area of interest in a sample. B. The same coverage profile after logarithmic transformation. C. Distribution of TSS identified by the procedure excluding noisy positions. Each dot represents the number of samples in which each TSS is identified. D. Clustering of TSS in subpopulation. Each color represents a different population. Blue line: end of the gene; red line: start of the gene; orange line: TSS annotated.

III. RESULTS

A. Classification of NDE genes

The analysis of microarray experiments identified 1145 NDE genes, while that of RNA-sequencing 2858. Before *inter-experiment* normalization, the genes have been intersected to consider only the common ones, which were 871. NDE genes were sorted according to the mean expression percentile. They were divided into 5 groups, every 20 percentiles. In each group, 5 genes with lowest CV of the expression were selected (Fig.3).

The validation of the first procedure has been based on the genes for which, in the literature, have been demonstrated to be constitutively expressed in different conditions registered. Only the genes with known promoter sequence, sigma factor

and experimental evidence code have been used for the validation process. The data have been collected from EcoCyc. The first procedure detected correctly 19 out 25 genes (~76%). 3 genes were wrongly classified because the molecules that influence their production were present in the considered experimental conditions. The other 3 genes were not well annotated in EcoCyc, so no classification was possible.

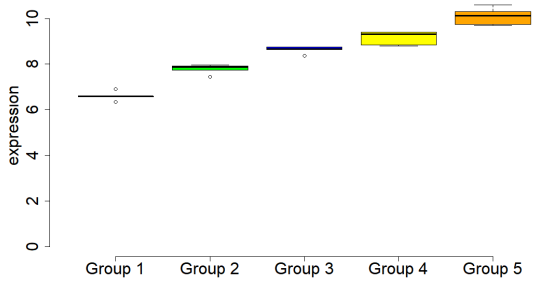

Fig. 3: Distribution of mean expressions of 25 genes selected during the analysis with lowest CV in five groups obtained dividing genes by percentile of expression.

B. Performance of the procedure for the identification of TSS

Although an increasing number of mapped reads to genomic locations downstream of TSS is expected, this may be more or less pronounced depending on the levels of gene expression. So, we limited the analysis on genes with mean percentile of expression higher than 60%.

At the end of the analysis of all samples, the identified TSSs were clustered in populations as described in II.B with N=10. For each gene, the TSS mode of the population with higher metric was identified.

The performance index of the procedure is based on TSS comparison with the literature. In fact, if the annotated TSS is included inside a window of ±5 bp on to the position of the putative TSS then the putative promoter is considered as true positive (TP).

$$performance\ index = \frac{\#\ TP}{all\ putative\ TSSs} \qquad (1)$$

The procedure has been tested in GSE60522 for *E. coli str. K12 substr. MG1655*, reaching a performance index of ~60%.

IV. Discussion and Conclusion

The increasingly demand of expanding the libraries of regulatory parts for non-model microorganisms motivated the development of novel strategies based on bioinformatics approaches for their *in-silico* prediction as an alternative to the high cost and time-consuming *in-vivo* search and characterization.

A new bioinformatics pipeline has been developed with the aim to detect constitutive endogenous promoters in microorganisms with annotated genomes, based on transcriptomics data in different experimental conditions.

Thanks to the RNA-seq resolution, it is possible to reconstruct reads coverage profiles base by base along the genome inferring the TSS genomic coordinate.

The two procedures adopted for promoter sequence detection and for selection of constitutively expressed genes have been tested for the model organism *E. coli* and the results compared with genomics data and scientific literature articles (promoter detection accuracy = ~60%; percentage of putative constitutive genes found = ~76 %).

A method to select RNA-seq experiment for the identification of TSS is needed to avoid the processing of large numbers of samples and to enable quality-based filtering: increasing the collection of experiments with desired characteristics could raise to better performance.

The pipeline performance is expected to depend on the number of experiments and assayed conditions, to sensitively detect NDE genes with robust expression. This may represent an issue when analyzing public data of non-model organisms for which a small number of experiments are available.

In parallel, new applications could be targeted to use the subset of Differentially Expressed (DE) genes. In fact, from the latter it is possible to infer the DNA operator sites linked to a particular perturbation, useful in the synthetic circuit design step to increase the circuit orthogonality from the enzymatic host machinery.

The pipeline can allow to expand the toolkit of biological parts implemented in synthetic genetic circuits to enable reliable engineering and gene expression control in model and non-model bacteria.

***Abstract*—β-cell dysfunction is a crucial factor of glycaemic deterioration in type 2 diabetes (T2D), but the role of circulating proteins in its progression is currently not understood.**

We studied the potential associations between β-cell glucose sensitivity progression over 3 years and baseline proteomics in a cohort of recently diagnosed T2D patients (*N* = 653) from the IMI-DIRECT project, through linear regression analysis.

We found that forty-six proteins have a significant association to β-cell glucose sensitivity progression. Subsequent functional analysis showed these proteins belong to functional modules linked to insulin secretion and T2D pathophysiology.

These findings, along with further investigation in longitudinal studies, may point to novel protein markers and processes of β-cell function deterioration.

***Keywords*—β-cell function, T2D, proteomics, glucose sensitivity.**

I. INTRODUCTION

β-cell dysfunction is a key feature of glycaemic deterioration in type 2 diabetes (T2D), alongside reduction in insulin sensitivity and clearance [1]. Recent IMI DIRECT studies highlighted that deteriorating β-cell function is independently associated with glycaemic progression [2].

The role of circulating proteins in β-cell dysfunction is less clear and defined. Many of the available studies on the subject explored the potential association between diabetes and circulating proteins, not specifically β-cell function [3][4]. The few that did so are limited to cross-sectional data [5].

In this study we performed regression analysis to identify possible, significant associations between β-cell glucose sensitivity progression and proteomics and explore the potential biological roles of these associations for T2D physiopathology through functional analysis.

II. METHODS

A. Data

The data utilized in this study were extracted from the prospective multicentre IMI DIRECT cohort of white Nord European T2D patients of recent diagnosis [6].

Mixed meal tests were performed and anthropometric data were collected at 0, 9, 18, and 36 months [6]. β-cell glucose sensitivity (GS) was derived by modelling [7] and chosen as indicator of β-cell function.

Olink targeted proteomics were recorded at month 0 (baseline), from five different panels – Metabolomics, Cardiovascular I and II, Cardiometabolic and Development – for a total of four hundred sixty considered proteins. Proteins concentrations were measured in EDTA plasma samples collected after overnight fasting through multiplex proximity extension assays.

Patients without available progression of glucose sensitivity or with ambiguous T2D (IA2 > 7.5 or GAD > 11) were excluded, reducing the cohort to a total of *N* = 653 individuals.

Only proteins with missing data frequency lower than 0.5 were kept for the study, for a total of four hundreds different proteins.

Protein distributions were adjusted with a linear mixed effects model for plate, centre, seasonality, time of day, and sample age with the R package *lme4* [8]. Lastly, distributions were scaled.

B. *β-cell glucose sensitivity progression*

GS values were modelled with linear functions of time, of which slopes were chosen to represent progression of GS (GSp) [2].

C. *PCA*

Principal component analysis (PCA) was conducted on the proteomics data to identify possible, important principal components that could arise from proteins distributions. PCA was performed through the R *factoMiner* and *factoextra* packages [9].

D. *Regression analysis*

The relationships between GSp and circulating proteins were investigated through linear regression analysis. We employed models that included single proteins from our dataset and several covariates: the first principal component of the proteomics data (21% of data variance explained), medications with reported effects on glycaemia taken or removed within the study, and clinical traits at baseline (sex, age, body mass index, GS, questionnaire-reported moderate physical activity, and glycated haemoglobin).

Influential points in the linear regressions, identified via residuals with excessive Cook's distance (over five times the mean of the Cook's distances), were removed from the dataset to re-run the regressions.

All regressions and influential points analyses were run on R with the *stats* package [10].

To account for multiple testing, regressions p-values were adjusted with the Benjamini-Hochberg procedure (FDR) [11].

E. Functional Analysis

Proteins with statistically significant regression coefficients (FDR-adjusted p-values < 0.1) were used to perform a functional gene enrichment analysis through Over-Representation Analysis (ORA) [12].

We also performed gene set enrichment analysis (GSEA) [13] on the entire proteins set. In this case, proteins were ranked with a score calculated as $-log_{10}(p\text{-}value)*sign_of_coefficient$.

The three gene ontologies Biological Processes, Molecular Functions, and Cell Components [14], and the KEGG [15], WikiPathways [16], and Reactome [17] repositories were used as databases for both analyses. Only results with p-values lower than 0.05 were considered significant.

All functional analyses were run on R with the *clusterProfiler* package [18].

III. RESULTS AND DISCUSSION

A. Proteins identified by linear regression

Linear regression analysis identified forty-six proteins out of the starting four hundreds as statistically significant, with standardized protein coefficients between -0.16 and 0.2 and R-squared higher than 0.27 (Fig.1). The protein with highest significance (FDR = 0.004), SCARF1, showed also the highest positive β-coefficient (0.2).

B. Functional analysis

Among the statistically significant annotations identified by the ORA test, some proved to be more interesting due to their potential role in insulin secretion: Rap1 signalling and MAPK/Ras pathways, involved in β-cell insulin secretion [19] and insulin receptors signal transduction [20], were found to be significant by the analysis on the KEGG database (Fig.2).

GSEA analysis showed many statistically significant terms and pathways describing tyrosine-kinases receptors activity, the class of receptors for insulin signalling and signal transduction [20].

Different terms and pathways related to inflammation signalling, extracellular matrix, cellular membrane organization and transport vescicles were also identified by both ORA and GSEA tests.

IV. CONCLUSION

The application of regression analysis on β-cell glucose sensitivity progression and proteomics allowed to identify a set of markers for β-cell function progression.

The enrichment analyses showed that some of these proteins belong to functional modules already related to insulin secretion or T2D pathophysiology, pointing to the potential role of these proteins and modules in the progression of β-cell dysfunction in T2D.

External and experimental validation of these findings is warranted.

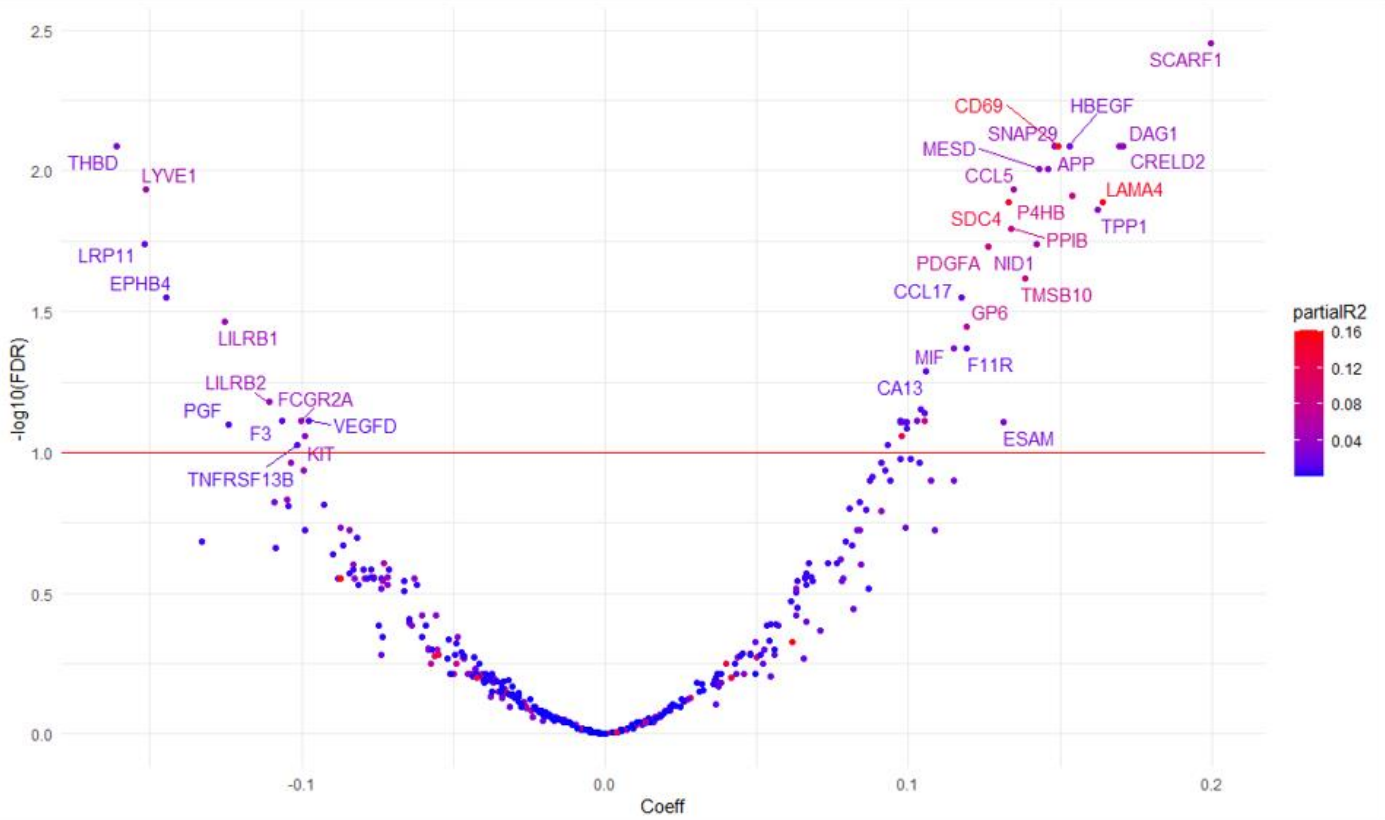

Fig. 1: Linear regressions results as volcano plot showing each protein β-coefficient with its statistical significance (FDR-adjusted p-values), colored by partial R^2 value. Forty-six proteins are above the red line that represents the significance threshold of 0.1.

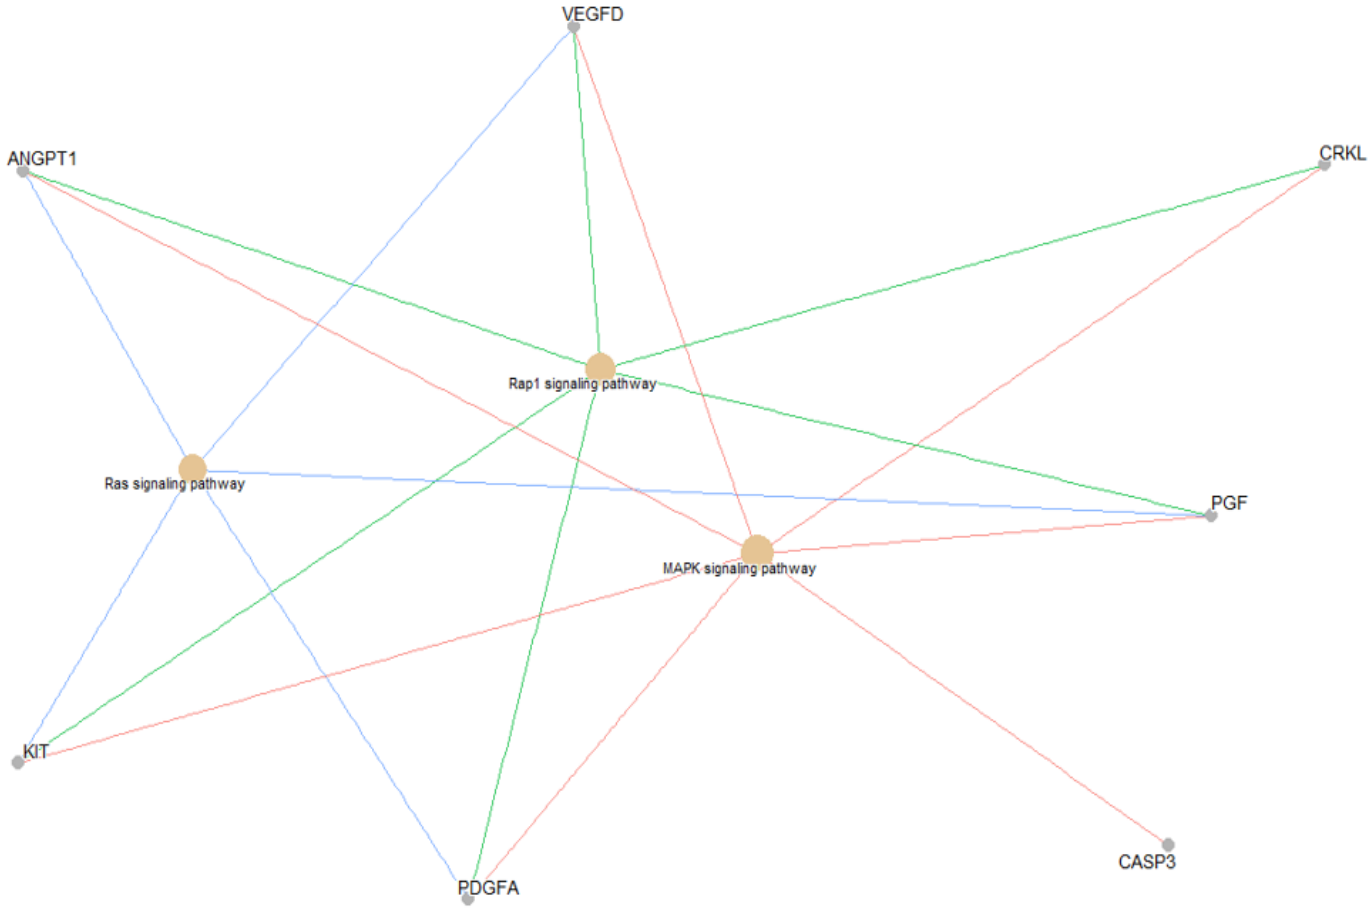

Fig. 2: Gene-concept network of statistically significant (p-value < 0.05) enriched pathways from Over-Representation Analysis on KEGG database, forming a potential functional module for insulin signal transduction and secretion.

ACKNOWLEDGEMENT

The work leading to this publication has received support from the Innovative Medicines Initiative Joint Undertaking under grant agreement 115317 (DIRECT), resources of which are composed of financial contribution from the European Union's Seventh Framework Programme (FP7/2007-2013) and European Federation of Pharmaceutical Industries and Associations companies' in-kind contribution. Lipid Droplets associated genes link HSV-1 infection to neurodegeneration pathways

***Abstract*— A growing body of evidence support the infectious hypothesis of Alzheimer's Disease (AD) and a possible role of HSV-1. Due to its ability to undergo multiple cycles of latency and reactivation in neurons, HSV-1 is considered a possible agent in triggering neurodegeneration and AD onset.**

In this work we focus on a particular aspect: the connection of lipid droplets (LDs) with viral infection and neurodegeneration. To corroborate this hypothesis, experimental and in-silico approaches have been synergistically adopted, in a rational multimodal framework: *in vivo* and *in vitro* models were exploited, from cytological imaging and flow cytometry to gene expression and protein interaction network analysis.

Our results point out that, after viral infection, not only LDs accumulate in both models, but also that differentially expressed genes can be related to key players, notoriously involved in neurodegeneration. Of note, infected neuronal cells are characterized by an in increase in ROS production, and in particular lipid peroxidation, which is again a known outcome in both viral infection and neurodegeneration.

***Keywords*—HSV1, Lipid Droplets, Neurodegeneration, Networks**

I. Introduction

Alzheimer's Disease (AD) is a neurodegenerative disease characterized by early neuronal death in brain and synaptic loss, events leading to cognitive decline in patients, that exhibit memory and language impairment. Among others, the main hallmarks of AD are the formation of neuronal β-amyloid plaques and neurofibrillary tangles, along with the presence of extensive oxidative stress [1]. Despite several aspects of the pathology have been unraveled, a lot of information are still missing, especially about its etiology: this is reflected in the absence of an effective treatment to date.

In the last decades, a growing body of evidence in literature support the profound link between AD onset and infectious agents. Among others, several suggestive data point out the Herpes simplex virus type 1 (HSV-1) as an extremely attractive putative player: it undergoes latency and it can establish chronic infections through evasion of host immune response and it can be subjected to multiple reactivations from latency during patient's life [2]. It has been demonstrated that HSV-1 infection leads to enhanced AD markers in neurons [3]–[5]; in particular, multiple reactivations from latency are thought to contribute to neuronal dysfunction, thus leading to neurodegeneration.

Lipid droplets (LDs) are intracellular organelles that store neutral lipids. LDs are well characterized in adipocytes where they perform the function of energy storage and their accumulation can be induced by several factors, such as metabolic alterations.

It has been reported that both ageing and neurodegenerating neurons can accumulate LDs in response to inflammation, lipotoxicity and oxidative stress [6], [7]. Interestingly, the increase in these organelles is detected also in several viral infections [8]. In particular, *in vitro* HSV-1 infection is found to induce LDs accumulation in astrocytes and to stimulate an antiviral response [9]. Anyhow, the literature on this topic is very limited and, as far as we know, no data is available regarding the relationship between HSV-1 and LDs in infected neurons.

