VIII Gruppo Nazionale di Bioingegneria

EIGHTH NATIONAL CONGRESS OF BIOENGINEERING

Proceedings

Organized by

Università degli Studi di Padova
(Dipartimento di Ingegneria dell'Informazione,
Dipartimento di Ingegneria Industriale,
Dipartimento di Neuroscienze,
Dipartimento di Ingegneria Civile, Edile e Ambientale)
and Consiglio Nazionale delle Ricerche
(Istituto di Neuroscienze)

Pàtron editore

ISSN 2724-2129

Emanuele Luigi Carniel, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Chiara Dalla Man, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Roberto Bizzotto, Istituto di Neuroscienze, Consiglio Nazionale delle Ricerche

Finance

Mattia Veronese, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Chiara Giulia Fontanella, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Morten Gram Pedersen, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Zimi Sawacha, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Francesca Maria Susin, Dipartimento di Ingegneria Civile, Edile e Ambientale, Università degli Studi di Padova

Venue

Andrea Bagno, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Fabio Scarpa, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Martina Vettoretti, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova

Event

Emanuela Formaggio, Dipartimento di Neuroscienze, Università degli Studi di Padova
Alice Berardo, Dipartimento di Ingegneria Civile, Edile e Ambientale, Università degli Studi di Padova
Monica Dettin, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Michele Schiavon, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova

Abstracts and contributions

Simone Del Favero, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Manfredo Atzori, Dipartimento di Neuroscienze, Università degli Studi di Padova
Alessandro Gandin, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Camillo Porcaro, Dipartimento di Neuroscienze, Università degli Studi di Padova
Silvia Todros, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova

Publicity, web and social media

Andrea Facchinetti, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Giacomo Baruzzo, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Marco Castellaro, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Maria Rubega, Dipartimento di Neuroscienze, Università degli Studi di Padova
Roberto Visentin, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova

Coordination

Alessandra Bertoldo, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova
Giovanna Brusatin, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Piero Pavan, Dipartimento di Ingegneria Industriale, Università degli Studi di Padova
Giovanni Sparacino, Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova

Scientific Committee

Track 1 - E-health and Clinical Engineering

Miloš Ajčević, Università degli Studi di Trieste
Sergio Casciaro, Consiglio Nazionale delle Ricerche
Danilo Pani, Università degli Studi di Cagliari
Pierangelo Veltri, Università della Calabria

Track 2 - Physiological and Neural System Modelling

Leonardo Bocchi, Università degli Studi di Firenze
Cristiano Cuppini, Alma Mater Studiorum - Università di Bologna
Chiara Dalla Man, Università degli Studi di Padova
Alessandra Sciutti, Istituto Italiano di Tecnologia

Track 3 - Biomechanics and prosthetics
Maria Cristina Bisi, Alma Mater Studiorum - Università di Bologna
Emanuele Luigi Carniel, Università degli Studi di Padova
Michele Conti, Università degli Studi di Pavia
Luigi La Barbera, Politecnico di Milano
Giuseppe Vannozzi, Università degli Studi di Roma "Foro Italico"
Track 4 - Biomaterials, Cell & Tissue Engineering, Biofabrication
Irene Carmagnola, Politecnico di Torino
Carmelo De Maria, Università di Pisa
Silvia Farè, Politecnico di Milano
Laura Pastorino, Università degli Studi di Genova
Marco Rasponi, Politecnico di Milano
Leonardo Ricotti, Scuola Superiore Sant'Anna
Chiara Tonda Turo, Politecnico di Torino
Enza Torino, Università degli Studi di Napoli Federico II
Francesco Urciuolo, Università degli Studi di Napoli Federico II
Track 5 - Biomedical Signal and Image Processing
Emilia Ambrosini, Politecnico di Milano
Gabriele Arnulfo, Università degli Studi di Genova
Laura Astolfi, Sapienza Università di Roma
Laura Burattini, Politecnica delle Marche
Cristiano De Marchis, Università degli Studi di Messina
Luca Faes, Università di Palermo
Manuela Ferrario, Politecnico di Milano
Alberto Greco, Università di Pisa
Giulia Matrone, Università degli Studi di Pavia
Kristen Meiburger, Politecnico di Torino
Micaela Morettini, Università Politecnica delle Marche
Giandomenico Nollo, Università di Trento
Mario Sansone, Università degli Studi di Napoli Federico II
Roberto Sassi, Università degli Studi di Milano
Silvia Francesca Storti, Università di Verona
Track 6 - Neural Engineering and Micro and Nano-technologies
Alfonso Gautieri, Politecnico di Milano
Alberto Mazzoni, Scuola Superiore Sant'Anna
Marta Parazzini, Consiglio Nazionale delle Ricerche
Track 7 - Biorobotics, rehabilitation & Assistive Technologies
Andrea Canessa, Università degli Studi di Genova
Gastone Ciuti, Scuola Superiore Sant'Anna
Francesca Cordella, Università Campus Bio-Medico di Roma
Taian Martins, Politecnico di Torino
Track 8 - Design and Validation of Biomedical Devices
Giovanni Calcagnini, Istituto Superiore di Sanità
Gianni Pedrizzetti, Università degli Studi di Trieste
Mara Terzini, Politecnico di Torino
Tommaso Villa, Politecnico di Milano