The aim of this study is to evaluate whether neuronal LDs and ROS production (a proxy for evaluating neuronal degeneration) are affected by HSV-1 infection. A replication-defective mutant of the virus (HSV-MUT) has been used to verify whether the infection per se can lead to the above-mentioned effect. The adopted mutant additionally lacks a specific pattern of viral genes[1], allowing a protein-specific evaluation of the mechanism under study. However, this depth of analysis goes beyond the aim of this study.

II. *In vivo* Hypothesis Validation

A. Mouse Model System

In order to evaluate whether HSV-MUT infection has an impact on LDs in neurons, we decided to exploit a murine model already well characterized by several previous studies that focused on persistent HSV-1 infection in the enteric nervous system [10], [11] (**Fig.1**).

Fig. 1: Mouse model of HSV-MUT infection and subsequent analysis. LMMP: Longitudinal Muscle/Myenteric Plexus

Mice were firstly subjected to intranasal infection with HSV-MUT (1×10^2 PFU) and, 4 weeks later, inoculated via intragastric gavage (1×10^7 PFU). Viral infection obtained in two phases was previously determined to minimize mortality rate among mice [12], [13]. Mice were sacrificed after 4 weeks from intragastric inoculum, and the whole ileum was flushed with PBS and fixed in paraformaldehyde (Whole Mount [WM]

[1] The specific mutant genotype is not reported, due to an existing conflict of interest with another work of the authors that was under revision when this manuscript was submitted.

preparation). Using a stereomicroscope, the Longitudinal Muscle/Myenteric Plexus (LMMP) was separated from the remaining ileal tissue. The same procedure was performed on ileum obtained from control mice (sham infection). To identify enteric neurons, immunofluorescence was performed using a β-III-tubulin primary antibody conjugated with Cy3 fluorophore (diluted 1:400, Millipore). Instead, to detect LDs the LMMP was stained with a green-fluorescent probe recognizing neutral lipids (BODIPY 493/503, diluted 1:1000, ThermoFisher). At least 5 images per sample were captured using Nikon TE200-C1 confocal microscope.

B. Confocal Microscopy Results

In **Fig.2A** enteric neuronal ganglia are clearly identified by β-III-tubulin staining. Interestingly, we detected LDs both in sham uninfected LMMP and in HSV-MUT infected one, with a stronger signal in the latter.

To perform a quantitative evaluation of neuronal LDs, images were analyzed with ImageJ software (n=5 per sample). Only LDs detected in colocalization with neuronal staining were considered and two parameters were measured: the total number of neuronal LDs normalized on β-III-tubulin-defined area and the mean LDs area (**Fig.2B**). While the total number of LDs seem to be comparable between sham and HSV-MUT neurons, there is a clear increase in LDs mean size in presence of infection (p-value <0,05).

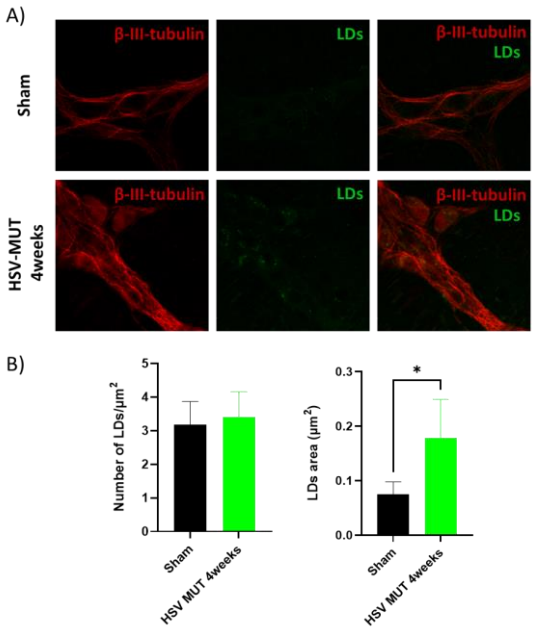

Fig. 2: A) Whole Mount of ileum LMMP from sham and 4-weeks HSV-MUT infected mice (in red: neuronal β-III-tubulin, in green: BODIPY 493/503 staining LDs). **B)** ImageJ quantification of LDs.

III. *IN VITRO* MODEL FOR NEURAL CELL ANALYSIS

A. Murine neuroblastoma cell line

To further explore the relationship between viral infection and LDs formation in the tissue of interest, we moved to an *in vitro* cellular model (**Fig.3**): murine neuroblastoma Neuro2A (N2A) cells are widely used to study neurodegenerative processes and they can be a suitable model to investigate HSV-MUT infection [14].

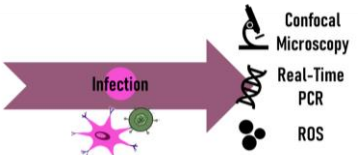

Fig. 3: Murine neuroblastoma model of HSV-MUT infection and subsequent analysis

Briefly, N2A cells were cultured following ATCC guidelines; 10^4 cells were seeded on sterile microscopy glass and cultured for 24 hours. HSV-MUT infection was performed at multiplicity of infection 1:1. Infected cells were maintained in complete culture medium for 48 hours and then processed for the following analysis: (i) confocal microscopy, (ii) gene expression analysis via real-time PCR and (iii) evaluation of oxidative stress with fluorescent probes.

B. Confocal Microscopy Results

For confocal microscopy analysis, cells were fixed with paraformaldehyde and subsequently stained in the same way as the Whole Mount preparations reported in the previous paragraph II-A. As negative control, the same procedure was performed on N2A cells not exposed to virus. At least five images per sample were captured using Nikon TE200-C1 confocal microscope (60X; 488nm and 561nm lasers).

Interestingly, the images obtained from confocal microscopy analysis (**Fig.4A**) show a very low signal for LDs in not infected N2A, while there is an evident increase in LDs after HSV-MUT infection. As previously shown in Whole Mount LMMP, LDs mainly colocalize with neuronal β-III-tubulin staining. ImageJ software was used to quantify the number of LDs per cell (normalized on β-III-tubulin-defined cell area) and the mean LDs area. As we can appreciate in **Fig.4B**, HSV-MUT infection induces an accumulation of LDs, both in terms of number and size. This *in vitro* data confirms the results obtained from the mouse model, in particular as regard the virus-induced increase in LDs dimension.

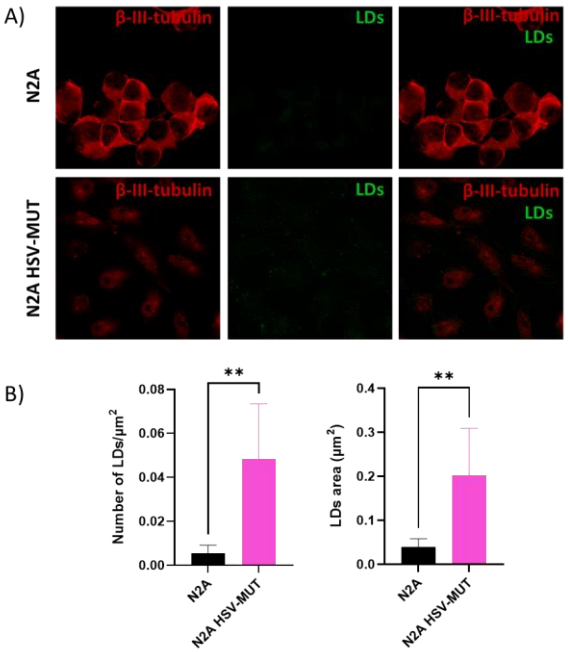

Fig. 4: A) Immunofluorescence analysis of control and HSV-MUT infected Neuro2A cells (in red: neuronal β-III-tubulin, in green: BODIPY 493/503 staining LDs). **B)** ImageJ quantification of LDs.

Nevertheless, LDs number *in vivo* seems to be unaffected during HSV-MUT infection, but this is not surprising, as this difference could be explained with the presence of other cellular types (e.g., glial cells) in LMMP, which could contribute in the response to viral infection.

Clearly, more data are needed to validate this hypothesis.

C. Real-Time PCR

Total RNA was extracted from both control and HSV-MUT infected cells. The expression of 12 genes, selected from literature as LDs-associated genes expressed in the nervous system [15]–[20], was analyzed via real-time PCR, using the iTaq Universal SYBR Green One-Step Kit (Bio-Rad). The expression of mRNA target was normalized to housekeeping GAPDH mRNA and plotted as mean fold expression (**Fig.5**).

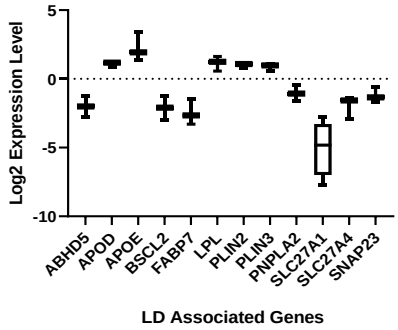

Fig. 5: Real-time PCR analysis of LD associated genes in HSV-MUT infected Neuro2A cells compared to non-infected control cells.

Interestingly, all the chosen genes resulted to be differentially expressed, with up to 5-fold change variation and always with a statistical significance with $p<0.05$ (computed via t-test using GraphPad Prism 8).

D. Oxidative stress and ROS production

To confirm the occurrence of neurodegeneration, an additional validation was performed by evaluating the oxidative stress and detect reactive oxygen species (ROS), as a proxy of neural degeneracy. N2A cells were incubate for 30 minutes with specific fluorescent probes: dichlorodihydrofluorescein diacetate H_2DCFDA, BODIPY 581/591 C11 and MitoSOX. Cells were subsequently analyzed via flow cytometry. This was performed by exploiting 3 different fluorescent probes, to gather information on different compartments, namely: (i) non-specifically localized intracellular free radicals were detected via H_2DCFDA, a compound converted into a fluorescent probe in presence of a broad spectrum of ROS [21]; (ii) lipid peroxidation, explicitly related to LDs, was evaluated through BODIPY 581/591 C11, a lipophilic probe binding cell membranes, which fluorescence emission is shifted from 520 nm to 595 nm in presence of oxidized lipids [22]; (iii) mitochondrial localization of superoxide was assessed with MitoSOX Red mitochondrial superoxide indicator [23]. The measurements were performed with a BD-FACSCalibur using CellQuest software.

Data presented in **Fig.6** clearly show that HSV-MUT infection induces an increase in general ROS production. This analysis highlights a strong raise in lipid peroxidation and the involvement of mitochondria in the establishment of an oxidative stress condition.

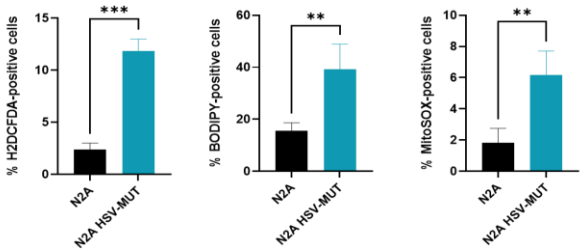

Fig. 6: Flow cytometry analysis of fluorescent probes detecting ROS in HSV-MUT infected Neuro2A cells compared to control cells.

E. Differential expression network analysis

To corroborate our hypotheses and identify further interesting putative proteins of interest, a network analysis was performed to highlight genes directly connected to the ones analyzed in the previous Section II-C.

BIOGRID-ORGANISM-Mus_musculus-4.4.217.psi25 protein, genetic and chemical interactions network (19k nodes, 97k edges) [24] was downloaded from the BioGRID website (https://thebiogrid.org/) and imported in Cystoscape [25] v.3.9.1. A first subnetwork (12.5k nodes, 69.5k edges) was obtained selecting nodes with "containing: Mus musculus" as "Species Full Name", to remove cross-species annotated interaction. Then, a second subnetwork (64 nodes, 142 edges) containing only the first neighborhood of the analyzed genes was generated; after the removal of multiple and looping edges, the latter was transformed into a STRINGfy network (62 nodes, 41 edges), via the Cytoscape-integrated STRING tool, integrating information on associated tissues and cellular compartments to each node. Lastly the nodes were filtered by "Tissue: nervous system" (24 nodes, 24 edges) with a threshold of 4.5 (**Fig.7A**) since a score of 5 (maximum level) resulted in an empty network.

The same pipeline was also performed on the BIOGRID-ORGANISM-Homo_sapiens-4.4.217.psi25 network (42.3k nodes, 1.1M edges), but in this case, the first subnetwork (34.7k nodes, 1M edges) was obtained by selecting nodes for "containing: Human" as "Species Short Label" to include possible Human Herpesvirus related nodes. However, the first neighborhood selection (956 nodes, 20k edges) removed all those nodes; on the other hand, the STRINGfy network (946 modes, 20k edges), obtained setting "Tissue: nervous system" filter at 4.99 resulted to have 35 relevant nodes (159 edges) (**Fig.7B**) and 5 nodes (4 edges) with threshold 5. (**Fig.7C**). Looking at STRINGfy Networks, both the mice and the 4.99-thresholded human ones highlight the APP and PRNP genes: the former is the Amyloid-beta Precursor Protein, the latter a

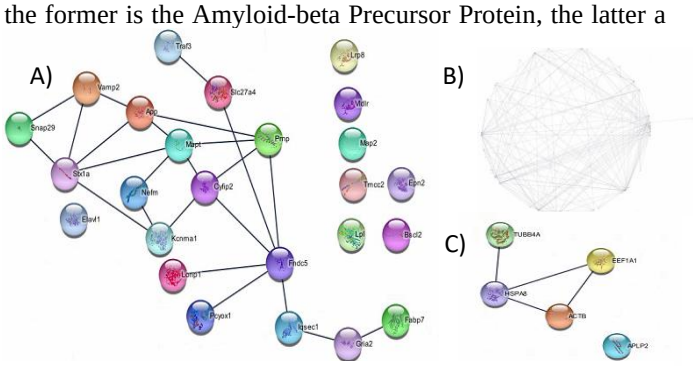

Fig. 7: STRINGfy networks. **A)** Mus musculus, threshold=4.5, **B)** Homo sapiens, threshold=4.99 **C)** Homo sapiens, threshold=5

prion protein involved in neuronal development and synaptic plasticity, required for neuronal myelin sheath maintenance. Additionally, it is worth to notice the presence of heat-shock proteins, associated to neurodegenerative diseases, that correct the folding of toxic misfolded protein under stress conditions.

Lastly, among the genes appearing in the 5-thresholded human network, APLP2 and TUBB4A are an Amyloid beta (A4) precursor-like protein and a Class IVa beta-tubulin, respectively, thus potentially involved in AD-like neurodegenerative processes.

IV. Conclusion and Future Perspectives

All the selected genes analyzed via RealTime PCR were differentially expressed up to a 5-fold in downregulation and 2-fold in upregulation. Of note, the gene APOE is involved in AD and indeed result upregulated. SLC27A1 gene and its homolog SLC27A4, coding for long-chain fatty acid transporter proteins, are both downregulated, thus indicating an impairment in lipid uptake and metabolism. Indeed, both *in vitro* and *in vivo* models highlight the increase of LDs following viral infection compared to the negative controls

Thanks to the network analysis, it was possible to confirm expected biological evidence, such as the APOE wide connection in all the observed networks; moreover, a panel of interesting additional genes that could be revealed as a causative link between LDs formation and AD-like neurodegenerative processes has been highlighted and will be further investigated in future analysis.

Additionally, we demonstrated that lipid peroxidation is linked with LDs accumulation, as the storage of peroxidated lipids can act as a mechanism to counteract lipotoxicity. In addition, oxidative stress and in particular mitochondrial ROS are considered a hallmark of neurodegeneration and AD [1], [26]. Extensive ROS production is well described in wild-type HSV-1 infection [27] and our data indicate that also HSV-MUT provokes a similar outcome. This could suggest that the only genes expressed in the mutant virus, play a fundamental role in oxidative stress.

Overall, these data seem to suggest an intriguing relationship between viral infection, LDs accumulation and oxidative stress in neurons. Being these processes reported in literature to be related to AD, the preliminary results of this work could pave the way to a new perspective aimed to investigate the role of HSV-1 in triggering neurodegeneration.

In this context, we will evaluate whether HSV-MUT infection determines an increase in further AD markers, exploiting both our mouse model and Neuro2A cells. Lastly, to characterize the outcomes' temporal evolution, different viral infection time points will be gathered and evaluated.

***Abstract* — In this work, we blueprint a Dashboard that allows users to simulate the bacterial community's evolution through an intuitive GUI. The underlying Python-coded simulator implements an agent-based model of bacterial species, nutrients, and environment, allowing full customization and upgradability of the tool, due to its intrinsic modularity. Specifically, the model aims to represent discretized spaces, hosting a certain number of bacteria for each species and a defined amount of nutrients characterizing the surrounding environment. Bacteria can migrate from one spatial unit into another, looking for different nutrients (i.e., metabolites) across the whole space path. Growth and survival are governed by bacterial metabolisms, which are in turn functions of the metabolites present in each specific spatial unit at a certain time. Thus, our tool simulates how bacteria consume and produce metabolites, following species-specific metabolism rules, letting the system dynamically evolve through bacterial growth, death, spatial migration, and continuous updates of the available metabolite pool.**

I. Introduction

HUMAN gut microbiota composition and behavior have been proven to be fundamental for our health; thus, proper modeling of microbial ecology is a hot topic in computational, systems and synthetic biology [1]-[2].

Classical ecological models, such as Generalized Lotka Volterra models (GLVm), describe the absolute abundance of each community mainly as a function of intrinsic growth rate and pairwise interactions with each community member; parameters need to be inferred by co-occurrence networks leveraging on bioinformatic approaches applied on metagenomic data and investigated via topological analysis [3]. The biases and variability in retrieved biological data to be used for training the models, arising from the adoption of different experimental setups and methods between different groups and studies, motivate the need for standardization in data production [4]-[5]. Additionally, these models usually rely on constant parameters to describe microbe-microbe interactions, which are instead determined, among others, by the time-varying biotic and abiotic environment. For this reason, they fail capturing community-level behaviors when the environment changes over time or in space [6]-[7].

Another promising approach relies on flux balance analysis (FBA) methods; in this case, information on bacteria metabolisms is included in the analysis through genome-scale models (i.e., structured information of possible reactions happening in a bacteria species based on annotated transcriptomes through metabolic networks), which are used to implement an optimization problem with biomass production as objective function [8]. While several groups are adopting FBA-derived to develop predictive tools, the lack of sufficiently annotated metabolic models is still a major issue; additionally, similarly to GLVm, this approach need nesting in more complex models to provide spatial information.

Microbe-effector models and, more specifically, agent-based modeling is an inspiring solution to implement efficient and robust methods to describe systems counting for billions of bacterial cells from hundreds of different species. This approach allows to develop mechanistic-level descriptions of simple agents, dynamically interacting with the surrounding environment that can be arbitrarily modeled; then, from agents decoupled behaviors, the complex microbial ecologies should emerge without the need of describing interaction network, which are hard to identify [9]-[10].

In this work we exploit the effectiveness of agent-based modelling to develop a Python-coded bacterial community simulator that is reliable, robust, efficient, reproducible, and scalable. Moreover, for the first time, great effort has been put into developing a functional and usable GUI that allows any user to exploit the full potential of the software setting the simulation parameters, such as bacterial metabolisms, and visualizing interactive summary results.

To date, the technology to characterize bacterial metabolisms in a cheap, reliable, and high-throughput fashion is still under development. However, we demonstrate that the intrinsically modular and incremental structure of our simulator is generalizable enough to be already used for roughly defined communities; indeed, despite the lack of complete information on bacterial metabolisms, it can resemble potentially realistic biological scenarios, potentially allowing computational simulations of mock communities (i.e., an in vitro defined mixture of microbial cells) involving functionally characterized species.

II. Methods

A. System abstraction and general workflow

The space is represented as a series of boxes called *cells*, each one containing a specific set of metabolites, connected with the closest neighborhood cells. This allows representing four different possible scenarios:

- Single cell: a well-mixed space with homogeneous bacteria and metabolites composition (e.g., a stirring bioreactor).
- 1D chain of cells: linear tract where metabolites and bacteria flow in 1 dimension (e.g., gut tract abstraction).
- 2D plane of cells: a surface where movements occur in 2 dimensions (e.g., a Petri dish, layered biofilms).
- 3D geometry of cells: a volume discretized in several cells (e.g., organoids, complex flake-like biofilms, organs).

The definition of neighborhood cells depends on the scenario and on the level of proximity we want to consider. Bacterial agents (i.e., bacteria of different species) can process

the metabolites in a *cell*, grow, die, and move into other neighborhood cells, if existent. In this work we considered a 1D linear tract representing an intestine tract and a neighbourhood proximity of 1 cell and mimic the bacterial evolution for a certain number of iterations, i.e., time points. At each iteration, bacteria can migrate from the i^{th} to the $(i+1)^{th}$ cell (to mimic the direction of chime), grow, die, metabolize the available metabolites, and produce a new set of metabolites for the next iteration (Figure 1).

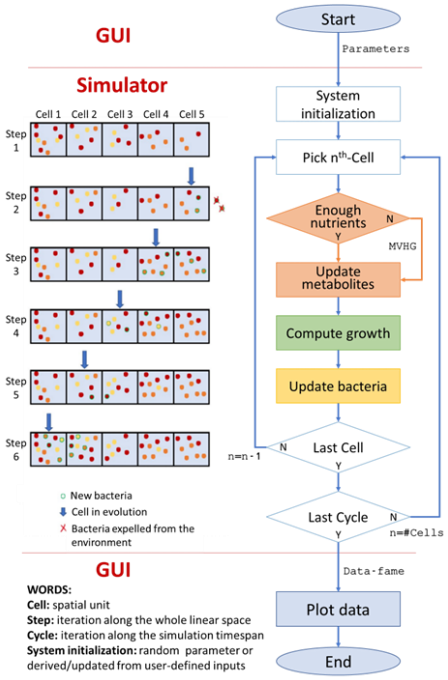

Fig. 1: Example of the simulation framework.

Lastly, after the pipeline has run over all the cells, for the number of iterations required to represent a certain required time window, the resulting data frames are passed to the GUI.

B. System implementation

Our simulator is implemented in Python through two classes: the class *Cell* and the class *Bact*. The class *Cell*, whose instances implement the spatial unity, is defined by:

- A vector $\boldsymbol{f}$ of metabolites available at the current iteration.
- A matrix of metabolites (rows) produced by the bacteria each iteration (columns).
- A dictionary of the bacteria in the cell, with the number of bacterial agents for each *Bact* instance.

The class *Bact*, whose instances implement bacteria species with specific metabolism, is defined by:

- A string with the species name.
- A vector $\boldsymbol{m}$ with the metabolisms, indicating for each metabolite if consumed (positive) or produced (negative).
- A vector $\boldsymbol{t}$ indicating which metabolites lead toxic effects.
- Two integers $\mu_{i,j}^{max}$ and $\mu_{i,j}^{t,max}$ describing the maximum growth rate and the toxicity level, to be adopted in the Hill equations for the population growth and death.

In addition to the accessor and set methods – which are fundamental for the interface between the simulator model and the GUI – the Cell class includes methods to update the concentration of metabolites and the number of bacteria in each cell at each iteration. Analogously, methods for the class *Bact* include methods to compute the variation in each species' abundance, depending on the nutrients available in a certain cell and the presence of toxic metabolites. The food update involves the sampling of the nutrients from a multivariate hypergeometric distribution so to model the propensity of remaining nutrients to be consumed by the most abundant and highly metabolizing species. As concerns the chain of cell implementation, a method describing the flux of microbes at each interaction from one cell to the next one is implemented by fixing the number of bacteria flowing as proportional to the species abundance and used to realize the system evolution.

C. Mathematical details

When computing the system evolution, for each j^{th} cell, the first evaluation considers whether the amount of nutrients $\boldsymbol{f_j}$ is enough to fulfil the whole metabolic request for all the bacteria $n_{i,j}^{bac}$ of all the i^{th} species in the space, as in Eq. (1). If the condition is true, each bacteria species access to all the requested nutrients and, in turn, produce a novel set or metabolites $\boldsymbol{p_{i,j}}$ through its species' metabolism $\boldsymbol{m_i}$, as in Eqs. (2-3). If the amount of nutrients is not overabundant, the metabolites are randomly distributed among the different species through a multivariate hypergeometric distribution (MVHG), as in Eq. (4); this is to prioritize the access to nutrients to the bacterial species that are more abundant and greedier for a specific resource. Then, the novel metabolic composition of the cell is computed as in Eq. (5).

$$IF \quad \boldsymbol{f_j} > \sum_i \left(n_{i,j}^{bac} \cdot \boldsymbol{m_i}|_{k>0}\right) \tag{1}$$

$$\boldsymbol{f_{i,j}} = n_{i,j}^{bac} \cdot \boldsymbol{m_i}|_{\boldsymbol{k>0}} \tag{2}$$

$$\boldsymbol{p_{i,j}} = n_{i,j}^{bac} \cdot |\boldsymbol{m_i}||_{\boldsymbol{k<0}} \tag{3}$$

$$ELSE \quad \{\mathbf{f_{i,j}}, \boldsymbol{p_{i,j}}\} \sim \mathbf{MVHG}(\boldsymbol{f_j}, \boldsymbol{m_i}, n_i^{bac}) \tag{4}$$

$$\boldsymbol{f_j} = \boldsymbol{f_j} - \sum_i (\boldsymbol{f_{i,j}}) + \sum_i (\boldsymbol{p_{i,j}}) \tag{5}$$

The second step involve the computation of the growth and death rates $\mu_{i,j}$ and $\mu_{i,j}^t$, respectively. These two values are computed as Hill's functions of the total amount of the processed nutrients $\boldsymbol{f_{i,j}^{tot}}$ and toxic metabolites $\boldsymbol{t_{i,j}^{tot}}$ in the cell, as in Eqs. (6-9).

$$\mu_{i,j} = \frac{\mu_i^{max}}{1+\left(\frac{k_i \cdot n_{i,j}^{bac}}{f_{i,j}^{tot}}\right)^{\eta_i}} \tag{6}$$

$$f_{i,j}^{tot} = \sum_k f_{i,j} \tag{7}$$

$$\mu_{i,j}^t = \frac{\mu_i^{t,max}}{1+\left(\frac{k_i^t \cdot n_{i,j}^{bac}}{t_{i,j}^{tot}}\right)^{\eta_i^t}} \tag{8}$$

$$t_{i,j}^{tot} = \boldsymbol{f_j} \cdot \boldsymbol{t_i} \tag{9}$$

The half saturation constant is multiplied by the number of bacteria $n_{i,j}^{bac}$ composing a population, so that the bigger is the population, the higher will be the required number of metabolites to expand or kill it. It is worth noting that, despite the definition of Hill's equation to model bacterial growth as a function of the processed metabolites is purely empirical (with only the maximum growth rates μ_i^{max} computed from doubling times randomly sampled from a log-normal distribution, with *E.coli* average doubling time as mean, while $k_i = 0{,}5$ and $\eta_i = 1$ where empirically chosen as default values) the modularity of the class allows to easily change this function into an alternative, more physiological, one.

The new bacterial composition $n_{i,j}^{new}$ is computed for each cell as in Eq. 10, proportional to the existent number of bacteria $n_{i,j}^{bac}$ and the related growth rate $\mu_{i,j}$. Analogously, the

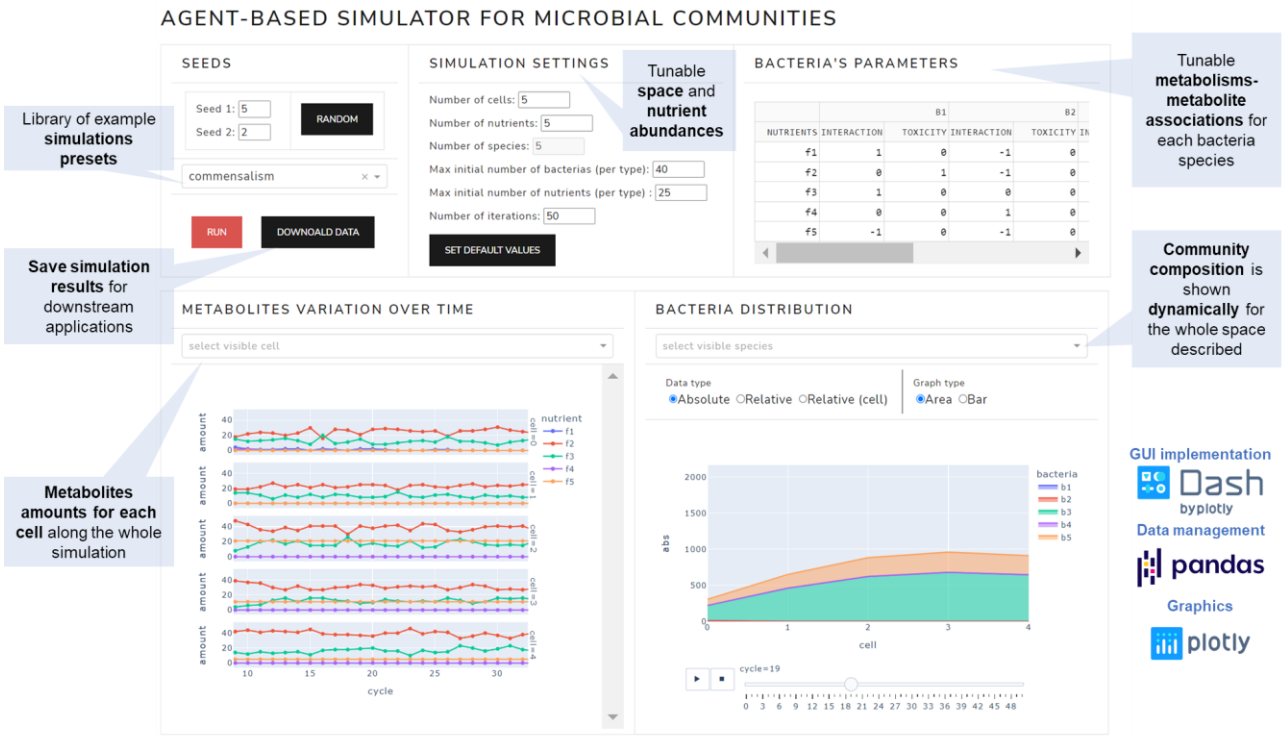

Fig. 2: Dashboard GUI schema.

number of dying bacteria is computed as in Eq. 11, including basal death and toxicity rates, while the bacteria migrating from the j^{th} cell to the $(j+1)^{th}$ are computed in in Eq. 12 as proportional to the migration rate ρ. Lasty, the new vector of bacteria is updated considering all the contributions, as reported in Eq. 13.

$$n_{i,j}^{new} = \lceil \mu_{i,j} \cdot n_{i,j}^{bac} \rceil \quad (10)$$

$$d_{i,j} = \lceil (\lambda + \mu_{i,j}^{t}) \cdot n_{i,j}^{bac} \rceil \quad (11)$$

$$n_{i,j}^{flow} = \lceil \rho \cdot n_{i,j}^{new} \rceil \quad (12)$$

$$n_{i,j}^{bac} = n_{i,j}^{bac} + (n_{i,j}^{new} - n_{i,j}^{flow}) - d_{i,j} + n_{i,j-1}^{flow} \quad (13)$$

Model parameters are summarized in Tab. I.

TABLE I: MODEL PARAMETERS

Symbol	*Meaning*	*Symbol*	*Meaning*
$\mathbf{f}_j$	Nutrients	μ_i^{max}, k_i, η_i	Hill parameters for growth rate
$\boldsymbol{m}_i$	Metabolism	$\mu_i^{t,max}, k_i^t, \eta_i^t$	Hill parameters for toxicity rate
$\boldsymbol{t}_i$	Toxicity	λ	Basal death rate
$\boldsymbol{f}_{ij}$	Nutrients consumed by the i^{th} bacteria	$\boldsymbol{p}_{ij}$	Metabolites produced by the i^{th} bacteria
$f_{i,j}^{tot}$	Consumed metabolites	ρ	Migration rate
$t_{i,j}^{tot}$	Toxic molecules	$MVHG(\boldsymbol{f}_j, \boldsymbol{m}_i, n_i^{bac})$	Nutrients multivariate hypergeometric distribution
$n_{i,j}^{bac}$	Number of bacteria		

D. Graphical User Interface

The GUI, implemented by adopting the Python Dash framework (in particular, Plotly and Pandas libraries for graphics and data frames management, respectively), allows simple setup and visualization of the simulation. Parameters defining the spatial structure and both initial nutrients and bacterial composition can be set on the Dashboard (Figure 2), also exploiting a table-like interface to modify the metabolisms for each bacterial species.

Additionally, the user can download simulation results as .xls tables and choose from a panel of preloaded parameter sets to start new simulations from relevant scenarios. Possible interesting random simulations, once obtained by casual selection of random seeds, can be re-called by selecting the previously adopted seed, automatically saved when downloading the data.

Metabolites and bacterial evolution over time can be observed in the bottom panels of the Dashboard, where the user can select the preferred visualization modality and graphical representation, by selecting the cell of interest for the metabolites and changing the view of the bacteria as absolute or relative, either as stack plot or histogram.

Moreover, the interactive graphs allow zooming, display information on mouseover and selection of the metabolites and species to be shown. All graphs can also be exported in a ready-to-publish format.

III. RESULTS

Starting from the same space definition (i.e., 5 bacterial species, able to interact with 5 different metabolites, migrating from left to right in a 5-unit linear space) but with differently distributed initial metabolites concentration and bacterial abundances along the whole space, the model is able to simulate different notable conditions and relevant scenarios, peculiar of natural bacterial communities (Figure 3) such as:

- Perfect fitness: most of the nutrients are highly metabolized by a single specific species (violet bacteria).
- Bad fitness: no nutrient in a cell is metabolized by any of the species causing a particularly hostile environment (only the nutrients in cell 0 allow a brief survival, consuming the present metabolites and producing the metabolite f1 as waste; migrating bacteria are not able to metabolize the

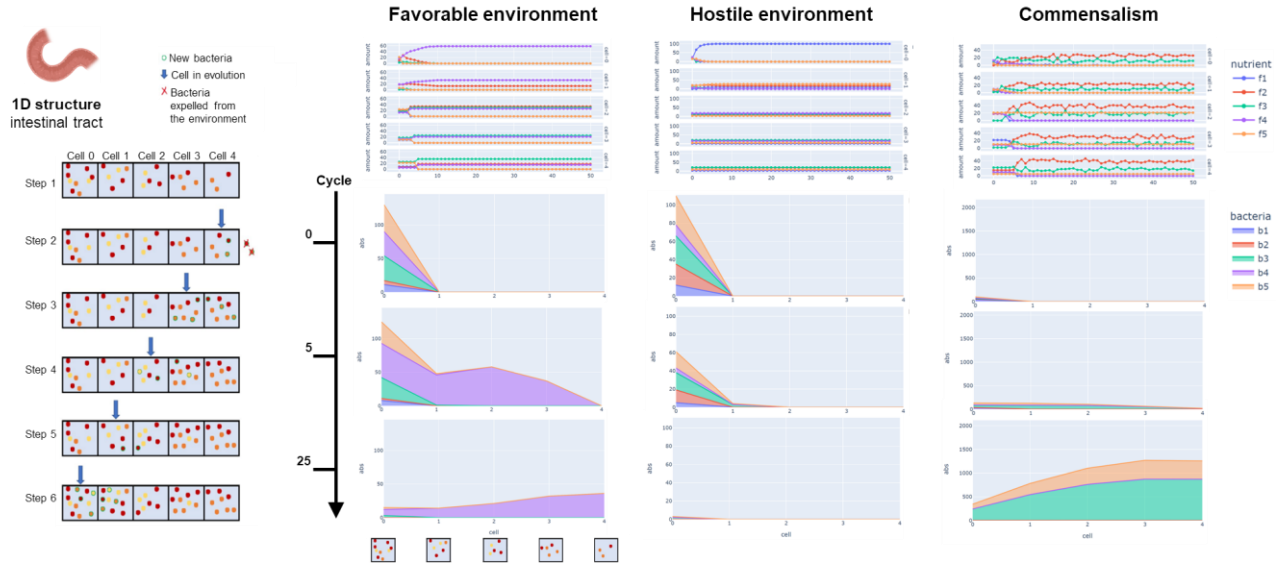

Fig. 3: Simulation of three significant scenarios in a gut-like environment.

nutrients in the following cells).

- Commensalism: most of the metabolites produced by a certain species are metabolized by another specific one and vice versa, i.e., bacteria b3 and b5 (green and orange) and metabolites f2 and f3 (red and green), creating a pseudo-periodic pattern in metabolite consumption and production.

IV. Conclusion

Despite the naive implementation of some features (e.g., migration, growth rate, etc.) of the current implementation, which is still undergoing significant enrichments and refinements, the simulator is already able to provide meaningful results; indeed, biologically sound characteristic and behaviors of the bacterial community emerge from random metabolic patterns and nutrient distribution, mimicking a natural evolution. The Python package implementing the model for a stand-alone use and the GUI will be available on our GitLab page (https://gitlab.com/sysbiobig).

So far, our model allows the description of bacterial communities growing on linear space (e.g., a gut tract), however, a 2D evolution framework is currently under development. In addition to spatial evolution refinements, ongoing activities are focused on the integration of specific nutrient lists and presets of known media composition from curated databases [11]-[12]. Moreover, information on actual bacterial species and related metabolisms are being added based on data contained in genome-scale metabolic models.

Lastly, a methodology to include and describe features related to bacterial communication (i.e., *quorum sensing*) is still under evaluation, to be exploited both in design and characterization in those studies where bacterial signaling significantly drives the overall community behavior [13]-[15].

Obviously, the GUI will also undergo changes in relation to the new features such as the possibility of selecting information from the database to automatically fill in the parameters which are now set by hand; or the possibility of visualizing space in 2D over time, always maintaining the interactivity characteristic. The ultimate goal will always be to maintain the characteristics of reliability, robustness, efficiency, reproducibility and scalability to allow a user to simulate, save and visualize the results in a single dashboard without necessarily writing code.

***Abstract*—Ensuring controlled environmental conditions during bacterial growth in a bioreactor is often crucial for the success of an experiment or to grant efficiency in an industrial procedure. For instance, in some experiments, temperature, oxygen and pH levels should be kept constant to achieve a good yield. Commercial bioreactors commonly provide proprietary automation systems for the regulation of some of the above mentioned variables, but the possibility to personalize the control algorithm, to jointly control multiple variables or to modify the control task, is usually rather limited. To surpass this limitation we aim to build an Arduino-based bioreactor, controlled by a PC and capable of running customized, possibly advanced, control algorithms. As a preliminary step toward this goal, in this contribution we present the design of a simple Arduino-based reactor for the control of the concentration of a substance (coffee) in a tank, by automatically pumping a concentrated solution of the same substance or pure water. The optimal command of the pumps is computed with a nonlinear model predictive control (MPC) by using a model of the mass balance occurring within the reactor. The controller is implemented in Simulink. The system is tested via hardware-in-the-loop (HIL) simulation. The controller proved to be able to drive the simulated concentration of caffeine to the desired value, and it was verified that the pumps were correctly commanded. Similarly, sensor readings were also successfully transferred to the Simulink scheme. Future experiments with the physical system will complete the validation and demonstrate the possibility of creating controller prototypes in Matlab for this toy problem.**

I. INTRODUCTION

In a bioreactor, automatic control systems are used to monitor and control various parameters, such as temperature, pH, dissolved oxygen, dissolved carbon dioxide and kinetic metabolic rates, in order to maintain optimal conditions for microorganisms growth and product production. Off-the-shelf equipment usually offers proprietary control systems to regulate these key parameters, for instance by using pumps to inject acids and bases to control pH, using heating jackets and coils to exchange heat and control temperature, blowing air or oxygen and managing stirring speed to control dissolved oxygen. Finally, by adjusting the amount of nutrients that are supplied in fed-batch and continuous bioreactors, one can affect the microorganisms metabolic activity and thus control their growth rate. Proprietary bioreactor systems do not always allow complete manipulation of the actuators and, in particular, of the peristaltic pumps adjusting the feed and uptake rates. Moreover, these setups are expensive and not easily affordable in low budget experiments or for teaching purposes.

On the contrary, do it yourself (DIY) projects are emerging as a low-cost alternative with the advantage of offering complete control of process variables through inexpensive components managed by microcontrollers such as Arduino boards [1], as well as allowing the manipulation of the feed rates with Arduino, via dedicated customized algorithms [2].

As a first step toward the construction of a fully customizable bioreactor, this paper will present a simple system for the automatic control of the concentration of a substance (coffee) by pumping either water, to dilute the solution, or a concentrated solution of the same substance. Specifically, the inflow rate of two peristaltic pumps is calculated in real-time with a nonlinear MPC on the basis of the concentration measured by an optical sensor. The non-linear control unit is implemented on a laptop computer and can interact with the peristatic pumps and the optical sensor thanks to an Arduino board that serves input-output interface. In this work, we present an hardware-in-the-loop (HIL) validation of the system, where the physical system is replaced by a model simulated in a different unit (another Arduino board). The controller and the simulation unit communicate via the input-output interfaces, so their functioning can also be verified.

Even if of limited practical impact by itself, this toy problem retains non-trivial control challenges, as it will be illustrated below. Furthermore, as a further step, one could use the same equipment to control bacterial growth in a bioreactor by controlling the concentration of a key nutrient (e.g. carbon sources or nitrogen sources). This second, more relevant problem, shares various analogies with the toy problem presented here, despite an higher complexity due to the dynamical interaction of biomass, substrates and products/by-products.