DAY 1

Podium session

Track 1 - E-health and Clinical Engineering

Health Information Technology Adverse Events Identification and Classification with Natural Language Processing and Deep Learning
Alessio Luschi, Paolo Nesi and Ernesto Iadanza

Dynamic Bayesian Networks and Transfer Learning Enable the Development of Deep Sequence-Based Models on Small-Sample Data
Enrico Longato, Erica Tavazzi, Adriano Chiò, Giovanni Sparacino and Barbara Di Camillo

EyeLab: a user-friendly Matlab tool for real-time monitoring of eye movements
Giulia Olla, Giulia Sedda, Annalisa Bonfiglio, Sebastiano Traccis and Danilo Pani

Track 2 - Physiological and Neural System Modelling

Multi-Input Multi-Output Model Predictive Control for Drugs Delivery in Clinical Anesthesia
Eleonora Manzoni, Jacopo Pavan, Mirco Rampazzo and Simone Del Favero

Non-linear analysis of HRV reveal lower signal complexity in patients with a prolonged Disorder of Consciousness
Piergiuseppe Liuzzi, Bahia Hakiki, Antonello Grippo, Francesca Cecchi and Andrea Mannini

Track 9 - Bioinformatics and Synthetic Biology

Study and characterization of bile acid biosensors in engineered probiotic bacteria
Daniele Pastorelli, Debora Dallera, Emanuele Persico, Massimo Bellato, Gabriella Cusella Maria, Lorenzo Pasotti and Paolo Magni

Modeling metabolic overload effects in bacterial growth rate in synthetic biology
Elisa Gaetan, Chiara Cimolato, Luca Schenato and Massimo Bellato

The long story of SWIM methodology: from grapevine to personalised medicine
Paola Paci

Poster session 1

Track 1 - E-health and Clinical Engineering

Wearable-based Sit-to-Stand transfers in Older Adults: context differences between in-lab and home-based assessments
Jose Albites-Sanabria, Pierpaolo Palumbo, Jorunn L. Helbostad, Luca Palmerini and Lorenzo Chiari

A novel tool for the annotation of bipolar electrograms for cardiac electrophysiology
Marco Orrù, Elisa Pitzalis, Giulia Baldazzi, Graziana Viola and Danilo Pani

Design and Evaluation of an Intuitive Administration Dashboard for a Platform used to Monitor Clinical Trials
Luca Cossu, Lorenzo Carlo Causin, Andrea Facchinetti and Giacomo Cappon

Automatic extraction of acoustic features to predict Alzheimer's disease among English-speaking subjects
Chiara Giangregorio, Emilia Ambrosini and Simona Ferrante

Development of an Integrated Software System for Medical Equipment Management: the experience of the Spedali Civili Hospital
Paola Picozzi, Gian Luca Viganò, Matteo Verga, Martina Capuzzo, Claudia Duri, Lucia Maria Ignoti, Sara De Paola and Veronica Cimolin

A tool to perform semi-supervised anomaly detection and annotation on 15 lead ECG signals
Ugo Lomoio, Patrizia Vizza, Raffaele Giancotti, Giuseppe Tradigo, Salvatore Petrolo, Sergio Flesca, Pietro Hiram Guzzi and Pierangelo Veltri

Identifying Extreme Profiles in Amyotrophic Lateral Sclerosis Patients at Diagnosis through Archetypal Analysis
Isotta Trescato, Erica Tavazzi, Martina Vettoretti, Rosario Vasta, Adriano Chiò and Barbara Di Camillo

Assessing Personal Exposure to Airborne Particulate Matter with Wearable Sensors and Ventilation Rate Models
Michele Atzeni, Caterina Grisi, Giacomo Cappon and Martina Vettoretti

Key points to design the MDs Library of a National implant Registry: lesson learned from the Italian experience
Simona Pascucci, Michela Franzò, Veronica Mari, Alessia Biondi, Stefania Ceccarelli, Fabiano Bini, Franco Marinozzi, Enrico Ciminello, Paola Ciccarelli, Paola Laricchiuta, Eugenio Carrani and Marina Torre

Improving data quality in healthcare: medical informatics tools and standards
Mauro Giacomini, Sara Mora, Elena Lazarova, Norbert Maggi and Carmelina Ruggiero

Commercial Smart Virtual Assistants to support medication adherence in chronic patients: a preliminary usability study
Emanuele Tauro, Enrico Gianluca Caiani, Giacomo Galuzzi, Margot Mazziotti, Fosco Cancelliere and Grzegorz Bilo

Prediction of Atrial Fibrillation using Deep Learning techniques
Francesco Goretti, Alberto Vassia Marzullo, Massimo Milli and Ernesto Iadanza

3D upper limbs tracking through inertial sensors: calibration, methodology, and validation
Elena Bardi, Carola Butera, Luca Pozzi, Marta Gandolla, Francesco Braghin and Emilia Ambrosini

Manual and automatic identification of ACMG evidence in scientific papers
Francesca Longhin, Alessandro Guazzo, Enrico Longato, Diego Boscarino, Dino Paladin, Nicola Ferro and Barbara Di Camillo

Development of predictive models for short-term prediction of disability progression in multiple sclerosis
Erica Tavazzi, Davide Albertini and Martina Vettoretti

A Distributed Multi-Centric Application for the Analysis of Cardiac Biomarkers
Nicola Cortese, Anna Procopio, Salvatore De Rosa, Giovanni Canino, Alessio Merola, Jolanda Sabatino, Claudia Critelli, Ciro Indolfi, Francesco Amato and Carlo Cosentino

Quantifying the contribution of single joint kinematics to the overall ergonomic discomfort
Emilia Scalona, Doriana De Marco, Gianluca Rossetto, Martina Mosso, Pietro Avanzini, Maddalena Fabbri-Destro, Giuseppe Andreoni and Nicola Francesco Lopomo

Co-design of a points-based reward system to boost motivation in children and improve adherence to learning serious games
Chiara Piazzalunga, Alice Donati and Simona Ferrante

Risk management in a medical device software: evaluation of the usability characteristics of a 3D viewer for reporting
Alessio Luschi, Laura Gatti, Eleonora Tiribilli, Elena Denisova, Leonardo Manetti, Leonardo Bocchi and Ernesto Iadanza

Track 2 - Physiological and Neural System Modelling

A computational platform to assess the metabolic-electrophysiological behaviour of neurons cultured in monolayers
Rachele Fabbri, Arti Ahluwalia and Chiara Magliaro

Full-scale point-neuron model of the mouse hippocampal microcircuits
Giulia Maria Boiani, Sergio Solinas, Giacomo Preti, Aurora Manini, Michele Migliore, Jonathan Mapelli and Daniela Gandolfi

A neural model of sensory interactions in young neurotypical and ASD children
Melissa Monti, Sophie Molholm and Cristiano Cuppini

Functional Connectivity of the EEG in epilepsy: a single case study
Giovanni Chiarion and Luca Mesin

The prediction of the patient's response to hemodialysis treatment: DialysIS vs InterACTIVE-HD 2.0 experience
Carlo Balsamello, Silvio Pianca, Antonio Bellasi, Carla Colturi, Gianvincenzo Melfa, Giuseppe Rombolà, Reto Venzin, Pietro Cippà, Giustina Casagrande and Maria Laura Costantino

Smart Titration of Long-Acting Insulin in Insulin-Naïve Type 2 Diabetic Subjects
Jacopo Bonet, Roberto Visentin, Martina Vettoretti, Andrea Facchinetti and Chiara Dalla Man

Toward Implicit Communication of Object Properties for Human-Robot Interaction
Linda Lastrico, Alessandro Carfì, Francesco Rea, Fulvio Mastrogiovanni and Alessandra Sciutti

Brain-heart interaction: an ECG-fMRI integrated study in physiology and major depressive disorder
Federica Goffi, Pierluigi Reali, Adele Ferro, Viviana Pescuma, Giandomenico Schiena, Ylenia Barone, Paolo Enrico, Yvan Torrente, Fabio Triulzi, Anna Maria Bianchi, Paolo Brambilla and Eleonora Maggioni

Modelling cerebral blood flow and neuroreceptor occupancy in dopamine blocking studies
Mario Severino, Pierluigi Selvaggi, Martin Osugo, Ottavia Dipasquale, Uzma Zahid, Thomas Whitehurst, Ellis Onwordi, Ben Statton, Tiago Reis Marques, Robin Murray, Mitul Mehta, Oliver Howes and Mattia Veronese

Modeling Doxorubicin Treatment Effect in Multiple Myeloma
Daniele Andrean, Francesco Da Ros, Mario Mazzucato, Morten Gram Pedersen and Roberto Visentin

Single region contribution to the brain dynamic (in)stability
Danilo Benozzo, Giorgia Baron, Giacomo Baggio, Alessandro Gozzi, Maurizio Corbetta, Alessandro Chiuso, Sandro Zampieri and Alessandra Bertoldo

A multiscale computational approach to replicate the full-scale mouse striatum model
Alberto Antonietti, Paolla Furquim Daud and Alessandra Pedrocchi

A Comprehensive Nonlinear Mixed Effects Model of Glucose, Insulin, and C-Peptide Interaction during IVGTT
Edoardo Faggionato, Paolo Denti, Anna Largajolli, Alessandra Bertoldo and Chiara Dalla Man

Model Assessment of Doxorubicin Pharmacokinetics in Multiple Myeloma
Matteo Baldan, Francesco Da Ros, Mario Mazzucato, Morten Gram Pedersen and Roberto Visentin

Numerical simulations of the cerebrospinal flow through the Sylvius aqueduct modeled as a diffuser/nozzle pump.
Paolo Peruzzo and Francesca Maria Susin

Mathematical model of glucagon kinetics during an oral glucose tolerance test based on a dual regulation mechanism
Micaela Morettini, Agnese Piersanti, Christian Göbl, Laura Burattini and Andrea Tura

Network model accounts for evolution of EEG functional connectivity in patients with cognitive decline
Lorenzo Gaetano Amato, Alberto Arturo Vergani, Michael Lassi, Riccardo Mannella, Valentina Bessi, Antonello Grippo and Alberto Mazzoni