The advantages of using Arduino to build the above illustrated system lies in the fact that it offers a cheap and flexible platform to read data from the the sensor and to

control the peristaltic pumps. Moreover, there are affordable Arduino-compatible sensors (temperature, pH and dissolved gas concentration), as well as several Arduino-compatible actuators, that can be added in future stages of the project, to enable the control of additional process parameters. Moreover, Arduino allows an easy interaction with a PC via serial port and a library of Arduino real-time control algorithms and functions is available in Matlab Simulink, allowing rapid implementation of, arbitrarily advanced, control schemes.

As far as the control technique is concerned, MPC is an appealing strategy in the control of bioreactors requiring feed rate manipulation, since it can manage multi-input multi-output systems, account for the strong saturation of the actuators and permits custom cost function to be minimized, making the controller versatile for different strategies. Several examples in the literature show the use of MPC in different cultures with different organisms, ranging from bacteria, mammalian cells, and microalgae [3], with the aims that include maximizing product concentration [4], minimizing by-product formation [5], maximizing productivity and biomass concentration [6], tracking of biomass and substrate concentration [7], [8] or regulation of kinetic rates, i.e., uptake and growth [9].

II. System description

A. Problem formulation

As discussed above, in this paper we consider the toy problem of steering the concentration $C(t)$ in $[mg/mL]$ of a single substance (coffee) in a tank, following a piece-wise constant target profile $C_{\text{ref}}(t)$ from an arbitrary initial value.

The system architecture is depicted in Fig. 1. It consists of three containers, namely the reactor in which mass exchange takes place, and two feeding reservoirs. Two peristaltic pumps are used to feed the reactor with the liquids contained in the two reservoirs, i.e., the highly concentrated coffee solution with concentration $C_{in,1}$, and pure water with caffeine concentration $C_{in,2} = 0mg/mL$ (i.e., no caffeine dissolved).

The control of the coffee concentration in the reactor is performed by adjusting the inflow of the two pumps, denoted respectively with $F_{\text{in},1}$ and $F_{\text{in},2}$, both in $[mL/min]$. We consider a continuous reactor framework where the volume in the bioreactor is kept constant by applying an harvest outflow F_{out} such that $F_{\text{out}} = F_{\text{in},1} + F_{\text{in},2}$.

The outflow is obtained thanks to an harvest pump, connected to the main reactor. All the three pumps are wired to an Arduino board, to turn power on and off as required, to achieve the commanded average flows during one sample time ($\tau = 10s$).

B. System modeling

The mathematical model can be derived directly from the mass balance on the system. In fact, the amount of mass in the reactor can increase if liquids are introduced with feed rates and can decrease due to dilution effect of introduced liquids [10]. Under assumptions of homogeneity (well mixed system), the concentration of caffeine in the reactor is perturbed according to the net balance of mass:

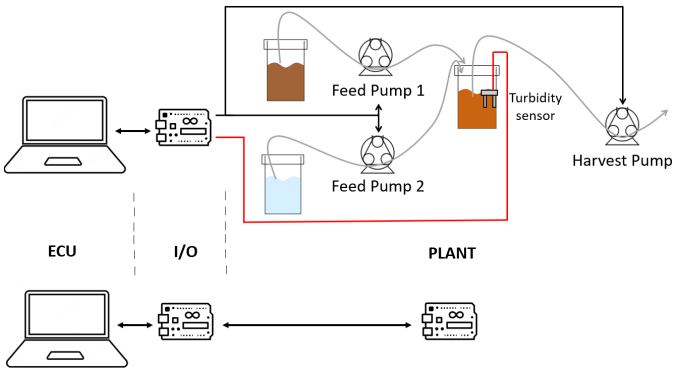

Fig. 1: Architecture of the system. Upper half: physical set-up, the control algorithm running on the PC interacts with pumps and sensor via the Arduino board. Bottom half: hardware in the loop simulation, the physical system is simulated on a second Arduino board.

$$\dot{C} = \frac{F_{in,1}(t)}{V} C_{in,1} - \frac{F_{in,1}(t)}{V} C(t) - \frac{F_{in,2}(t)}{V} C(t) \qquad (1)$$

where V $[mL]$ is the total volume of the reactor. Since the second feed bottle solution has no caffeine, there is no mass increase by pumping the solution but only mass decrease given by dilution effect. Since we set $F_{\text{out}} = F_{\text{in},1} + F_{\text{in},2}$ (continuous bioreactor), the volume does not change

$$\dot{V} = F_{in,1}(t) + F_{in,2}(t) - F_{out}(t) = 0 \qquad (2)$$

and thus can be treated as a parameter rather than as a state. The final model has a single state, two inputs and one output:

$$x = [C], \quad \bar{u} = \left[F_{in,1},\ F_{in,2}\right]^T, \quad y = x \qquad (3)$$

All the parameters, variables and constants involved in the model are reported in table I. The state is directly measured with a sensor based on optical absorbance and we will neglect the noise affecting the sensor. Therefore, the construction of an observer is superfluous.

As a final comment, it should be stressed that this simple dual-input-single-output system is strongly nonlinear, as the inputs are both multiplied by the state in Eq.(3). This makes this toy problem non trivial. For the physical implementation and software methodologies used, see Section II-D.

C. Control design

The nonlinear MPC was implemented in Matlab via *nlmpc* function and based on model described in the previous section. The differential Eq.(1) was solved numerically using the Matlab routine ODE45 (implementing a Runge-Kutta integration). The objective function J for the optimization include a penalty term based on the deviation between the target reference for coffee concentration and the model prediction. In addition, a nominal input value of zero was imposed to ensure that the pumps were turned-off once the set-point was reached.

$$J = \sum_{j=0}^{p} (q(\hat{C}((k+j+1)\tau) - C_{\text{ref}}((k+j+1)\tau))^2 + \bar{u}((k+j)\tau))^T \bar{u}((k+j)\tau))$$

where $C_{\text{ref}}(k\tau)$ is the reference value for caffeine concentration at time instant $k\tau$, p is the prediction horizon and q is the

weight on control aggressiveness. A suitable tuning for q was found trough trial and error in simulation and set to $q = 10$. Similarly, the prediction horizon was set to $p = 10$. The control horizon m was instead set to $m = 2$. The constraints are dictated by the physical flow rate limitations of the pumps. The maximum flow rate of each pump is $62\ mL/min$, so the maximum and minimum constraint value assigned for the input are:

$$0\frac{mL}{min} \leq F_{in,i}(k\tau) \leq 62\frac{mL}{min} \quad \text{with } i \in \{1,2\} \qquad (4)$$

TABLE I: SYSTEM PARAMETERS and THEIR VALUES

Symbol	*Description*	*Value*	*Unit*
τ	sampling time	10	s
C	caffeine concentration in the main reactor	*var*	mg/mL
$C_{in,1}$	caffeine concentration in first feed reservoir	2	mg/mL
V	volume of the reactor	35	mL
$F_{in,1}$	flow rate of coffee solution	*var*	mL/min
$F_{in,2}$	flow rate of water	*var*	mL/min
F_{out}	flow rate for the exhaust pump	*var*	mL/min

C_{ref}	reference for caffeine concentration	*var*	mg/mL
q	control aggressiveness weight	10	[-]
p	prediction horizon	10	[-]
m	control horizon	2	[-]

D. Control implementation

1) Hardware: Data storage and control algorithms were performed using a HP laptop running Windows 10, equipped with an Intel Core i3-8145U processor $2.1GHz$ frequency, $8GB$ of RAM and integrated graphics.

The computer was connected to an *Arduino Mega2560 board* via USB cable, to provide power supply and serial communication for data exchange. A second Arduino Mega2560 board, was used to simulate the system in the HIL scheme. The pumps used were the *12V peristaltic pump* (Adafruit ID:1150), powered by a $12V$ *Switching Power Supplies* (Delta Eletronics). Three digital output ports were used to command the pumps flow rates, using pulse width modulation (PWM) through three *Motor driver board* (Adafruit ID:3190), one for each pump. Lastly, an *Analog turbidity sensor* for Arduino (SKU:SEN0189 DFRobot) was also tested, to be used for future measures of turbidity, assumed proportional to the caffeine concentration.

The reading of the model output implemented by the Arduino board was accomplished by building a RC low pass filter circuit that extract the mean value of PWM digital output that could be read by the analog input pin of the I/O board. A $10k\Omega$ resistor and a $10\mu F$ capacitor were used for the circuit. The same type of circuit was used in the unit in charge of simulating the system to read the voltage commands sent to the pumps by the controller.

TABLE II: HARDWARE COMPONENTS USED (WITH LINK TO THE WEBSITE USED TO PURCHASE THEM)

Hardware	*Quantity*
Analog turbidity sensor	1
12V peristaltic pump	3
12V Switching Power Supplies	1
Arduino Mega2560 board	1
Motor driver board	3

2) Software: The controller was implemented using the MathWorks' Simulink programming environment, integrated in Matlab, see Fig.2. Specifically, the Simulink Desktop Real-Time and Arduino Support from Simulink packages were used for reading and writing of Arduino analog inputs and outputs, as well as for digital inputs and outputs in real time.

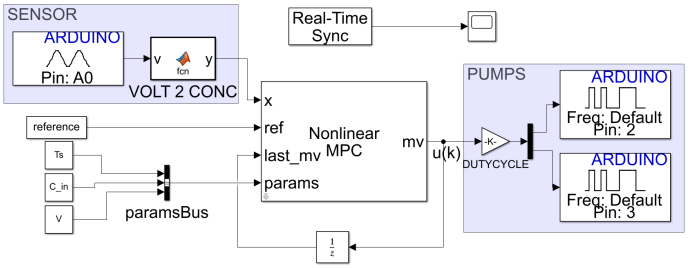

Fig. 2: Simulink control scheme for the HIL simulation.

The control scheme in Fig.2 is structured as follows:

- The area SENSOR reads the sensor data and converts the voltage value into the corresponding coffee concentration;
- The MPC block receive this value and computes the optimal flow rates value of the peristaltic pumps. For the creation of the MPC object and the MPC block, the Model Predictive Control Toolbox was used.
- In the PUMPS area, the value provided by the MPC is used to compute the dutycycle for the PWM blocks of digital output of Arduino.
- The real-time execution is ensured by the *real-time sync* block for which the sampling time must be provided.

Also the simulation unit was programmed using Simulink and porting the code on the Arduino Board. The plant simulated using *ode4* integration see Fig.3.

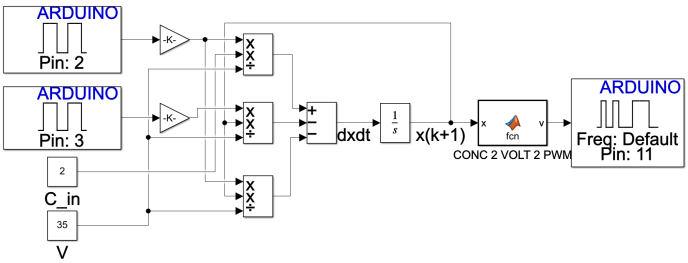

Fig. 3: Simulink model of the plant running on the Arduino board.

III. SIMULATION RESULTS

We show the results for a 3 minutes experiment in which the coffee concentration reference profile $C_{\text{ref}}(t)$ changes 3 times. It starts at $1.3mg/mL$, then drops to $0.7mg/mL$ after $30s$ and finally rises again to $1.7mg/mL$ at $90s$. The initial concentration is $C(0) = 1mg/mL$

Fig.4 shows that the control by nonlinear MPC is consistent with the physical understanding of the system: when the concentration in the bioreactor is higher than the reference value, the water is pumped to dilute the coffee concentration, while the pump connected to the solution with coffee is not

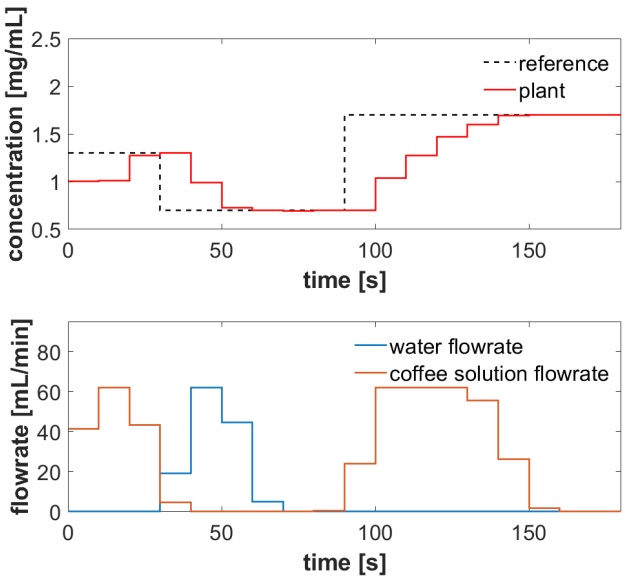

Fig. 4: Simulation results. Caffeine concentration tracking of the reference profile and pump commands computed by MPC.

activated. On the other hand, the opposite occurs when the state is below the reference value. Finally, it can be seen that when the concentration has reached the set-point, both pumps are switched off and the system dynamic becomes zero.

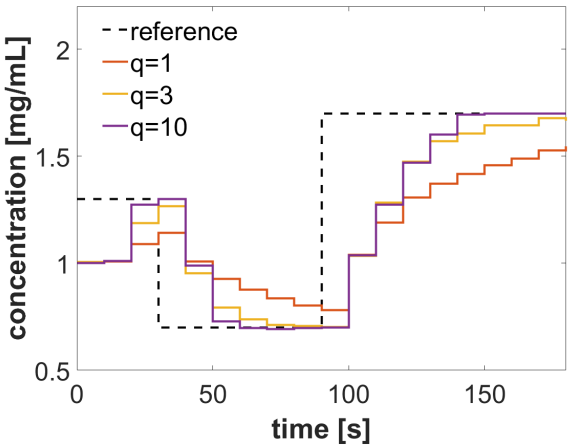

Fig. 5: Caffeine concentration tracking of the reference obtained for different values of the tuning parameter q in the cost function.

In Fig. 5 it is shown the output of the plant for different values of the weight $q \in \{1, 3, 10\}$. When the weight is small, the controller is less aggressive, causing the rise time to be slower. Increasing the weight, on the other hand, results in a faster response, as expected. Lastly, in these experiments, we verified that the activation time of the pump correctly satisfy the MPC requests.

IV. Conclusion and future perspectives

In this manuscript, we illustrated the design and testing of simple system for the automatic control of the concentration of a substance in a simple reactor, achieved by modulation of the inflow of two pumps. A non linear model predictive controller was developed in Matlab Simulink to track a reference trajectory for the concentration of a substance. The MPC leveraged a model built taking into account the mass balance in the reactor. Arduino support from Simulink package made it possible to use block diagrams to communicate with Arduino board and implement physical activation of input pumps for a HIL simulation. The MPC proved helpful in handling a single concentration and two manipulated variables.

Future works will include the physical realization of this simple system and its experimental validation.

Once the system will be validated on this toy problem, the same hardware will be used for a more practically relevant task: the control of the growth of a microorganism population by administration of a key nutrient. This objective will be pursued by equipping the MPC with a model capable to link the consumption of nutrients with bacterial growth.

We then envision, by leveraging the modularity offered by Arduino and the flexibility of the MPC framework, to build a customizable facility to control biomass concentrations and metabolic activity by exploiting different input substrates and input substances.

***Abstract*—SWIM is a recently developed network-based tool that fulfils the criteria of the new quickly emerging field of Network Medicine in finding disease-associated genes, called switch genes. The phenotype-specific applications of SWIM are broad and include the identification of switch genes in grapevine berry maturation as well as in complex diseases, including but not limited to human cancers.**
Here, a brief summary of the promising results obtained by applying SWIM in different biological contexts is presented.

***Keywords*—Network Medicine, Network Theory, Disease genes.**

I. INTRODUCTION

Recently, I developed a new promising methodology, called SWIM (SWItch Miner), which integrates different network-based methods to analyse the correlation network arising from large-scale gene expression data [1]. Considering the topological properties of the nodes and assessing their functional roles according to their ability to convey information within and between modules in the network, SWIM identifies a small pool of genes (called switch genes) that are associated with intriguing patterns of molecular co-abundance and play a crucial role in the observed phenotype.

The phenotype-specific applications of SWIM are broad and include the identification of switch genes in grapevine berry maturation (*Vitis vinifera*) as well as in human cancers, including Glioblastoma (Fig. 1).

In viticulture, SWIM has been gainfully applied to the global gene expression atlas of grapevine in order to identify switch genes between immature and mature phase of the developmental program of grapevine [2]. In cancer research, SWIM network analysis has been gainfully applied to a large panel of TCGA (The Cancer Genome Atlas) cancer datasets in order to characterise disease etiologies and identify potential therapeutic targets [1]. SWIM has also been used to investigate glioblastoma multiforme (GBM) and to uncover new insights into the molecular mechanism determining the stem-like phenotype of glioblastoma cells [3], [4].

Recently, SWIM methodology has been successfully applied to the chronic obstructive pulmonary disease (COPD), a severe lung disease characterized by progressive and incompletely reversible airflow obstruction [5]. The results of this study would both support known pathways and provide evidence for novel pathways in COPD pathogenesis. In the last two years, SWIM has been applied within the framework of Network Medicine to study the interplay between switch genes and human diseases in the human interactome (i.e., the cellular network of all physical molecular interactions) [6].

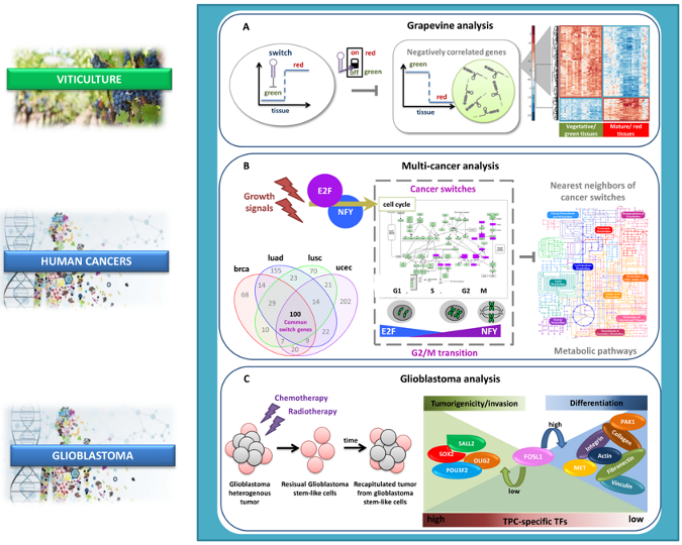

Fig. 1: Phenotype-specific applications of SWIM methodology.

In the following, a detailed description of the more recent applications of SWIM to complex diseases is provided.

II. METHODS

SWIM is a freely downloadable network-based tool, developed both in MATLAB [1] and in R language [7], which predicts important (switch) genes that are strongly associated with drastic changes in cell phenotype. SWIM first computes the differentially expressed genes (DEGs) between two conditions of interest (e.g., normal state versus tumor state) and then builds a gene correlation network (GCN) by calculating correlations (positive and negative) between the expression profiles of each gene pair. Specifically, SWIM implements a hard thresholding approach to build a GCN where nodes are DEGs, and a link occurs if their expression profiles are highly correlated or anti-correlated (according to a defined threshold). Then, SWIM classifies each network hub (i.e., nodes with degree at least equal to 5 according to [8]) as date, party, or fight-club on the basis of the Average Pearson Correlation Coefficient (APCC) between its expression profile and that of its first nearest neighbours. Date hubs show a positive and mild APCC value; party hubs show a positive and high APCC value; fight-clubs hubs show a negative APCC

value. To assign a role to each node in the GCN, SWIM firstly searches for clusters (or modules) using the k-means algorithm and evaluates the quality of clusters by minimising the Sum of the Squared Error (SSE), depending on the distance of each object to its closest centroid. The position of an elbow (i.e., change of the slope) in the behaviour of the SSE as function of the number of clusters (scree plot) indicates the number of clusters to use. Then, SWIM draws the heat cartography map by evaluating two coordinates related to their intra- and inter-modular connections: the clusterphobic coefficient, which is a measure the fear of each node to be confined in its own cluster and measures the links of each node to nodes outside its own cluster; the within-module degree, which measures how "well-connected" each node is within its own cluster. In the heat cartography map, dots (i.e., nodes of the correlation network) are distributed across seven regions (R1 to R7) according to their clusterphobic coefficient (x-axis), and to their within-module degree (y-axis). Each node is coloured according to its APCC value. Nodes having much more external than internal links present high values of the clusterphobic coefficient and are called connectors, whereas high values of the within-module degree denote nodes that are hubs within their community and are called local hubs. Switch genes are defined as a subset of fight-club nodes with the following features: i) they are network connectors that mainly interact outside their own cluster (very high value of the clusterphobic coefficient); ii) they are not local hubs (very low value of the within-module degree); iii) they are mainly anti-correlated with their interaction partners (negative value of the APCC).