Noise-Induced Dynamics and Stochastic Slow Manifolds in the Bistable Xiong-Ferrell Model
Matteo Martin and Morten Gram Pedersen

From data to knowledge: definition of an exploratory dataset for deep brain stimulation
Marco Prenassi, Manuel Ellero, Annamaria Caruso and Sara Marceglia

How to assess vascular dysfunction during septic shock and resuscitation
Marta Carrara, Pietro Antenucci and Manuela Ferrario

Track 3 - Biomechanics and prosthetics

A novel artificial urinary sphincter and comparison with reference device
Maria Vittoria Mascolini, Joseph Vannel Fotso Fogang, Valentina Salomoni, Chiara Giulia Fontanella, Emanuele Luigi Carniel and Arturo Nicola Natali

A dexterous hand prosthesis based on additive manufacturing
Manfredo Atzori, Henning Müller, Alessandro Buosi, Franco Reggiani, Jacopo Lazzaro, Giosuè Alberti, Cesare Tiengo, Franco Bassetto and Nicola Petrone

Adaptation of cardiac deformation pattern during exercise in children
Dario Collia and Gianni Pedrizzetti

Development of novel computational tool to support surgical planning for the treatment of Anomalous Aortic Origin of the Coronary Arteries (AAOCA)
Serena Anglese, Mauro Lo Rito, Antonio Rosato, Valentina Ceserani, Giovanni Maria Formato, Ariel Fernando Pascaner and Michele Conti

3D Finite Element Analysis of a Percolating Cluster inside the Mineralized Collagen Fibril
Andrada Pica, Andrea Marinozzi, Franco Marinozzi and Fabiano Bini

The effect of CFR-PEEK cross-link in short fixation for the stabilisation of lumbar metastasis: an in-vitro comparative study.
Simone Borrelli, Giovanni Putame, Alberto Audenino, Andrea Ferro, Stefano Marone and Mara Terzini

Inertial measurements unit validation for countermovement jump (CMJ) tests in athletes
Federica Camuncoli, Luca Barni, Sebastiano Nutarelli, Jacopo Emanuele Rocchi, Matteo Barcillesi, Irene Di Dio, Andrea Sambruni and Manuela Galli

Advances in the development of a instrumented head surrogate for brain injury investigation
Giuseppe Zullo, Elisa Baldoin, Andrey Koptyug, Mikael Bäckström and Nicola Petrone

Towards a Wearable System for Complete Collection of Clamp Loads in Transfemoral Paralympic Sprinters
Giacomo Fabris, Mattia Scapinello, Samira Breban, Sara Barbacane, Gianluca Migliore, Andrea Cutti and Nicola Petrone

Face mobility analysis in Spinal Muscular Atrophy
Elena Pegolo, Elena Carraro, Federica Cibin, Fabiola Spolaor, Francesca Salmin, Andrea Lizio, Maria Chiara Frisoni, Stefano Becchiati, Valeria Sansone and Zimi Sawacha

Structural Simulation of Transcatheter Heart Valve in Transcatheter Heart Valve
Roberta Scuoppo, Stefano Cannata, Caterina Gandolfo and Salvatore Pasta

A Workflow for Biomechanical Simulation of Patient-specific Atherosclerotic Carotid Artery
Nicoletta Curcio, Antonio Rosato, Daniela Mazzaccaro, Michele Conti and Giulia Matrone

Experimental Analysis of the biomechanics of healthy porcine corneas
Ilaria Toniolo, Maria Vittoria Mascolini, Simona Neri, Antonella Peruffo, Anna Perazzi and Chiara Giulia Fontanella

Numerical Analysis of the Bicaval Transcatheter System for the Treatment of Severe Tricuspid Regurgitation
Fabrizio Crascì, Stefano Cannata, Caterina Gandolfo and Salvatore Pasta

Biomechanical characterization of human plantar fascia through experimental tests
Sofia Pettenuzzo, Alice Berardo, Elisa Belluzzi, Assunta Pozzuoli, Pietro Ruggieri, Emanuele Luigi Carniel and Chiara Giulia Fontanella

Static strength of lower-limb prosthetic sockets for the activities of daily living
Francesca Gariboldi, Mattia Scapinello, Nicola Petrone, Gian Luca Migliore, Gregorio Teti and Andrea Giovanni Cutti

Computational modelling of the contractile behavior of cardiomyocytes on hydrogel scaffolds for cardiac tissue regeneration
Silvia Spadoni, Silvia Todros, Michael Magnussen, Dominique Scaglioni, Anna Urciuolo, Nicola Elvassore and Piero Pavan

The biomechanical behaviour of fascial system: Superficial VS Deep Fascia
Lorenza Bonaldi, Chiara Giulia Fontanella, Carmelo Pirri, Carla Stecco and Alice Berardo

Analysis of an Elite Amputee Paralympic Sprinter in Track Running Pilot Tests
Sara Barbacane, Samira Giuliana Breban, Giacomo Fabris, Mattia Scapinello, Roberto Di Marco, Giuseppe Marcolin, Gian Luca Migliore, Andrea Giovanni Cutti and Nicola Petrone

Lumped-parameter hemodynamic model as a non-invasive tool to assess coronary blood flow in AAOCA
Valentina Ceserani, Mauro Lo Rito, Giovanni Maria Formato, Mauro Luca Agnifili, Antonio Rosato, Ariel Fernando Pascaner and Michele Conti

Comparative Analysis of Steady and Resisted Accelerated Treadmill Running of an Elite Amputee Paralympic Sprinter
Samira Giuliana Breban, Sara Barbacane, Valerio Pelusi, Roberto Di Marco, Giuseppe Marcolin, Andrea Giovanni Cutti and Nicola Petrone

Integrated Protocol for Multidimensional In Vivo Assessment of Glenohumeral Joint Function during Dynamic Tasks
Emilia Scalona, Gianluca Rossetto, Martina Mosso, Maristella Francesca Saccomanno, Giuseppe Milano and Nicola Francesco Lopomo

Motor performances evaluation of female soccer players from AC Trento Women
Giacomo Villa, Marta Galeotti, Foivos Papaioannou, Veronica Cimolin and Manuela Galli

Development of a contrast-enhanced micro tomography protocol for human meniscus: a pilot study
Chiara Falsina, Melania Maglio, Nicola Francesco Lopomo, Gianluca Giavaresi, Alberto Grassi, Stefano Zaffagnini, Massimiliano Baleani, Gregorio Marchiori and Matteo Berni

Biomechanical assessment of the anomalous coronary compression by patient-specific finite element analysis
Antonio Rosato, Mauro Lo Rito, Giovanni Maria Formato, Serena Anglese, Valentina Ceserani, Ariel Fernando Pascaner and Michele Conti

Mechanical evaluation of synthetic meshes: definition and verification of a rigorous test protocol
Vittoria Civilini, Vincenzo Giacalone, Alberto L. Audenino and Mara Terzini

An Inverse Analysis for the Assessment of Material Properties of TAVI Patients
Chiara Catalano, Stefano Cannata, Caterina Gandolfo and Salvatore Pasta

Mechanical characterization of hybrid membrane suitable for biomedical application
Roberto Gemelli, Martina Todesco, Emanuele Luigi Carniel, Gino Gerosa and Andrea Bagno

Track 9 - Bioinformatics and Synthetic Biology

Exploring heterogeneity in lymphoid malignancies from mouse to human gene expression profiles
Martina Vescio, Matteo Bulloni, Andrea Brendolan and Linda Pattini

Network-based integration of clinical, imaging and molecular biomarkers of dementia
Caterina Alfano, Lorenzo Farina and Manuela Petti

Genetic Algorithms for the identification and design of physiologically relevant 3D constructs
Flavio Fontana, Piera Mancini, Ermes Botte, Chiara Magliaro and Arti Ahluwalia

A preliminary version of a Genome-Scale Metabolic Model for Induced Human Pluripotent Stem Cells (hiPSCs)
Anna Procopio, Elvira Parrotta, Stefania Scalise, Nicola Cortese, Alessio Merola, Francesco Amato, Giovanni Cuda and Carlo Cosentino

Giving new life to seafood waste: in silico engineering of a chitinolytic LPMO enzyme
Andrea Ricci, Alfonso Gautieri, Giulia Di Rocco and Carlo Augusto Bortolotti

Oxygen metabolism in in vitro ecosystems
Ermes Botte, Piera Mancini, Chiara Magliaro and Arti Ahluwalia

A bioinformatic pipeline for identifying bacterial constitutive promoters based on transcriptomic data analysis
Debora Dallera, Stefano Quaranta, Davide De Marchi, Giovanni Cipriano, Paolo Magni and Lorenzo Pasotti

Longitudinal Relationships Between Proteomics and Beta-Cell Dysfunction in Type 2 Diabetes: An Imi Direct Study
Carlo Alberto Rossi, Ana Vinuela, Jochen M. Schwenk, Ewan R. Pearson, Andrea Mari and Roberto Bizzotto

Lipid Droplets associated genes link HSV-1 infection to neurodegeneration pathways
Veronica Zatta, Massimo Bellato, Alice Pegoraro, Giulia Bernabè, Sara Letrari, Astghik Stepanyan, Barbara Di Camillo, Paola Brun and Ignazio Castagliuolo

Simulating microbial communities' evolution via Agent base modelling: a Python tool
Massimo Bellato, Marco Cappellato, Andrea Calzavara, Alessandro Lucchiari, Sara Rebecca and Barbara Di Camillo

Automated control of bioreactors: An hardware-in-the-loop proof of concept test towards an experimental facility
Alessandro Bernardi, Massimo Bellato, Riccardo Antonello, Barbara Di Camillo, Luca Schenato and Simone Del Favero

A workflow for the construction of reproducible living biosensors built by printing bacterial materials
Francesca Usai, Giada Loi, Franca Scocozza, Massimo Bellato, Paolo Magni, Michele Conti and Lorenzo Pasotti

Uncovering quorum sensing and quenching structural properties: a systems biology approach
Chiara Cimolato, Gianluca Selvaggio, Massimo Bellato, Luca Marchetti and Luca Schenato