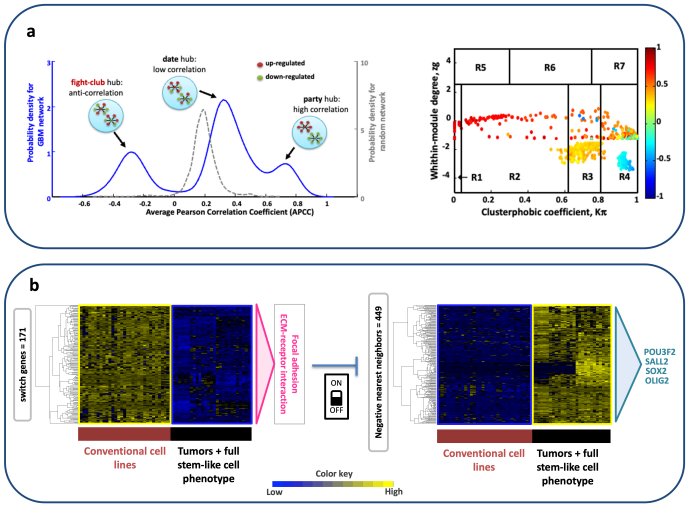

Fig. 2: SWIM application to the GBM dataset of [13]. (a) Left: probability distribution of APCC for hubs identified in the GBM correlation network (blue solid line) and in its randomized counterpart obtained by shuffling the edges but preserving the degree of each node (grey dashed line). Differently from the randomized case, the true APCC distribution shows a clear trimodal pattern where peaks correspond to previously reported hub categories (such as party and date hubs) but also to the new category of hubs, the fight-club hubs. Right: heat cartography maps where dots correspond to network nodes colored according of APCC. (b) Dendrogram and heat map of switch genes (left) and of their negative nearest neighbors (right) with their corresponding enriched pathways The expression profiles of the switch genes and their negative nearest neighbors are clustered according to genes (rows) and GBM cell lines (columns), using Pearson correlation distance as metrics. Heat map colors represent different expression levels increasing from blue to yellow.

III. Results and Discussions

A. Glioblastoma

Glioblastoma is the most aggressive and frequent brain tumour, with a median survival time of 12–15 months from diagnosis [9], [10], [11]. The mortality rate is extremely high with the 5-years survival rate achieved for only 5% of patients. This tumour is resistant to the standard therapies like radio and chemotherapy. Its aggressiveness is due to the presence of cancer stem-like cells that sustain tumour growth and are hence named "tumour fuel". Cancer stem-like cells are cancer cells that have characteristics typical of normal stem cells: i) self-renewal that is the ability to maintain their undifferentiated state; ii) potency that is the ability to differentiate into specialised cell types. Cancer stem-like cells are resistant to many conventional cancer therapies and cause relapse and metastasis by giving rise to new tumours [12]. Thus, targeting cancer stem-like cells could pave the way for new therapeutic strategies.

A recent study identified 19 neurodevelopmental transcription factors (TFs) that are selectively expressed in glioblastoma stem-like cells to maintain their stem-like phenotype and prevent differentiation [14]. A subset of only four of them (named 4-core TFs), SOX2, OLIG2, POU3F2, and SALL2, has been shown to be sufficient to fully reprogram differentiated cells into glioblastoma stem-like cells [14].

In order to identify switch genes related to the stem-like phenotype, SWIM was applied to glioblastoma dataset of [14] and then the further dataset of [13] was used to validate the results [3], [4]. In Fig. 2 the results obtained by applying SWIM to the GBM dataset obtained in [13] are shown. The APCC behaviour (blue solid line) shows a clear peak for negative values indicating the fight-club hubs (Fig. 2a left). The APCC randomised counterpart (grey dashed line), obtained by shuffling the edges but preserving the degree of each node, indicates that fight-club hubs are not a random event. A subset of the fight-club hubs falling in the region of connectors (R4) of the heat cartography map corresponds to switch genes (Fig. 2a right, blue dots). The expression profiles (z-score normalised) of the switch genes (Fig. 2b left) and their negative nearest neighbours (Fig. 2b right) indicates that switch genes are all up-regulated in differentiated cells, and their activation strongly correlates with the inhibition of their first network interactors, including the 4-core TFs. By performing a functional enrichment analysis, switch genes were found to be involved in cell-cell communication pathway. Thus, while their activation could promote differentiation and restrain tumour growth, their repression could promote tumour invasiveness due to the loss of cell-cell adhesion.

Among the common switch genes obtained by running

SWIM on the two GBM datasets of [13] and [14], there is FOSL1. It is up-regulated in differentiated glioblastoma cells and this up-regulation highly correlates with the over-expression of genes involved in cell-cell communications (Fig. 3 top left/middle). It is down-regulated in stem-like cells and this down-regulation highly correlates with the up-regulation of the 4-core of TFs (Fig. 3 top right). In order to investigate possible co-regulation of the 4-core of TFs, their promoter regions were inspected to search for enriched motifs and they were found to harbour a consensus binding site for FOSL1 (Fig. 3 bottom right).

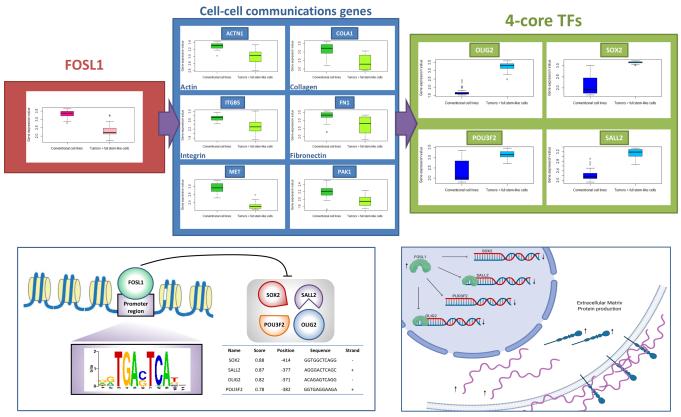

Fig. 3: FOSL1 mode of action. Upper panel: from left to right, boxplot of the expression of FOSL1, its positive and negative nearest neighbours in the GBM correlation network, in conventional GBM cell lines with respect to cancer stem-like cells in GBM dataset of [13]. Lower panel: logo plot for the statistically significant enriched motif found by using JASPAR to analyse the promotore regions of the 4-core of TFs (left). This motif corresponds to a consensus binding site for FOSL1. A schematic representation of the FOSL1 mode of actions: it acts as putative repressor of the 4-core of TFs and its activation reduces the cells' ability to generate aggregates increasing the extracellular matrix component.

Altogether these findings suggest FOSL1 as possible therapeutic biomarker of glioblastoma, which could promote the differentiation of cancer stem-like cells by repressing the 4-core TFs. This hypothesis has been partially experimentally validated in [15], where the NTERA-2 and HEK293T cells where selected for an in-vitro study to investigate the role of FOSL1 in the reprogramming mechanisms (Fig. 3 bottom right). The two cell lines where transfected with a constitutive FOSL1 cDNA plasmid. This study showed that FOSL1 i) directly regulates the 4-core of TFs binding their promoter regions and reducing their expression; ii) is involved in the deregulation of several stemness markers; iii) reduces the cells' ability to generate aggregates increasing the extracellular matrix component FN1. Although further experiments are necessary, these findings support the hypothesis that FOSL1 may reprograms the stemness by regulating the 4-core TFs.

This result could have a significant impact on personalized healthcare, since promoting differentiation and thus restraining tumor growth may support rational, personalized planning of disease prevention or treatment.

B. COPD

COPD is a heterogeneous and complex syndrome influenced by both genetic and environmental determinants, and is one of the main causes of morbidity and mortality worldwide.

By applying SWIM on COPD [5], the correlation network turned out to be formed by three well-characterised modules (data not shown, see [5]): i) one (module 3) populated by switch genes, all up-regulated in COPD cases and involved in COPD-related pathways, like B cell receptor signalling pathway; ii) one (module 1) populated by negative interactors of switch genes, down-regulated in COPD cases, including well-known GWAS genes like AGER and CAVIN1; iii) one (module 2) populated by well-recognised immune signature genes, all up-regulated in COPD cases. Switch genes appear to form localised connected subnetworks displaying an intriguingly common pattern of up-regulation in COPD cases compared with controls. A more sophisticated analysis revealed that they were not only topologically related, but also functionally relevant to the observed phenotype as witnessed by their enrichment in the regulation of inflammatory and immune responses.

In order to demonstrate the disease specificity of switch genes, SWIM was applied on another COPD dataset and on the acute respiratory distress syndrome (ARDS), another severe lung disease with an inflammatory component. The two lists of COPD switch genes were found to form overlapping modules in the human interactome that are topologically separated with the ARDS switch genes (data not shown, see [5]). This observation demonstrates that even though different diseases can share similar endophenotypes, the molecular network determinants responsible for them are disease-specific.

Interestingly, ARDS switch genes were different from COPD switch genes, but the major pathways affected in the two diseases were similar, emphasising that different diseases often have common underlying mechanisms and share intermediate endophenotypes (convergent phenotypes) [16].

C. Network Medicine

Network Medicine is a new emerging paradigm in medicine, where disease proteins are assumed not to be randomly scattered, but agglomerate in specific regions of the molecular interactome, suggesting the existence of specific disease network modules for each disease [17], [18], [19].

To quantify the interplay between switch genes and human diseases in the human interactome, the results obtained by the pan-cancer [1] and COPD [5] SWIM-based analysis were complemented with the application of SWIM tool on two cardiac disorders (i.e., ischemic and non-ischemic cardiomyopathy) and on Alzheimer's disease (AD) [6]. Switch genes associated with specific disorders were found to be not randomly scattered but they form localised connected subnetworks (Fig. 4a). These subnetworks overlap between similar diseases (like cancers or cardiac disorders) and are situated in different neighbourhoods for pathologically distinct phenotypes (like AD and COPD), showing a direct relation between the pathobiological similarity of diseases and their

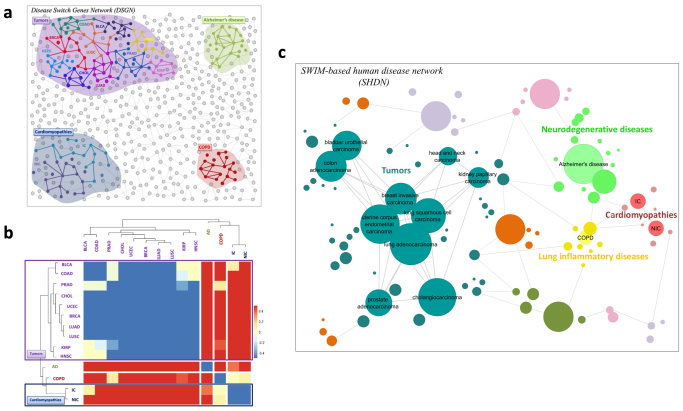

Fig. 4: SWIM and Network Medicine. (a) Switch genes mapping on the human interactome. (b) Hierarchical clustering where the network-based separation measure was used as a distance metric: blue color corresponds to overlapping modules, red color corresponds to non-overlapping modules. (c) SHDN where nodes are the disorders and the size of each node is proportional to the number of switch genes involved in the corresponding disorder. Nodes are coloured based on the disorder class to which they belong. Labeled nodes correspond to the diseases analysed, while unlabelled nodes are artificial.

relative distance in the human interactome (Fig. 4a). These results were confirmed by the hierarchical clustering where two main clusters were found: one including all tumour datasets and one including the two cardiomyopathies along with AD and COPD datasets as isolated branches (Fig. 4b). Finally, the first SWIM-informed Human Disease Network (SHDN) was built (Fig. 4c), where nodes correspond to distinct disorders and a link occurs between two diseases if they share a substantial number of switch genes. Clustering of nodes of similar color (denoting the same disease class) means that similar pathophenotypes have a higher probability of sharing switch genes than do pathophenotypes that belong to different disease classes.

These findings support the hypothesis that SWIM-based correlation network analysis can serve as a useful tool for efficient screening of potentially new disease gene associations. When integrated with an interactome-based network analysis, it not only identifies novel candidate disease genes, but also may offer testable hypotheses by which to elucidate the molecular underpinnings of human disease and reveal commonalities between seemingly unrelated diseases.

The dissemination of synthetic biology into materials science allows to realize engineered living materials (ELMs). By being alive, ELMs represent a radically different paradigm compared to traditional materials, enabling new functionalities, with decreased costs and environmental impact. This work aims to set up a bioprinting workflow to reproducibly fabricate bacteria-laden materials with biosensing capabilities, to address field-relevant applications.

***Keywords*— Bioprinting, synthetic biology, engineered living materials, biosensors.**

I. Introduction

ELMs are rapidly emerging as an innovative class of materials with tailored morphologies and functions. Born at the intersection of synthetic biology and materials science, the field of ELMs allows to realize 3D structures composed by living and non-living components [1]. These systems can take advantage of the broad range of modalities now readily achievable with modern genetic engineering, including sensing and responding functions, molecule production, and self-assembly.

Whole-cell biosensors are generally confined in vials into which the sample to be tested is added manually. In contrast to the liquid culture, there has been an increasing interest in trying to trap cells into abiotic materials. This advanced system allows to exploit biological properties to perform a specific functionality, leveraging non-living matter for structural mechanical characteristics and enabling portability of sensing devices. Bioprinting brings advantages of reproducibility, spatial control, customization of the product in terms of shape, and automation. Functional bacteria-laden structures in the form of ELMs are considered as a transformative technology as they can address real life challenges, e.g., in therapeutics [2], [3], diagnosis, pollutant detection [4], [5], and industrial manufacturing [6], [7]. The genetic circuits of this type of devices are designed to emit fluorescence, luminescence or pigmentation upon detection of the specific contaminant, creating low cost biological sensors compatible with remote detection [8]. In contrast to systems with additional substrates for activation, the ease of use and visualization may allow ELMs biosensors to be employed for rapid, on-site use. Furthermore, some examples of multi-strain materials are reported in the literature [1], [9], [10], [11], which can contribute to increase the complexity of the device functionality and to multiplexed sensing. Finally, these materials with the addition of appropriate biocontainment strategies avoid ethical, safety, and acceptance issues of using living biosensors in the field.

Here, the idea is to establish a workflow to create bacteria-laden biosensor materials. To realize and validate this platform, bioprinting and synthetic biology techniques were used and the reproducibility of fabricated structures as well as their functions were addressed. We anticipate that ELMs can be used for prototyping and automation of a new generation of smart materials, relevant for real-world biosensing purposes.

II. Materials and Methods

Non-pathogenic *Escherichia coli* strains were engineered to carry out biosensing functions via synthetic circuits including a signaling molecule (*Vibrio fischerii* autoinducer, VAI) inducible promoter and a reporter gene providing visible pigmentation as readout.

Engineered bacteria suspended in 2-fold concentrated LB media were mixed with a sodium alginate (SA)- and gelatin-(GEL) based hydrogel (1:10 ratio) to obtain the bioink. The living materials were printed using the INKREDIBLE+ bioprinter (Cellink AB, Sweden) and crosslinked with $CaCl_2$. The structures can be used immediately and incubated the overnight at 37 °C on LB agar plate with or without inducers, or stored in the refrigerator for future use. Variations of hydrogel composition (e.g., concentration of SA, removal of GEL, concentration of LB), incubation protocol (e.g., LB media, no media), crosslinking procedure (e.g., supplementation of $CaCl_2$ in LB medium) were also tested to screen for the optimal bioprinting workflow.

Viability tests of bacteria within the material, using the colony forming units method (CFUs), were performed for two weeks by dissolving the ELM with sodium citrate.

In this work, we used engineered bacteria that express the red fluorescent protein (RFP), also allowing observation of red color development at naked eye. Protein expression was verified by fluorescence microscopy (Eclipse 80i microscope, Nikon), and image analysis of ELMs, taking the only red component through the CIELAB space. Color data derived from pictures were confirmed by fluorescence measurements in the microplate reader (Infinite F200Pro, Tecan), by transferring cut pieces of ELMs into 96-well plates and measuring red fluorescence in 3-by-3 square-filled acquisitions per well (RFP gain = 30) and averaging the obtained values.

For biosensing experiments, after the construction of the libraries of interest, we first characterized the biosensors with liquid assays in the microplate reader, then we studied printed ELMs incubated under optimal laboratory conditions (LB agar plates containing chemical inducers).

Finally, experiments in more realistic environments under non-optimal incubation conditions (e.g., soil and clinical samples as matrices), were carried out. Non-optimal incubation conditions refer to incubation of the structures on plastic or cut LB agar, both by inducing with a 200 µl drop of inducer pipetted on the ELMs. For sensing tests in environmentally relevant samples, VAI was added to the soil by adding about 10% (w/w) water containing the autoinducer at a 400 nM concentration, and structures were placed in the induced soil (incubation at RT). For experiments with clinical samples the structures were tested by pipetting 200 µl the sample on the ELMs, incubating the structures overnight at 37 °C on a cut LB agar.

III. Results and Discussion

A. *ELM bioprinting*

A workflow for printing living bacterial materials was established and optimized to create tailored shapes and single/multi-strain structures. In order to obtain the optimal workflow for bacterial printing, we first investigated the bioink composition in terms of hydrogels and nutrients, growth conditions, printing support, and crosslinking procedure (Fig. 1).

For the composition of the hydrogels we tested 6% SA, 8% SA, 10% SA, and 8% SA + 4% GEL (w/v). The first confirmed to give the weakest structure, while among the last two, the one with the addition of gelatin was chosen due to reliable handling and to avoid any breakage of the structures over time.

We also investigated how incubate the ELMs, testing solid LB, liquid LB medium, plastic, or PBS. The conditions with LB proved to be the best, allow a naked eye color development (using a constitutive bacterial strain of RFP, named MCred), suggesting that these external nutrients provide the necessary support for growth and gene expression. Furthermore, solid LB led to better results in terms of viability than the liquid condition, avoiding also situations as the collapse of the constructs.

In addition, incubation in liquid media caused a rapid contamination of the liquid by planktonic growth, probably depleting some nutrients.

The addition of nutrients directly into the bioink was also studied, comparing the viability of the bacteria inside the structures with LB, 2-fold and 4-fold concentrated LB. Since there were only differences with the first option, between 2-fold and 4-fold the former was selected as there were no significant improvements with 4-fold concentrated nutrients.

For the crosslinking procedure, we tested the traditional one, i.e., the addition of $CaCl_2$ to the structure after printing in a plastic support, and the alternative with the crosslinking agent in the culture medium by printing directly over the LB agar. The latter showed problems such as clogging of the nozzle with agar, due to non-perfectly flat media surfaces, so we chose the traditional method.

Bioprinting reproducibility was demonstrated analyzing print fidelity parameters in terms of coefficient of variation, both for filament size and filament distance in at least 30 values measured from grid-like structures (Fig. 2A). In addition, reproducibility was also proven in terms of weight of the printed structures, both for 20x20x2.5 mm grids (CV = 18%) and 10x10x0.7 mm (CV = 1%).

B. *ELM functionality*

The first step to validate the platform from a biological point of view was to study cell viability of bacteria within the material. The results demonstrated that, without changing culture media, after two days there is a decrease in viability probably due to nutrient deficiency and accumulation of waste products. Cell viability of ELMs is reported after being printed and after one day of overnight incubation at 37 °C (Fig. 2B), demonstrating the bacterial growth in the bioink.

Gene expression investigation, by analyzing sections of printed structures with fluorescence microscopy, confirmed what emerged in the literature. In fact the fluorescence resulted greater in the surface rather than the core, probably related to the different oxygenation and therefore a different viability of the bacteria between the outside and inside, and a different

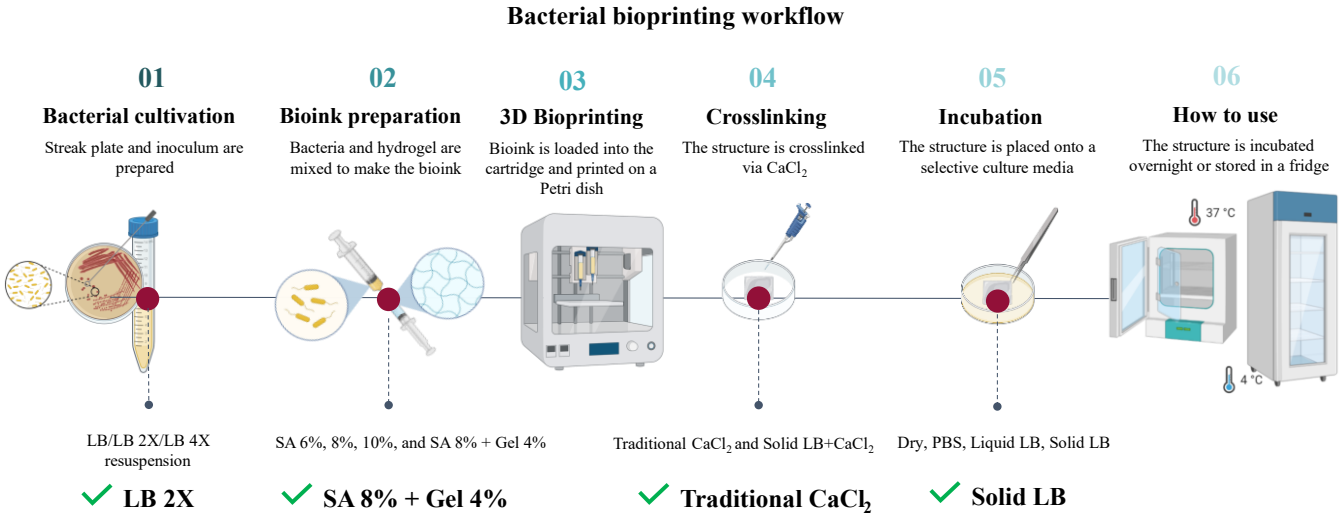

Fig. 1: Optimized bacterial bioprinting workflow. An INKREDIBLE+ bioprinting platform (Cellink AB, Sweden) was used to fabricate the bacteria-laden materials. Starting from a saturated culture, the biosensing strain was mixed (1:10 ratio) with an alginate- and gelatin-based hydrogel with LB nutrients, obtaining a bioink that was extruded on a Petri dish. The structure was crosslinked via $CaCl_2$ and moved to selective agar plates. The printed structure can be incubated overnight at 37 °C or stored in a regular fridge for future use. Red circles refer to the main variables screened during the development of the protocol: nutrients concentration included in the bioink, composition of hydrogel, crosslinking method, and type of incubation. Green single ticks refer to the screening outcomes.