Bioinformatics analyses to identify molecular gene signatures associated with breast cancer phenotypes
Federica Conte, Giulia Fiscon and Paola Paci

A network-based algorithm for identifying drug repurposing opportunities for complex diseases
Giulia Fiscon, Federica Conte and Paola Paci

Day 2

Podium session

Track 3 - Biomechanics and prosthetics

Assessment of a parametric thoracic spine model for the generation of in silico cohorts
Alice Perego, Alice Pezzinga, Emilia Bellina and Luigi La Barbera

Synergy-dependent patterns of reaction forces in sit-to-stand movements
Simone Ranaldi, Leonardo Gizzi, Giacomo Severini and Cristiano De Marchis

A numerical finite element methodology of the EVAR procedure
Anna Ramella, Francesco Migliavacca, Jose Felix Rodriguez Matas, Erica Mariani, Tim J. Mandigers, Daniele Bissacco, Antonio Freyrie, Santi Trimarchi and Giulia Luraghi

Track 6 - Neural Engineering and Micro and Nano-technologies

Coupled Hydrodynamic Flow Focusing to design Lipid-Polymer NPs (LiPoNs) for theranostics
Felicia Roffo, Alfonso Maria Ponsiglione, Paolo Antonio Netti and Enza Torino

Development of a microfluidic system for impedance-based cell sorting
Cristian Brandi, Sergio Spanò, Gian Carlo Cardarilli, Enrico Verona, Luca Businaro, Paolo Bisegna, Adele De Ninno and Federica Caselli

Magnetoelectric nanoparticles as promising tools for motor nerve stimulation
Valentina Galletta, Emma Chiaramello, Serena Fiocchi, Alessandra Marrella, Giulia Suarato, Marta Bonato, Marta Parazzini and Paolo Ravazzani

Track 8 - Design and Validation of Biomedical Devices

Reducing bone plates standard fatigue test time with an analytical runout load prediction
Federico Bologna, Alberto Audenino and Mara Terzini

Zwitterionic coatings for an implantable artificial pancreas
Erika Roventini, Giulia Ballardini, Aliria Poliziani, Lorenzo Arrico and Leonardo Ricotti

Track 5 - Biomedical Signal and Image Processing

Development of a novel surface-based approach to quantify fNIRS-fMRI spatial correspondence
Augusto Bonilauri, Alice Pirastru, Francesca Sangiuliano Intra, Sara Isernia, Marta Cazzoli, Valeria Blasi, Giuseppe Baselli and Francesca Baglio

Discriminatory power of Global Longitudinal Strain and Left Ventricular Ejection Fraction for Identification of Dilated Cardiomyopathy
Katerina Iscra, Aleksander Miladinovic, Milos Ajcevic, Laura Munaretto, Jacopo Giulio Rizzi, Marco Merlo and Agostino Accardo

Autonomic response to virtual reality in oncological patients in real-world context
Serena Moscato, Silvia Orlandi, Andrea Giannelli, Rita Ostan, Silvia Varani and Lorenzo Chiari

Supervised Learning-based Detection of Pressure-induced Failures in Continuous Glucose Sensors
Elena Idi, Eleonora Manzoni, Andrea Facchinetti, Giovanni Sparacino and Simone Del Favero

Quantitative validation of an automatic videoPPG technique during autonomic elicitations
Andrea Costanzo Palmisciano, Maximiliano Mollura, Riccardo Barbieri and Luca Mainardi

Assessment of cerebral autoregulation in patients undergoing anaesthesia with propofol: a comparison among spontaneous variability methods
Roberta Saputo, Laura Sparacino, Riccardo Pernice, Francesca Gelpi, Vlasta Bari, Alberto Porta and Luca Faes

Early stages of cognitive decline are characterized by different EEG microstates dynamics
Michael Lassi, Carlo Fabbiani, Salvatore Mazzeo, Rachele Burali, Alberto Arturo Vergani, Giulia Giacomucci, Valentina Moschini, Filippo Emiliani, Maenia Scarpino, Silvia Bagnoli, Assunta Ingannato, Benedetta Nacmias, Sonia Padiglioni, Silvestro Micera, Sandro Sorbi, Antonello Grippo, Valentina Bessi and Alberto Mazzoni

Hessian-based neck tracing of dendritic spines: a preliminary study on confocal images
Ester Bruno, Simone Cauzzo, Alejandro Callara, Arti Ahluwalia, Chiara Magliaro and Nicola Vanello

Quality enhancement of dermatological images using GANs: a proof of concept
Francesco Branciforti, Kristen Meiburger, Elisa Zavattaro, Federica Veronese, Vanessa Tarantino, Paola Savoia and Massimo Salvi

Poster session

Track 5 - Biomedical Signal and Image Processing

Associations between fatigue and functional connectivity of dopamine and noradrenaline circuits in Parkinson's disease
Manuela Moretto, Ilaria Di Vico, Agnese Tamanti, Giovanni Tomelleri, Daniel Martins, Ottavia Dipasquale, Mattia Veronese, Alessandra Bertoldo, Sarah Ottaviani, Francesca Benedetta Pizzini, Michele Tinazzi and Marco Castellaro

Breast Cancer Detection via Two-dimensional Ultrasound Tomography
Stefano Franceschini, Michele Ambrosanio, Maria Maddalena Autorino, Vito Pascazio and Fabio Baselice

Computer Vision and Deep Learning for Human Motion Analysis
Matteo Moro, Vito Paolo Pastore, Giorgia Marchesi, Luca Garello, Chiara Tacchino, Paolo Moretti, Matilde Inglese, Francesca Odone and Maura Casadio

fMRI characterization of intrinsic brain networks relevant for motor control with and without visual feedback by fractal dimension
Camilla Sala, Camillo Porcaro, Stephen D. Mayhew and Andrew Bagshaw

Radiofrequency Echographic Multi Spectromery for Fragility Fracture prediction through Fragility Score
Fiorella Anna Lombardi, Paola Pisani, Alessandra Natale, Ernesto Casciaro, Fabiola Rosa Contaldo, Roberto Franchini, Maurizio Muratore, Francesco Conversano and Sergio Casciaro

Towards 3D Virtual Histology of melanoma tissue by means of lab-based X-ray Phase Contrast Computed Micro-Tomography
Giulia Saccomano, Francesco Brun, Diego Dreossi, Giuliana Tromba, Luca Brombal and Maurizio Pinamonti

Comparison of autonomic signals between healthy subjects and chronic low back pain patients at rest and during noxious stimulation
Serena Moscato, Wenchao Zhu, Yikang Guo, Sagar Kamarthi, Carin Ann Colebaugh, Kristin L. Schreiber, Robert Randolph Edwards, Richard D. Urman, Yan Xiao, Lorenzo Chiari and Yingzi Lin

XGBoost vs. TabPFN in Neuroimaging Machine Learning-based analysis
Alessandro Pasquale De Rosa, Alessandro d'Ambrosio, Chiara Marzi, Mario Cirillo, Alvino Bisecco, Manuela Altieri, Stefano Diciotti, Maria Assunta Rocca, Nicola De Stefano, Patrizia Pantano, Massimo Filippi, Gioacchino Tedeschi, Antonio Gallo and Fabrizio Esposito

Effect of EDA-driven sympathetic responses on the central processing of faces cued by hedonic odors: a preliminary ERP study
Gianluca Rho, Alejandro Luis Callara, Cinzia Cecchetto, Roberto Garofalo, Tommaso Lomonaco, Enzo Pasquale Scilingo and Alberto Greco

Comparative analysis of EMG-based classifiers for recognizing hand/wrist gestures and forces
Roberto Billardello, Francesca Cordella, Francesca Leone, Federico Mereu, Emanuele Gruppioni and Loredana Zollo

Osteoporosis Identification at Lumbar Vertebrae through a Neural Network Classifier
Manuel Maggio, Tommaso De Marco, Francesco Conversano, Giulia Macchia, Ivan Primitivo, Fiorella Lombardi, Paola Pisani and Sergio Casciaro

Cardiotocography in antenatal fetal monitoring of diabetes-complicated pregnancies
Giulio Steyde, Edoardo Spairani, Beniamino Daniele, Giovanni Magenes and Maria Gabriella Signorini

Control Theory Measures for Dynamic Analyses of Human Functional Connectome Data
Simone Papallo, Ester Riccio, Alessandro Pasquale De Rosa, Mario Cirillo, Francesco Amato, Mario Sansone and Fabrizio Esposito

EEG-based quantitative measures to support the clinical diagnosis of disorders of consciousness
Ilaria Quattrociocchi, Donatella Mattia, Angela Riccio, Mariagrazia D'Ippolito, Marta Aloisi, Rita Formisano and Jlenia Toppi

A Novel Authentication System Based on Hand Gesture Ultrasound Signatures
Stefano Franceschini, Maria Maddalena Autorino, Michele Ambrosanio, Vito Pascazio and Fabio Baselice

A comparative study of Super-Resolution methods in fetal MRI
Tommaso Ciceri, Letizia Squarcina, Adele Ferro, Florian Montano, Alessandra Bertoldo, Nicola Persico, Simona Boito, Fabio Triulzi, Giorgio Conte, Paolo Brambilla and Denis Peruzzo

Brugada Syndrome: Characterization of QT Interval Components and Correction
Agnese Sbrollini, Sofia Romagnoli, Emanuela Teresina Locati, Micaela Morettini and Laura Burattini

Interhemispheric functional connectivity: an fMRI study in two split-brain patients
Ilaria Marcantoni, Giusi Piccolantonio, Elena Vitti, Gabriele Polonara, Mojgan Ghoushi, Marco Valenti, Luca Reversi, Nicoletta Foschi, Simona Lattanzi, Laura Burattini and Mara Fabri

A convolutional neural network to identify osteoporosis from femoral echographic scans: a preliminary study
Antonio Colucci, Giusy Peluso, Fiorella Anna Lombardi, Mauro Bellone, Francesco Conversano, Roberto Franchini, Paola Pisani, Italo Epicoco, Massimo Cafaro and Sergio Casciaro

Comparison of Machine Learning Approaches for Physiological States Classification Using Heart Rate and Pulse Rate Variability Indices
Marta Iovino, Michal Javorka, Luca Faes and Riccardo Pernice