O_2-dependent maturation of the RFP protein (Fig. 2C).

To further explore the capabilities of our bacterial bioprinting workflow, we used bacterial biosensors of signal molecules (e.g., bacterial hormone), first analyzing their dose-response profiles in liquid assays, and then printing them to evaluate the performance and the reproducibility of the output.

Functionality of biosensing ELMs was successful in optimal lab conditions exploiting a VAI biosensor (named LUX_{lac}-MCred), characterized in previous works [12], [13], [14], [15], and it exhibited promising stability up to 1 month of refrigerated storage conditions.

C. *ELM robustness*

In addition, we extended the characterization of ELMs in optimal and non-optimal incubation, starting from batches of different materials by printing 8 biological replicates in three different days.

A first experiment was carried out in optimal lab conditions evaluating the a* values of the images, confirmed by the reading on the microplate reader (Fig. 2D). These results demonstrated not only the correlation between the two measures adopted (r = 0.97), but also a good reproducibility of the output among different bacterial culture batches (average CV = 26% among replicates in the same day), and among different days (average CV = 27% among the mean outputs obtained in different days). A second experiment was designed to study the VAI-sensing response under non optimal conditions. From these data it emerged that a variation of the experimental condition corresponds to a variation of the output of the device (Fig. 2E). The biosensor readout can be deeply influenced by factors such as temperature (RT or 37 °C) or nutrient deficiency.

D. *ELM application*

Finally, to demonstrate that our ELMs biosensors can function in a real-world setting, we used the LUX_{lac}-MCred-based ELMs in soil containing VAI, either by covering them completely or by placing them on top. The induced materials reported a distinguishable color compared to the negative controls without VAI, but the color was less intense than that under optimal conditions, probably due to the lower amount of nutrients in the soil compared to LB and the lower concentration of VAI.

By exploiting the non-specific activation of the lux-based machinery, we were able to use the same biosensor also to detect PAI (*Pseudomonas aeruginosa* autoinducer) and not just as a laboratory molecule, but in clinical-derived complex matrices. The sterile-filtered supernatants of 4 clinical isolates of *P. aeruginosa* grown to saturation were collected and applied to biosensing patches. The a∗ values were examined to quantify the red pigmentation, reporting a successful result for two samples (Fig. 2F), confirming the capability of such ELM to detect molecules directly produced by pathogenic

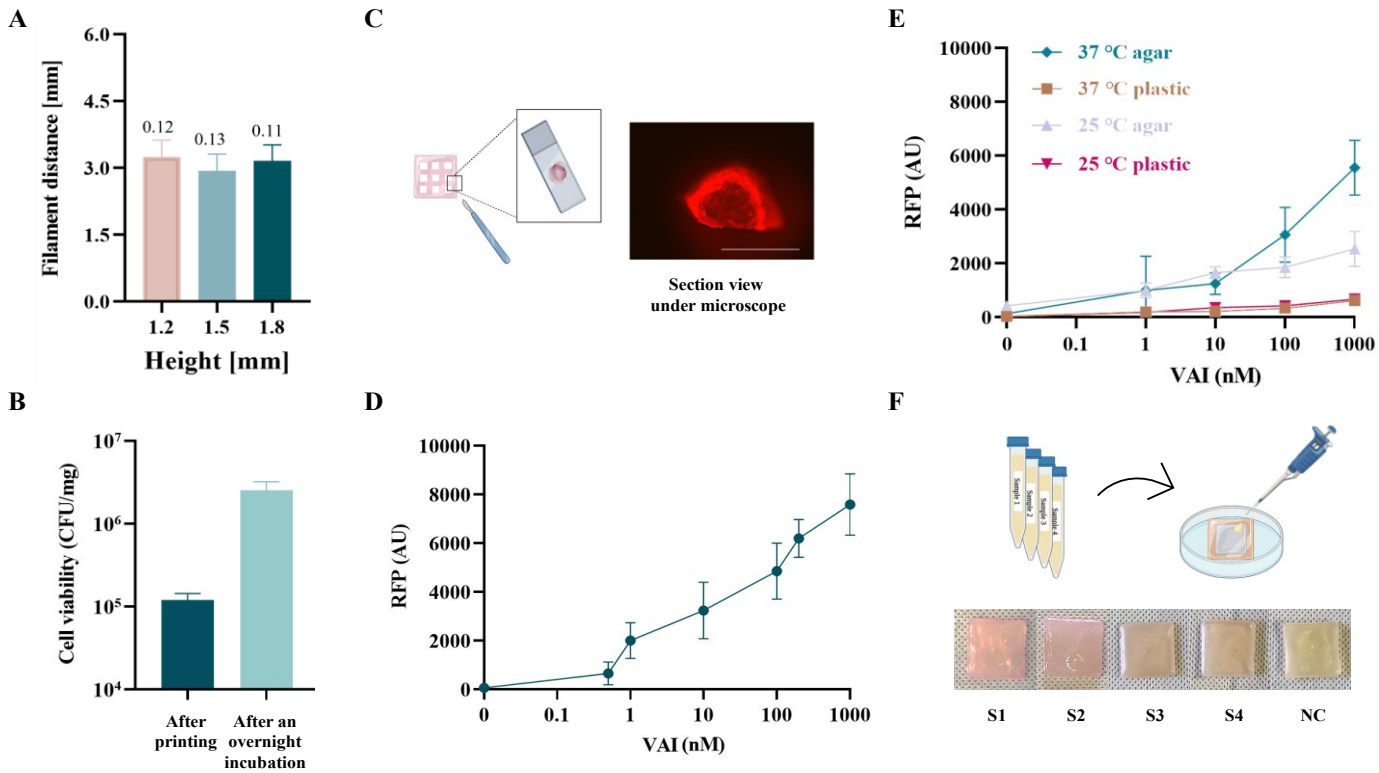

Fig. 2: A) Bar showing filament distance for grid structures printed at different heights (1.2, 1.5, 1.8 mm). Bars represent the average values, and error bars represent standard deviations (N > 30). The CV is reported above each bar. B) Bar chart showing bacterial viability obtained just after printing and after an overnight incubation at 37 °C. Data refer to biological triplicate, and error bars represent standard deviations. C) Microscopic image of the section of a strand in a 20x20x1 mm grid structure with MCred strain. The microscopy picture was acquired using the TRITC filter channel, 150 ms exposure. D) Dose-response curves of bioprinted ELMs tested in optimal laboratory conditions, in terms of RFP (AU) as a function of VAI concentrations. Data points represent mean values with the relative standard deviations as error bars (N=8). E) Dose-response curves of bioprinted ELMs, in terms of RFP (AU) as a function of VAI concentration, in different non-optimal conditions tested. Data points represent mean values with the relative standard deviations as error bars (N=3). F) ELM response upon PAI sensing from filter-sterilized supernatants of four *P. aeruginosa* clinical isolates (S1–S4). Negative control (NC) refers to the supernatant of an MG1655-Z1 strain grown at 37 °C, 220 rpm overnight, not producing PAI. ELMs were stored at 2–8 °C for 1 day before use.

bacteria. Taken together, these results demonstrated the sensing efficiency for environmentally- and clinically-relevant applications.

IV. Conclusions

A workflow for bacterial printing has been established to make biosensors reproducible in output and shape, usable for realistic conditions of use, such as environmental and clinical settings.

The preliminary step of protocol optimization led us to choose SA and GEL (8% (w/v) + 4% (w/v)) to have robust and easy to handle constructs. The extrusion was set on solid support (e.g., on a petri dish), and for the nutrients we chose the condition in which they are supplied both by the presence of LB agar, and by including within the bioink itself.

Then, we demonstrated how bacterial viability and gene expression are compatible with our printing platform, moving on to biosensing experiments demonstrating the feasibility and success in realizing biosensing materials, functional up to one month if stored in fridge.

We then focused on the reproducibility of the biosensor intended as robustness of the output, in laboratory and non-optimal set-ups by tuning conditions such as temperature and nutrient supply, not yet addressed in literature. This has allowed us to establish good reproducibility even in prints of different days, and to understand how the environment can dramatically affect the output, to consider for the use in realistic settings.

We next demonstrated that our biosensor ELMs can be used even in complex matrices, such as soil and clinical samples. In the last point, the biosensor was tested in the presence of supernatants and it was capable of sensing a molecule directly produced by a pathogen.

These results, taken together have demonstrated how our platform can be used for bacterial printing, leading to the creation of low-cost, customizable and user-friendly biosensor devices significant in real world challenges.

***Abstract*—Bacteria have the ability to coordinate their behavior in a cell density-dependent manner by using diffusible signal molecules. The mechanism, known as quorum sensing, is a cell-to-cell communication process exploited either by pathogens to regulate the expression of virulence and antimicrobial resistance-related genes and by synthetic biologists to engineer bacterial density-dependent functions. Using a systems biology approach, we developed a novel quorum sensing mathematical model and performed a comprehensive study of the equilibrium properties of this communication process. This analysis highlighted crucial structural properties as a result of bistability in the genetic circuit and underlined that bacteria exploit feedback control strategies to produce a unified and robust response. Due to increased antibiotic-resistant infections, researchers investigated enzymatic methods to interfere with quorum sensing. In this paper, we simulated two quorum quenching strategies. Using a modeling approach, we discovered core parameter values which guarantee the effectiveness of these strategies and could be exploited in rational design of synthetic biology based engineered bacteria.**

I. INTRODUCTION

The Food and Agriculture organization of the United nations and the World health organization raked antimicrobial resistance (AMR) among the major alarming global threats to medicine and public health [1]. Up to 60% of current hospital infections are caused by AMR strains [2]. In this respect, in many pathogens, physiological processes related to AMR have proven to be strongly dependent on the population size. As a consequence, during an infection, when the population density is low, the immune system is not able to detect their presence, but, when bacterial density reaches a critical level, they exploit their communication mechanisms to coordinate their response and switch on the expression of antimicrobial resistant genes (ARGs). This unanimous response enables bacteria to overcome the immune defenses. This phenomenon is known as quorum sensing (QS). It is a cell-to-cell communication system by which bacteria can modify the expression of several ARGs based on microbial population density and consequently coordinate their response, acting together in the same manner through positive feedback regulation. Most of Gram-negative bacteria exploit similar QS networks, which are homologous to the *Vibrio Fischeri*'s LuxI/R system (hereinafter referred as Lux system). We focused on this system, not for its clinical relevance, but to leverage on the many experimental data that already exist in the literature [3].

The key element of the communication process is enclosed in the signal molecule, also called autoinducer, which is a small molecule able to quickly diffuse inside and outside the cell through the bacteria membrane. At a low cell density, communication system is in its off-state and bacteria produce the autoinducer at a basal level. As the population size grows, the autoinducer reaches a critical concentrations that moves the state of the system to the on-state, by activating the expression of ARGs and by further increasing the autoinducer synthesis.

State of the art: In light of the crucial role that QS plays in antibiotic resistance of bacteria, in the last decades, the interest of researchers focused on the development of QS mathematical models, using either a deterministic or a stochastic approach [4], and on the study of different strategies to control this cell-to-cell communication processes. The increasing threat prompted researchers to develop a new research area, focused on studying the so called quorum quenching (QQ) mechanisms, which aims to discover QS inhibitors to treat bacterial infections [5].

Contributions: In this paper, we carried out a detailed mathematical and computational analysis of the equilibrium behavior and structural properties of a deterministic mathematical model representing the proposed system, showing that bistability plays a crucial role. We then investigated two QS inhibition strategies, performing computational simulations to infer the possible system response and variations in its equilibria. To conclude, we identified key threshold parameters crucial to design and perform QQ experiments.

II. LUX QUORUM SENSING SYSTEM MODELING

A. Quorum sensing system description

Most of the QS systems are comprised of three principal elements: (i) A gene encoding for a synthase, which is an enzyme able to synthesize a specific signal molecule (autoinducer); (ii) A gene encoding for a receptor, which is a protein able to bind the same signal molecule creating an active complex; (iii) A regulated promoter inducible by the above mentioned active complex, which drives the expression of the synthase itself.

This structure implements a positive feedback loop which, up-regulating the concentration of the receptor-autoinducer complex, leads to a further increment in synthase production. Interestingly, this latter activation often involves other AMR-, pathogenic- and biofilm- related genes, thus strictly correlating

QS thresholds with the enhancement of bacterial virulence and resistance to therapies.

As an example of prototypical QS mechanism, in the Lux system (reported in Fig. 1), the gene *luxI* encodes the synthase LuxI, an enzyme which synthesizes a small signal molecule called acyl-homoserine-lactone (AHL), which can rapidly diffuse across the membrane and accumulate in and out of the cell. When it spreads inside bacteria, AHL can be detected and bounded by the dimerized form of the receptor LuxR, encoded in the gene *luxR*, constitutively expressed by the promoter (P_R); the resulting LuxR-AHL complex is able to induce the regulated promoter P_{lux}, driving the expression of *luxI* and thus closing the positive feedback loop. Previous studies suggested that the activated complex has a hetero-tetrameric structure in which two molecules of LuxR are bound to two molecules of AHL [6].

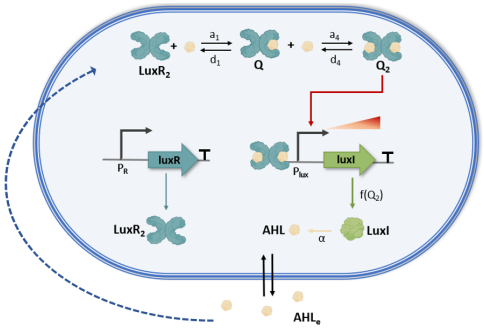

Fig. 1: Schematic of Lux quorum sensing network.

B. The model

We developed a novel cell-based dynamical model for a engineered system of Lux quorum sensing mechanism implemented in host strains of *Escherichia Coli* [6], [8] (Fig. 1):

$$\frac{dI}{dt} = \beta_{lux} + \frac{\alpha_{lux} - \beta_{lux}}{1 + \frac{K_{lux}}{Q_2}} - \gamma_I I \quad (1)$$

$$\frac{dL}{dt} = \alpha_I I - \gamma_L L + d_1 Q - K_1 d_1 R_2 L + \quad (2)$$
$$+ d_4 Q_2 - K_4 d_4 Q L + K_{15}(L_e - L)$$

$$\frac{dL_e}{dt} = K_{15}\frac{NV_I}{V - NV_I}(L - L_e) - \gamma_{L_e} L_e \quad (3)$$

$$\frac{dR_2}{dt} = d_1 Q - K_1 d_1 R_2 L \quad (4)$$

$$\frac{dQ}{dt} = K_1 d_1 R_2 L - d_1 Q - K_4 d_4 Q L + d_4 Q_2 \quad (5)$$

$$\frac{dQ_2}{dt} = K_4 d_4 Q L - d_4 Q_2 \quad (6)$$

whose parameters are summarized in Table I, where I denotes the concentration of protein LuxI, L and L_e are the intracellular and extracellular concentrations of AHL, respectively, and R_2 indicates the concentration of LuxR homodimer. Finally, Q and Q_2 define the concentrations of LuxR dimer bound to one or two molecules of AHL, respectively.

TABLE I: MODEL PARAMETERS

Symbol	*Description*	*Value*	*Units*	*Ref.*
β_{lux}	Basal LuxI synthesis rate per cell regulated by P_{lux}	0.08	$[AUmin^{-1}]$	[8]
α_{lux}	Maximum LuxI synthesis rate per cell regulated by P_{lux}	4.99	$[AUmin^{-1}]$	[8]
K_{lux}	Concentration of Q_2 corresp. to half-maximum induction of P_{lux}	194	$[nM]$	[8]
α_I	Synthesis rate of AHL	1.826	$[nMAU^{-1}min^{-1}]$	[9],[6]
R_2^{TOT}	Total concentration of dimer R_2 per cell	499.66	$[nM]$	[6]
$K_1 = \frac{a_1}{d_1}$	Equilibrium constant	0.0055	$[nM^{-1}]$	[6]
$K_4 = \frac{a_4}{d_4}$	Equilibrium constant	0.001375	$[nM^{-1}]$	[6]
K_{15}	AHL permeability rate	30	$[min^{-1}]$	[7]
γ_I	Degradation rate of LuxI	0.0173	$[min^{-1}]$	[8]
γ_L	Degradation rate of intracellular AHL	$2 \cdot 10^{-4}$	$[min^{-1}]$	[8]
γ_{L_e}	Degradation rate of extracellular AHL	$2 \cdot 10^{-4}$	$[min^{-1}]$	[8]
V_I	*E.coli* volume	1.1	$[\mu m^3]$	[12]
V	Culture environment volume	1	$[mL]$	[-]

The LuxI rate equation (Eq. 1) is composed by β_{lux}, which corresponds to the basal synthesis rate at the off-state, an inducible synthesis term which depends on the concentration of the complex Q_2, and a degradation term with spontaneous degradation rate γ_I. The Q_2-dependent synthesis rate is described as a Hill equation where α_{lux} is the maximum synthesis rate per cell and K_{lux} corresponds to the AHL concentration to reach the half-maximum synthesis rate.

In Eq. 2, α_I is the AHL synthesis rate and γ_L denotes its degradation rate. a_1 and d_1 are, respectively, the forward and reverse rate constants for the binding and unbinding reactions of the first AHL molecule to the LuxR homodimer. The equilibrium constant for this reaction is defines as $K_1 = a_1/d_1$. The forward and reverse rates describing the second AHL binding reaction are defined by a_4 and d_4, respectively. We assumed that the AHL binding and unbinding probability to the sites of R_2, Q and Q_2 are equal, therefore $a_4 = \frac{a_1}{2}$ and $d_4 = 2d_1$ implies that $K_4 = \frac{a_4}{d_4} = \frac{K_1}{4}$, where K_4 is the equilibrium constant of the second binding reaction. The last term in Eq. 2 counts the diffusion process of the autoinducer across the membrane and K_{15} is the AHL permeability rate of the *E. coli* wall [7]. Eq. 3 describes the dynamics of extracellular AHL, where N is the number of spatially homogeneous bacteria in the culture, V_I is the volume of a single *E.coli* and V is the entire culture environment volume. The degradation rate of L_e is described by γ_{L_e}.

Since LuxR is constitutively produced, we assumed R_2 has already reached its steady-state concentration. For this reason, its synthesis and degradation terms were omitted from Eq. 4. Moreover, in Eqs. 5 and 6 degradation terms for Q and Q_2 are neglected since the binding of AHL on the LuxR homodimer stabilizes the latter.

Below are the R_2 and L conservation of mass laws:

$$R_2^{TOT} = R_2 + Q + Q_2 = R_2^{TOT}(0) \quad (7)$$

$$L^{TOT} = L + Q + 2Q_2 \quad (8)$$

It is worth noticing that, since LuxR is produced at a constant basal rate, once it reaches its steady-state level, its total concentration can be assumed unchanged.

C. Deciphering the equilibrium properties of a QS system

In this section, we performed the analysis of the equilibrium behavior of the set of Eqs. 1-6. The following assumptions were made: reactions to form complexes Q and Q_2 and vice versa are reasonably much faster than the others. Under this assumption, Q and Q_2 immediately reach their steady state values and, exploiting the quasi-steady state approximation and the conservation law in Eq. 7, the model Eqs. 1-6 can be reduced to the following system:

$$\frac{dI}{dt} = \beta_{lux} + \frac{\alpha_{lux} - \beta_{lux}}{1 + \frac{K_{lux}}{Q_2}} - \gamma_I I \tag{9}$$

$$\frac{dL}{dt} = \alpha_I I - \gamma_L L + K_{15}(L_e - L) \tag{10}$$

$$\frac{dL_e}{dt} = K_{15}\frac{NV_I}{V - NV_I}(L - L_e) - \gamma_{L_e} L_e \tag{11}$$

$$Q_2 = \frac{\frac{K_1^2}{4}L^2}{1 + K_1 L + \frac{K_1^2}{4}L^2} R_2^{TOT}. \tag{12}$$

To investigate the equilibrium behavior, we assumed the steady state of all intracellular processes of the above system, by setting Eqs. 9-11 equal to 0. After some manipulations, this leads to the following equilibrium conditions:

$$L_e = \frac{\Delta}{\Delta + \gamma_{L_e}} L, \qquad L = \underbrace{\frac{\alpha_I}{\gamma_L - \Psi}}_{=:\chi} I, \tag{13}$$

where $\Delta = K_{15}\frac{NV_I}{V - NV_I}$ and $\Psi = K_{15}(\frac{\Delta}{\Delta + \gamma_{L_e}} - 1)$. Now, rewriting Q_2 as a function of LuxI:

$$Q_2 = \frac{\frac{K_1^2}{4}\chi^2 I^2}{1 + K_1 \chi I + \frac{K_1^2}{4}\chi^2 I^2} R_2^{TOT}, \tag{14}$$

where $\chi = \frac{\alpha_I(\frac{K_{15}NV_I}{V - NV_I} + \gamma_{L_e})}{(\frac{K_{15}NV_I}{V - NV_I} + \gamma_{L_e})\gamma_L + K_{15}\gamma_{L_e}}$, and substituting Eq. 14 into Eq. 9, the steady state levels of LuxI are obtained by solving the following equation:

$$\frac{dI}{dt} = \beta_{lux} + \frac{(\alpha_{lux} - \beta_{lux})(\frac{K_1}{2}\chi I)^2}{(\frac{K_1}{2}\chi I)^2 + \frac{K_{lux}}{R_2^{TOT}}(1 + \frac{K_1}{2}\chi I)^2} - \gamma_I I = 0. \tag{15}$$

It is worth noting that the equilibria of the system strongly depend on the number N of cells inside the culture environment. For this reason, we computed the solution pairs (I, N) of Eq. 15 for different values of N. Fig. 2 displays the bifurcation diagram of the steady state LuxI concentration per cell against the population density.

For low values of cell density, the system has one stable equilibrium point corresponding to a the basal concentration of LuxI (off-state). Increasing the population density, the system exhibits three different steady states, two of them stable and one unstable. The further increase in cell density brings the system back to a single stable equilibrium point, this time corresponding to a high LuxI concentration per cell (on-state).

Moreover, the bacteria colony exhibits hysteretic behavior: the system response is not simply a function of the cell density, but it also depends on its history. Indeed, the cell density level at which the communication process switches on is higher than the one at which switches off, conferring robustness to the communication process.

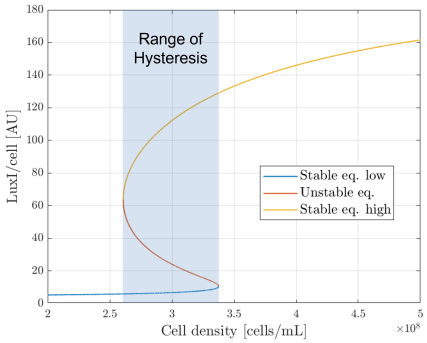

Fig. 2: Bifurcation diagram of LuxI.

III. Quorum Quenching

To address the problem of increasing antimicrobial resistant bacteria, researchers developed novel therapeutic techniques, some of which based on QQ i.e., the inhibition of bacterial communication [2]. In the QS pathway, there are several possible sites where it is possible to interfere. In this work, we explored the following two strategies to destroy AHL communication system: (i) Degradation of the extracellular AHL molecule, exploiting AHL-degrading enzymes which prevent the accumulation of extracellular AHL, as exploited in [8]; (ii) Sequestration of the AHL-receptor protein via antagonist compounds, as studied in [10].

A. QQ simulation via parameter sensitivity analysis

We exploited the developed model and the equilibrium analysis just performed to evaluate the effectiveness of these two therapeutic strategies. We addressed the problem from a parametric point of view, increasing or decreasing specific parameters which resembled the possible effect of the intended therapeutic strategy. Indeed, the degradation of the extracellular AHL can be numerically simulated by increasing the degradation rate γ_{L_e} of Eq. 3. On the other hand, the sequestration of LuxR dimer antagonizes its interaction with AHL to form complexes Q and Q_2 and it is equivalent to reduce binding rates a_1 and a_4 or, equivalently, the equilibrium constants K_1 and K_4. Results are reported in Fig. 3.

B. Critical parameter thresholds identification

Our goal is to simulate the effect of the described inhibition mechanisms and to find the key threshold values of γ_{L_e} and $K_{1,4}$ that prevent the activation of quorum sensing, even at high population sizes. In nature, there is an upper limit on the cell density that can be reached in the culture environment. Therefore, to destroy QS communication, it is sufficient to require that the autoinducer synthesis remains at the basal level until the maximum density is reached. In this way, the QS system cannot be activated at any feasible cell density.

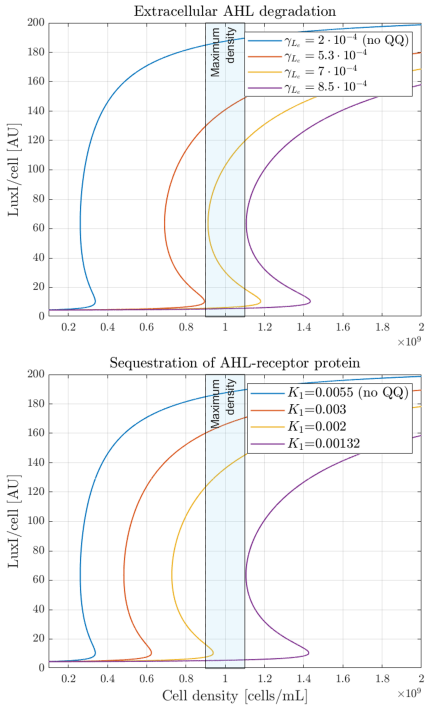

Fig. 3: QQ simulation highlighting critical parameter values forcing off-states. Top: AHL degradation. Bottom: receptor sequestration.

In literature, the maximum value of *E.coli* cell density found is around $1.1 \cdot 10^9$ cells/mL [11] and, using a conservative approach, this is the upper limit that we considered in our analysis. We simulated the two QS blocking strategies described above varying the corresponding parameters and, in Fig. 3 the resulting LuxI bifurcation diagrams are illustrated. Note that, with the parameter values corresponding to the purple curves, we reached our goal: at all feasible cell densities the system has a unique stable equilibrium which corresponds to the basal level of autoinducer. Therefore, $\gamma_{L_e} > 8.5 \cdot 10^{-4}$ min^{-1} or $K_1 < 1.32 \cdot 10^{-3}$ nM^{-1} guarantee the inhibition of QS.

These simulations clearly indicate that QS switching from off-state to on-state strictly depends on the population size: while each bacterium must produce a sufficiently low amount of AHL to avoid self-activation of QS, on the other they must produce enough autoinducer to switch on QS once the threshold cell density has been reached. This behavior strongly depends on the hysteretic curve displayed in Fig. 2 and is a consequence of the underlying positive feedback loop.

The effort required to activate the communication process is considerable, and hysteresis ensures that once triggered, it is more difficult to reverse it by a cell density decrease. Indeed, our analysis proved that the system requires a significantly lower level of cell density to reset the autoinducer production to the basal level, compared to the QS activating threshold one. This finding confirms that bacteria exploit control strategies to perform disturbance rejection to cell density variations. In this case, the positive feedback ensured robustness to autoinducers perturbations and reduced susceptibility to noise.

Lastly, while higher *E.coli* cell density thresholds could be considered (e.g., for bioreactors), this would only imply that a stronger QQ action would be required to achieve the same results in that type of systems. Despite some parameters could be affected by unmodeled aspects, e.g., pH-dependant AHL stability [13] or altered synthase/receptor degradation rates, a sensitivity analyses on those parameters is beyond the aim of this study and will be addressed in future works.

IV. Conclusion

Due to the rise in antibiotic resistance and the need to prevent new emergence of such strains, there will be in the near future a progressive application of synthetic biology studies exploiting QQ enzymes and CRISPR interference [14], [15]. This will enable the development of new therapeutic approaches against AMR bacteria and a better understanding of the structural properties of QS mechanisms. In this regard, this work identified key threshold parameters that are essential for designing and carrying out quorum quenching experiments, highlighting design requirement for pharmacological- and synthetic biology-based therapeutic approaches.

***Abstract*— Breast cancer is a heterogeneous and complex disease as witnessed by the existence of different subtypes with distinct morphologies and clinical implications. Despite the remarkable advances in understanding the mechanisms underlying breast cancer, this disease is still a major public health problem worldwide and poses significant open challenges. Here, we show how a multi-omics data integration analysis may provide useful insights in the identification of promising molecular signatures associated with the different breast cancer subtypes.**

***Keywords*— breast cancer subtypes, bioinformatics, computational medicine, gene signature**

I. Introduction

BREAST CANCER (BC) is the most common female cancer and, despite important advances in early detection and research development, it continues to be the second leading cause of death in women worldwide [1]. BC is a heterogeneous pathology as witnessed by the existence of different subtypes with distinct morphologies and clinical implications [2]. These subtypes are usually defined by using the immunohistochemical (IHC) classification, which is based on immunoprofile (i.e., Estrogen Receptor-ER, Progesterone Receptor-PR and Human Epidermal growth factor Receptor2-HER2 status) and Ki67 index [3]; or by using the genetic (PAM50) classification, based on the expression of a 50-gene signature [4], [5]. According to the IHC classification, breast cancers are stratified into four subtypes, i.e. luminal A, luminal B, Her2 positive and triple negative. According to the PAM50 classification, they are classified into four molecular intrinsic subtypes that are luminal A, luminal B, Her2 positive and basal-like. The most aggressive BC pathophenotypes are the triple-negative and the basal-like for the two classifications, respectively. Although triple-negative and basal-like are not the same by definition, these two terms are often used interchangeably, since most basal-like breast cancers also have a triple-negative phenotype (i.e., ER-negative, PR-negative, HER2-negative) [6] and since triple-negative breast cancers overlap with the molecular entity of basal-like [7], [8]. The identification of BC-associated biomarkers and the development of effective therapeutic strategies for the different subtypes are ongoing challenges to be faced.

Here, we present a bioinformatics approach for the integration of multi-omics data (e.g., transcriptomics, genomics, epigenomics, clinical) that can offer promising insights for understanding BC-related molecular mechanisms.

II. Materials and Methods

A. Data retrieval

Transcriptomic, clinicopathological, Copy Number Variations (CNVs) and DNA methylation data of patients affected by breast cancer were retrieved from The Cancer Genome Atlas (TCGA) repository [9]. Male samples, as well as samples undergoing a neoadjuvant treatment, were removed from the TCGA-BC cohort. The Human Protein Atlas (HPA) website [10] was leveraged to retrieve immunohistochemistry images and to evaluate changes in the proteins expression patterns.

B. SWIM algorithm

SWIM (SWItch Miner) is a recently developed tool able to unveil key (switch) genes within gene co-expression networks strongly associated with drastic changes in cell/tissue phenotype [11], [12]. SWIM algorithm has been implemented both in Matlab and in R language and encompasses a series of steps described in details in [11], [12].

C. In vitro and ex vivo experiments

To validate the common gene signature found to be altered in all BC subtypes, in vitro and ex vivo experiments were performed by using BC model cell lines and tissue specimens. The detailed description of these experiments was provided in [13].

D. Survival analysis

To analyze the correlation between the expression level of the basal-like specific switch genes and patient overall survival and therefore to evaluate their prognostic value, we used the RNA-sequencing data from TCGA to split the entire cohort of BC patients (1049 samples) into two groups (called low-expression and high-expression group) according to the upper and lower expression quartile. Low- and high-expression groups refer to patients with expression levels of the given switch gene lower and greater than the 50th percentile (i.e., median), respectively. For each patient cohort, the cumulative survival rates were computed for each switch gene according to the Kaplan-Meier (KM) method [14] on the clinical metadata provided by TCGA. For each switch gene, the survival outcomes of the two patients' groups were compared by the log-rank test. Switch genes with log-rank p-values less than 0.05 were suggested as candidate prognostic biomarkers.

E. Gene regulatory network analysis

To investigate putative transcription factor activities on the regulation of the basal-like specific switch genes, we built a gene regulatory network by integrating information from Pscan web tool [15], TRRUST database [16] and the human interactome assembled by Cheng and coauthors [17]. In particular, we firstly exploited Pscan web tool to predict TFs putatively able to bind the promoter regions of the selected switch genes. Then, we filtered the Pscan predictions keeping only the TFs known to physically interact with at least one switch genes in the human interactome. These TF-target relationships were finally complemented with those experimentally validated from TRRUST database.

III. Results and Discussion

A. Identification of a common gene signature altered in all BC subtypes

In our recent study [13], we applied SWIM methodology on the transcriptomic data of TCGA-BC patients stratified according to two different subtype classification (i.e., PAM50 and IHC classification) in order to identify switch genes both shared among all subtypes and specific for each subtype (Fig. 1). We focused on switch genes common to all subtypes of both classifications and we found a common gene signature composed of 11 genes.

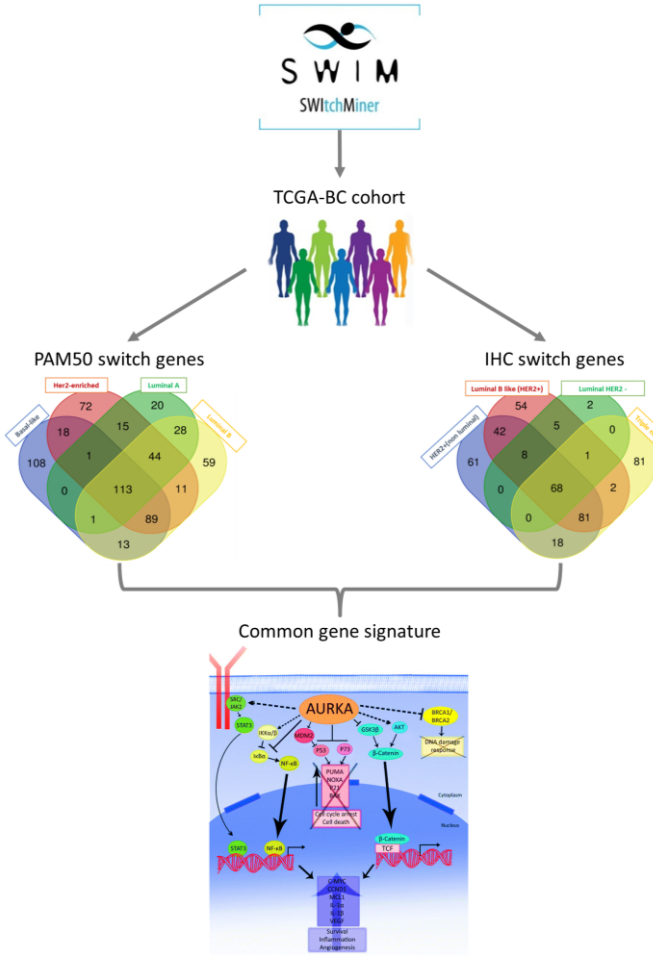

Fig. 1: Workflow for the identification of a common gene signature altered in all BC subtypes

Among them, Aurora Kinase A (AURKA) appears to be very promising since: i) it is a kinase known to have a key role in cell division and cell-cycle progression; ii) it plays a critical role in regulation of mitotic events like spindle assembly and chromosomal segregation; iii) it is deregulated in many human cancers; iv) it collaborates with several tumor suppressors like P53, BRCA1 and BRCA2; v) it is suggested as a pharmaceutical target for the treatment of various cancers [18].

The key role of AURKA in the context of BC subtypes was experimentally validated by showing that the encoded protein is always over-expressed both in BC cell lines (Fig.2A) and tissues (Fig.2B).

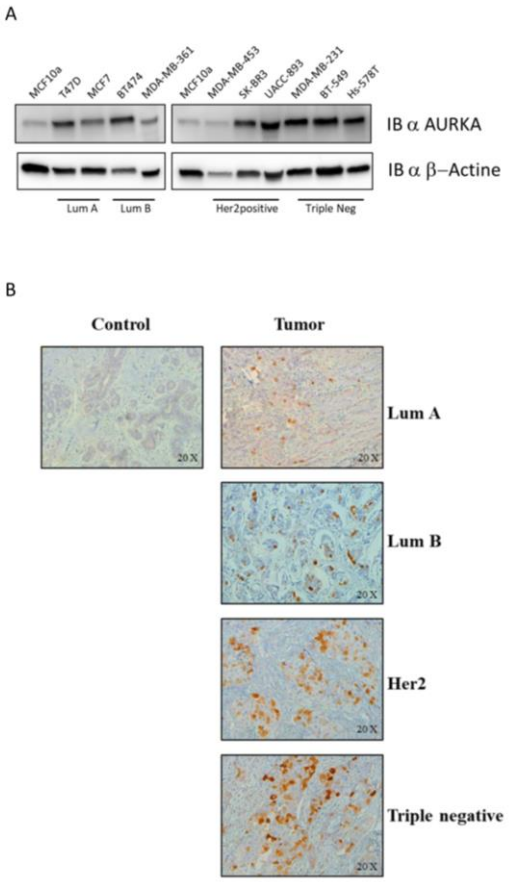

Fig. 2: AURKA protein expression examined in vitro by immunoblotting on BC subtype cell lines (A) and ex vivo by immunohistochemical analysis on surgical BC tissue specimens (B).

Moreover, we demonstrated that the AURKA inhibition by using alisertib drug led to a reduction in the cell growth of all BC subtype cell lines (Fig.3A) and to arrest their cell cycle (Fig.3B) up to 72 h after the treatment.

Taken together, all these findings supported the hypothesis that AURKA pathway could be a common mechanism univocally altered in all BC subtypes.

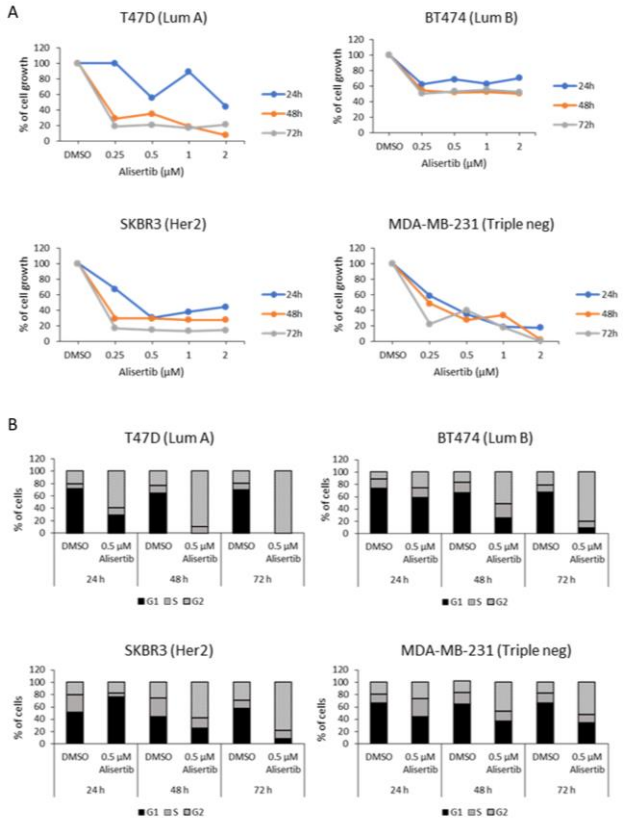

Fig. 3: Effect of AURKA's inhibitor (alisertib) assessed on cell growth (A) and cell cycle (B) of BC subtype cell lines.

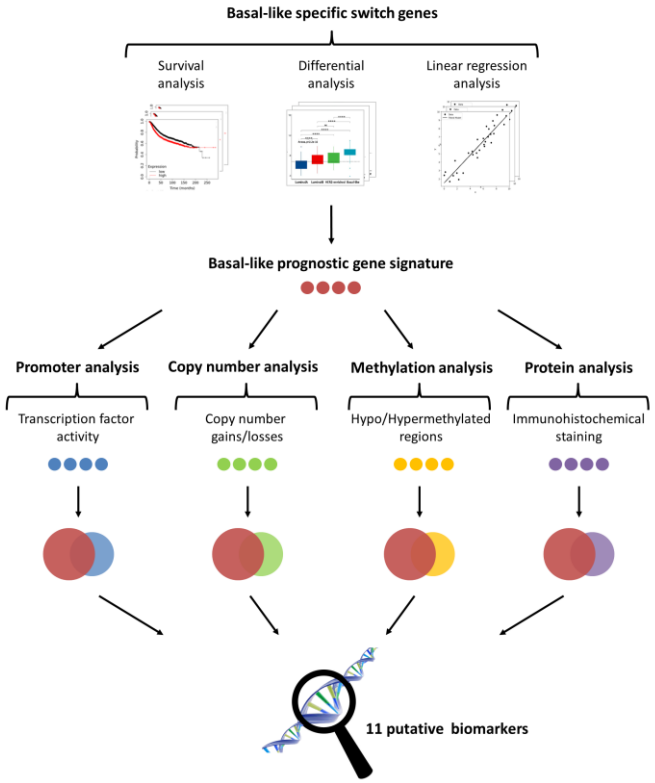

Fig. 4: Workflow for the identification of a prognostic gene signature for basal-like subtype.

B. Identification of a prognostic gene signature for basal-like subtype

Among the various recognized BC subtypes, basal-like is the most aggressive with a poor prognosis, a high risk of relapse and a high resistance to pharmacological treatments [19]. Currently, there are not available widely accepted prognostic biomarkers to predict the outcomes of basal-like patients. Therefore, in our recent study [20], we carried out a bioinformatics pipeline integrating transcriptomic, genomic, epigenomic, and clinical data in order to identify a prognostic gene signature for the basal-like subtype (Fig.4).

Our pipeline started from the 108 basal-like specific switch genes identified in [13] and performed a Kaplan-Meier (KM) survival analysis in order to explore their clinical relevance with respect to BC patients' overall survival (OS). This first step allowed us to identify 11 basal-like specific switch genes, i.e., CENPN, LRP8, DSCC1, CTPS, RCOR2, GINS4, TUBA1C, PRAME, SLC7A11, CDCA7, GSDMC, acting as unfavourable prognostic biomarkers (i.e., their higher expression was significantly associated with poorer BC patients' OS). The clinical relevance of these 11 switch genes was also confirmed using other larger BC datasets collected in the KM plotter website [21].

Next, we evaluated the gene expression of these 11 putative basal-like prognostic biomarkers demonstrating that they always reached the highest level in the basal-like condition.

To statistically quantify the increasing trend of their expression values as the phenotype varies from physiological to pathological condition passing across the different BC subtypes, we performed a linear regression analysis, where the index R-squared estimates the goodness-of-fit. We found that all of them showed a very strong straight-line relationship (R-squared >= 0.7) with respect to the tumor aggressiveness. These results were mostly confirmed also by performing the same analysis with respect to the pathological staging of the BC patients.

Moreover, we explored the expression patterns of the proteins encoded by the 11 prognostic switch genes through the HPA. We found that six of these proteins were overexpressed in BC tissues compared to normal breast tissues. For the remaining ones, there are pending cancer and normal tissue analysis on the HPA and the immunohistochemistry images are not currently available.

Eventually, we investigated if the overexpression of the 11 basal-like prognostic biomarkers may depend on the action of important transcription factors (TFs) as well as basal-like specific genomic alterations (CNVs) and/or epigenomic alteration (DNA methylation changes). In particular, to provide some hints on which TFs could regulate the expression of the 11 basal-like switch genes, we built a gene regulatory network by combining information on both computationally predicted and experimentally validated TF-target relationships (see Materials and Methods). The final gene regulatory network was composed of seven switch genes and twelve TFs, including well-known TFs that, if deregulated, contribute to neoplastic transformation as MYC, TP53 and NFKB. By performing hierarchical clustering analyses, we highlighted different CNVs (copy number gain/loss) and DNA methylation (hypo/hypermethylated

regions) status of the 11 putative prognostic biomarkers in basal-like subtype with respect to the less aggressive BC subtype, i.e., luminal A [20].

Taken together, all these findings prompted us to propose the 11 basal-like specific switch genes as a specific gene signature to evaluate the prognosis of basal-like BC patients.

IV. Conclusion

In the present work, we showed how bioinformatics may be exploited to provide a contribution in the identification of putative gene signatures associated with one of the most heterogeneous and widespread disease, i.e. breast cancer, thus helping in the discovery of effective therapies as well as prognostic biomarkers.

***Abstract*— SAveRUNNER is a recently developed network-based tool to efficiently identify novel medical indications for currently approved drugs (known as drug repurposing strategy). Up to now, SAveRUNNER has been gainfully applied to unveil repurposable solutions for several diseases, including viral infection (e.g., SARS, COVID-19, HIV, Malaria, Ebola), breast cancer, progressive disorders of central nervous system (e.g., Amyotrophic Lateral Sclerosis, Multiple Sclerosis), and other neurodegenerative diseases (e.g., Alzheimer's Disease). Here, SAveRUNNER algorithm and its main applications are described.**

***Keywords*— Network Theory, Network Medicine, Drug Repurposing.**

I. Introduction

Drug repurposing represents an effective drug discovery strategy to find new uses from existing drugs out of the scope of their original medical indication, which can shorten the time, reduce the cost, and increase the success rate of molecular entities compared to the traditional de novo drug discovery [1].

In this context, we recently developed a network-based algorithm, called SAveRUNNER (Searching off-lAbel dRUg aNd NEtwoRk) [2], [3], which predicts new uses for already approved drugs by exploiting concepts from the emerging field of Network Medicine [4]. According to the Network Medicine paradigm, the human interactome network (i.e., the cellular network of all physical molecular interactions) [5] can be considered as map, where the molecular determinants of a given disease (*disease genes*) tend to co-localize and agglomerate in specific regions (*disease modules*), whose perturbation can contribute to the manifestation of the pathophenotype [4]. In this perspective, even the action of a drug can be considered as a local perturbation of the human interactome and thus, for a drug to be effective against a specific disease, its target proteins should be in the immediate vicinity of the corresponding disease module [6]. Following these principles, SAveRUNNER predicts drug-disease associations by quantifying the interplay between the drug targets and the disease-associated genes in the human interactome through the computation of a novel network-based similarity measure, which prioritizes associations between drugs and diseases located in the same network neighbourhoods.

In the last two years, SAveRUNNER has been acknowledged as promising tool to find drugs repurposable opportunities for several diseases (Fig. 1). In particular, the pioneer application was for predicting repurposable drugs against COVID-19 [3], [7]. In the same study, we also analyzed other related diseases linked to the COVID-19 infection as genetic similarity (i.e., Severe Acute Respiratory Syndrome - SARS), as risk factors (e.g., cardiovascular diseases, diabetes mellitus), or other viral infections (i.e., malaria, HIV and Ebola), and immune disorders (i.e., rheumatoid arthritis) [3]. More recently, it has been successfully applied to identify candidate repurposable drugs also for Amyotrophic Lateral Sclerosis (ALS) [8], Multiple Sclerosis (MS) [9], breast invasive carcinoma subtypes [10], and neurodegenerative diseases, such as Alzheimer's Disease (AD) [11] (Fig. 1). In all these studies, SAveRUNNER turned out as a novel promising tool for an efficient screening of the repurposable opportunities, outlining where looking at for further ad-hoc experimental validations.

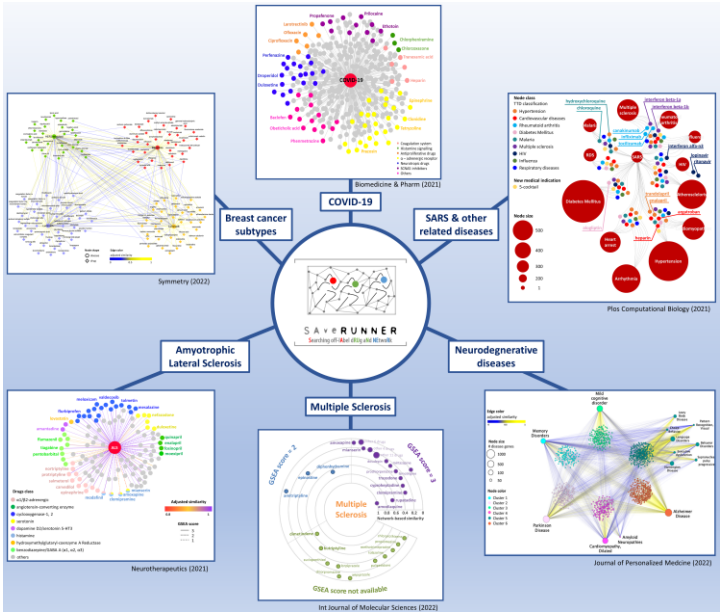

Fig. 1. Overview of SAveRUNNER applications. Each panel corresponds to a different study, where the drug-disease network computed by SAveRUNNER was shown. In these networks, nodes refer to drugs (smaller nodes) and diseases of interest (bigger nodes), and a link occurs between a drug and a disease if their corresponding drug-target proteins and disease-associated genes are proximal in the human interactome more than by chance. The link is weighted according to the novel network-based similarity measure implemented by SAveRUNNER [3].

II. Methods

A. Input data

1) Human interactome network

The human interactome used in all the SAveRUNNER applications was downloaded from [6], including 217,160 interactions connecting 15,970 unique proteins.

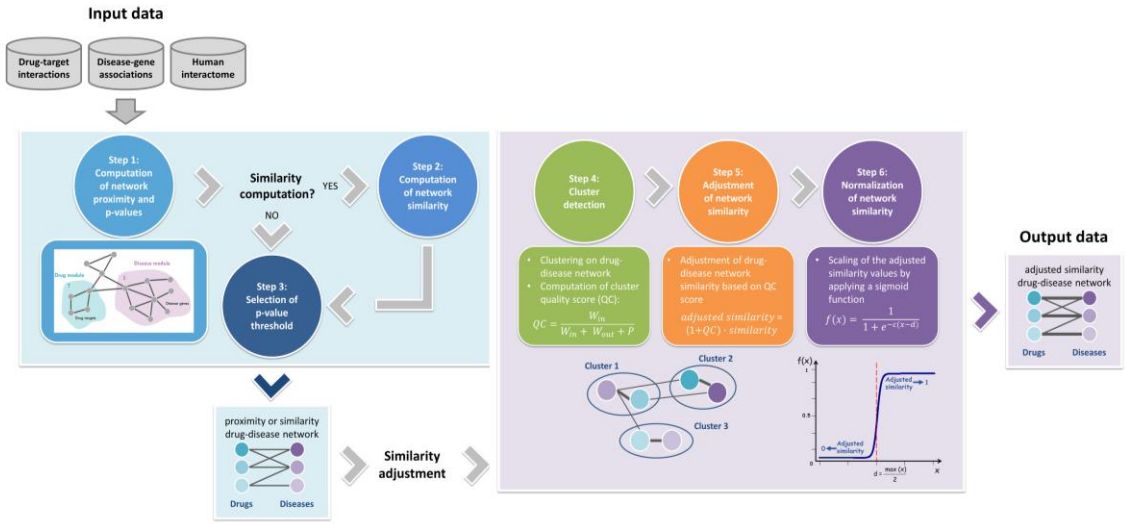

Fig. 2. Overview of SAveRUNNER algorithm [2], [3]**.** Taking as input a list of disease genes, drug targets, and the human interactome, SAveRUNNER releases a drug-disease network via six steps. In steps 1-3, it builds a proximity-based bipartite drug-disease network, where nodes are both drugs and diseases and edges are the statistically significant drug-disease associations. In steps 4-7, it builds a similarity-based bipartite drug-disease network, where the weights represent the adjusted similarity measure computed to prioritize the predicted drug-disease associations by rewarding the associations between drugs and diseases belonging to the same network cluster.

2) Disease gene associations

Disease-associated genes were retrieved from Phenopedia (last release April 2020) [12] and DisGeNET (last release October 2021) [13], two of the most popular and largest publicly available collections of disease genes obtained by integrating and homogeneously annotating data from expert-curated repositories and GWAS catalogues. For one of SAveRUNNER application to COVID-19 [7], transcriptomic data from whole blood cells of patients with COVID-19 was retrieved from GEO repository (GSE152641) and differentially expressed genes between infected cells and heathy controls were used as *disease genes*. Yet, for SAveRUNNER application to breast cancer subtypes [10], due to a poor knowledge of the genes associated with each subtype, transcriptomic data from patients affected by breast invasive carcinoma was retrieved from The Cancer Genome Atlas (TCGA) repository and stratified according to PAM50 classification [14]. Then, a list of genes (known as *switch genes*) previously identified by SWIM software [15] as likely associated to each subtype were used as *disease genes* [14].

3) Drug-target interactions

Drug-target interactions were retrieved from DrugBank [16] (5.1.6 release of April 2020), the most acknowledged database about drugs information and drug-target interactions. The targets' Uniprot IDs provided by DrugBank were mapped to Entrez gene IDs by using the BioMart – Ensembl tool (https://www.ensembl.org/), obtaining a total of 2,165 genes interacting with 1,873 drugs.

B. Algorithm

SAveRUNNER algorithm takes as input the human interactome, a list of disease-gene associations related to disease(s) of interest, and the list of drug-target interactions and, via the implementation of several steps depicted in Fig. 2 and detailed in [2], [3], gives as output a weighted drug-disease bipartite network.

In the network released by SAveRUNNER, nodes are drugs and diseases, and a drug and a disease are connected if the corresponding drug targets and disease genes are closer in the interactome than expected by chance (p-value ≤ 0.05). The weight of their association is based on the implementation of a novel network-based similarity measure, known as *adjusted similarity* (AS), defined in Eq. (1).

$$AS(p) = \frac{1}{1+e^{-c\left[\frac{(1+QC)(m-p)}{m} - d\right]}} \quad (1)$$

In Eq (1), p refers to the network proximity measure described in Eq. (2) [6].

$$p(T,S) = \frac{1}{\|T\|}\sum_{t\epsilon T} \min_{s\epsilon S} d(t,s) \quad (2)$$

where $p(T,S)$ represents the average shortest path length between drug target t in the drug module T and the nearest disease gene s in the disease module S; QC is a quality cluster score that rewards associations between drugs and diseases located in the same network cluster; m is max(p); c and d are the steepness and the midpoint of AS(p), respectively. A comprehensive description of SAveRUNNER methodology can be found in [2], [3].

C. GSEA

To test whether the repurposable drugs predicted by SAveRUNNER could counteract the gene expression perturbations caused by the disease of interest (i.e., up-regulate genes down-regulated by the disease or vice versa), the so-called gene set enrichment analysis (GSEA) was downstream performed [3] in most of the studies. This analysis takes as input: (i) differentially expressed genes of the understudied disease (generally obtained by GEO or TCGA repository) to use as *disease signature*; (ii) differentially expressed genes of drug-treated human cell lines (obtained by Connectivity Map (CMap) database [17]) to use as *drug signature*. For each drug both included in the CMap database and predicted by SAveRUNNER, an enrichment score (ES) was computed to evaluate whether the effect of the drug could counteract the effect of the disease (ES < 0, drug and disease signature negatively correlated) or

not (ES > 0, drug and disease signature positively correlated) [17]. For each tested drug, a GSEA score equal to 1 was assigned if that drug was found to have ES < 0 with respect to a given disease, or equal to 0, otherwise. By repeating this procedure for several independent disease signatures, the final GSEA score ranges from 1 to *n* (with *n* is the total number of disease signatures tested): the greater the GSEA score, the greater the number of disease datasets satisfying this criterion.

III. Results

A. COVID-19, SARS, and other related diseases

SAveRUNNER was first applied to COVID-19 and a panel of 14 diseases COVID-related for genetic similarity, comorbidity, or for their association to drugs with ongoing clinical trials for treating COVID-19 patients [3]. In particular, we tested: SARS, as it is caused by the coronavirus with the highest sequence identity with SARS-CoV-2 [18] and there existed a well-established knowledge of its associated disease genes; diabetes, cardiovascular diseases, and hypertension, whose comorbidity in COVID-19 patients was observed; and finally other viral infections (i.e., malaria, HIV and Ebola) and immune disorders (i.e., rheumatoid arthritis), since drugs approved for their treatment were investigated for their potential effect to fight coronavirus disease [19]. In this study, SAveRUNNER prioritized 282 potential anti-SARS repurposable drugs and 98 anti-COVID-19, including ACE-inhibitors, monoclonal antibodies, and thrombin inhibitors that were further in-silico corroborated by GSEA, considering drug-treated cell lines from CMap and coronaviruses-induced transcriptomics data from GEO repository.

SAveRUNNER was also used to study COVID-19 starting from differentially expressed genes obtained by exploiting transcriptomic data from COVID-19 infected patients and healthy control samples [7]. In this study, SAveRUNNER identified 399 repurposable drugs for COVID-19, whose top-ranked ones were molecules involved in the modulation of the coagulation system (e.g., *heparin* and *tranexamic acid*), antihistaminic drugs, mast cell stabilizers (e.g., *chlorzoxazone* and *chlorpheniramine*), anti-proliferative drugs including tyrosine kinase (TRK) inhibitors and antibiotics (e.g., *larotrectinib* and *ciprofloxacin*), alpha-adrenergic receptor agents (e.g., *clonidine* and *prazosin*); drugs affecting the central nervous system (e.g., *perfenazine* and *droperidol*), and inhibitors of the sodium voltage-gated channel alpha subunit 5 (SCN5A) involved in cardiac rhythm control (e.g., *propafenone* and *prilocaine*).

B. Amyotrophic Lateral Sclerosis and Multiple Sclerosis

SAveRUNNER was applied to study ALS [8] and MS [9]. In both cases, by prioritizing the network-predicted drugs according to the decreasing value of their network similarity with ALS and MS, SAveRUNNER highlighted some interesting drug modulators of histamine receptors. The expression of histamine receptors were shown to increase in cortical tissues of patients affected by MS [9], thus suggesting that histamine-related molecules can be potential therapeutic strategies for the disease. Moreover, it has been shown that the histaminergic modulation might participate to the mechanisms of ALS insurgence, progression, and therapy as well, since other studies found that histamine-related genes could be modifiers in ALS, and thus supporting their role as candidate biomarkers and therapeutic targets [20]. The histaminergic compounds predicted by SAveRUNNER were also in-silico-validated by GSEA analysis, considering drug-treated cell lines from CMap as drug signatures, and three different datasets of transcriptomics data of cortex tissues from patients affected by ALS [8] and MS [9] collected from GEO repository as disease signatures for ALS and MS, respectively.

C. Breast cancer subtypes

SAveRUNNER was applied to study four subtypes of breast invasive carcinoma stratified based on PAM50 classification (i.e., luminal A, luminal B, Her2-enriched, and basal-like) [10]. In this study, SAveRUNNER predicted: (i) 74 repurposable drugs for luminal A, including as top-ranked *teniposide* that has been studied as suppressor of the growth of subcutaneous cell lines of luminal A (MCF-7) [21]; (ii) 54 repurposable drugs for luminal B, including as top-ranked *ivabradineI*, recently repurposed as a novel therapy for breast cancer [22]; (iii) 79 repurposable drugs for HER2-enriched, including as top-ranked several compounds for the treatment of bacterial infections; and (iv) 77 repurposable drugs for basal-like, whose top-ranked one was *metergoline*, acting as antagonist of certain subtypes of 5-HT receptor, which has been showed to induce cell proliferation of triple-negative breast cancer via 5-HT7 receptor signaling [23]. Yet, the 20% of the total predicted drugs have also an indication originally related to cancer treatment, including *dexrazoxane*, *ixabepilone*, *capecitabine* already approved for fighting breast cancers. Most of the predicted repurposable drugs were also in-silico-validated by GSEA, considering breast cancer drug-treated cell lines from CMap as drug signatures and transcriptomics data of breast cancer patients from TCGA as diseases signature.

D. Neurodegenerative diseases

SAveRUNNER was applied to study AD and other 13 AD-related disorders, including Mild Cognitive Impairment (MCI), which is the stage between the expected cognitive decline of normal aging and the more serious decline of dementia, other neurological diseases (i.e., Parkinson's disease, Huntington disease, supranuclear palsy progressive, and Lewy body disease), and other diseases that can be symptoms, risk factors, or consequences of AD (i.e., language disorders, memory disorders, visual pattern recognition, executive dysfunction, choice behavior, cardiomyopathy, amyloid neuropathies). SAveRUNNER predicted some interesting compound belonging to the family of: (i) beta-blockers, including *betaxolol*, originally used for hypertension treatment and already linked to a lower risk of developing AD [24]; (ii) multi-kinase inhibitors, including *regorafenib*, whose beneficial effects were recently investigated on neuroinflammation and AD pathology in vitro and in vivo [25]; (iii) anti-platelet inhibitors, including *clopidogrel*, whose therapy has been associated with lower risk of developing AD and whose anti-inflammatory effect has been recently studied in in-vivo model of AD [26]; and mTOR inhibitors, including *sirolimus*, an immunosuppressant drug used in transplantation medicine to prevent organ rejection, whose modulation could have

potential application to delay memory loss and age-related neurodegenerative diseases [27]. All these compounds were also corroborated by GSEA, considering neural drug-treated cell lines available from CMap as drug signatures and three different datasets of transcriptomic data from brain tissues of patients affected by AD from GEO as disease signature.

IV. Conclusion

We presented an overview of SAveRUNNER, a network-based approach that offers a promising framework to efficiently detect putative novel uses for marketed drugs against diseases of interest. We reviewed its main applications, including but not limited to viral infections, breast cancer, and neurodegenerative progressive disorders.