Bayesian Surprise from a Deep Learning Model of Italian Language to Model Neural Activity
Andrea Gerardo Russo, Assunta Ciarlo, Francesco Di Salle, Mario Sansone, Gioacchino Tedeschi and Fabrizio Esposito

The role of hemodynamics in arteriovenous fistula remodelling and failure. A CFD longitudinal study
Luca Soliveri, Michela Bozzetto, Paolo Brambilla, Anna Caroli and Andrea Remuzzi

Abnormal Ventricular Potentials Identification Using a Siamese Neural Network
Andrea Pitzus, Giulia Baldazzi, Graziana Viola, Luigi Raffo and Danilo Pani

Evaluation of breast density variability between right and left breasts
Francesca Angelone, Alfonso Maria Ponsiglione, Maria Paola Belfiore, Gianluca Gatta, Roberto Grassi, Francesco Amato and Mario Sansone

Estimating the degree of Non-Alcoholic Fatty Live Disease (NAFLD) from ultrasound images: preliminary results
Simone Kresevic, Milos Ajcevic, Mauro Giuffrè, Pierpaolo Pupa, Carlo Moretto, Simone Pennini, Lory Saveria Crocè and Agostino Accardo

Soft-tissue alterations identified with a CNN trained with simulated ultrasound images integrating expert knowledge
Luigi Antelmi, Antonio Colucci, Fiorella Anna Lombardi, Alessia Centonze, Tommaso De Marco, Francesco Conversano, Paola Pisani and Sergio Casciaro

Exploring the potential of MCVAE for patients stratification and skewed data compensation across the AD continuum
Federica Cruciani, Ettore Cinquetti, Lorenza Brusini, Anonino Aparo, Carlo Combi, Ilaria Boscolo Galazzo and Gloria Menegaz

A deep learning network from downsampled diffusion-weighted MRI k-space to image-space
Marta Gaviraghi, Baris Kanber, Antonio Ricciardi, Fulvia Palesi, Francesco Grussu, Carmen Tur, Alberto Calvi, Rebecca Samson and Claudia Angela Michela Gandini Wheeler-Kingshott

Distinguishing lymph nodes in head and neck cancer patients using MRI-based radiomics
Jiaying Liu, Anna Corti, Giuseppina Calareso, Valentina Corino and Luca Mainardi

A deep learning approach for the analysis of voxel composition in magnetic resonance imaging
Maria Maddalena Autorino, Stefano Franceschini, Michele Ambrosanio, Fabio Baselice and Vito Pascazio

Association between inflammation and brain microstructure in First Episode Psychosis investigated with DTI
Letizia Squarcina, Giuseppe Delvecchio, Matilde Pavan, Cinzia Perlini, Marcella Bellani, Antonio Lasalvia, Annamaria Finardi, Mirella Ruggeri, Roberto Furlan and Paolo Brambilla

Analysis of muscular activity of a cashier during different modalities of human robot collaboration
Giovanni Corvini, Silvia Conforto, Simone Ranaldi, Maurizio Schmid and Daniele Bibbo

Machine learning-based classification of cortical response to visual stimuli recorded with an ECoG array in mice: a case study
Daniela De Luca, Sara Moccia, Raffaele Mazziotti, Leonardo Lupori, Tommaso Pizzorusso and Silvestro Micera

Effects of State Representation on a Reinforcement Learning Based Decision Support System
Cristian Drudi, Maximiliano Mollura and Riccardo Barbieri

Driver drowsiness detection relying on infrared thermal imaging: a machine learning approach
Daniela Cardone, David Perpetuini, Michele Tritto, Sergio Nocco, Alessandro Tiberio and Arcangelo Merla

Decoding Emotions through Music: A Physiological Analysis of Emotion Recognition
Edoardo Maria Polo, Maximiliano Mollura, Alessia Paglialonga and Riccardo Barbieri

Assessing Multisite PET Neuroimaging Harmonisation for Normative Modelling
Alessio Giacomel, Daniel Martins, Giovanna Nordio, Rubaida Easmin, Oliver Howes, Steven C.R. Williams, Federico Turkheimer, Marius de Groot, Ottavia Dipasquale and Mattia Veronese

A Multiparameter Statistical Approach for Cardiotocographic Signals Analysis
Alfonso Maria Ponsiglione, Annarita Tedesco, Noemi Pisani, Leandro Donisi, Carlo Ricciardi, Maria Romano and Francesco Amato

Disclosing brain functional connections with multi-dimensional approaches
Laura Marzetti, Alessio Basti, Roberto Guidotti, Guido Nolte and Vittorio Pizzella

Enhancing Safety in Industry 4.0: The Use of Passive Brain Computer Interfaces for Vigilance Monitoring
Ettore Cinquetti, Ilaria Siviero, Silvia Francesca Storti and Gloria Menegaz

Optimization of a cardiac tissue segmentation pipeline in murine whole-heart reconstructions
Francesco Giardini, Eleonora Barcali, Martino De Santis, Benedetta Olmi, Erica Lazzeri, Cosimo Nardi and Leonardo Bocchi

Combining high-density electromyography and ultrafast ultrasound to assess individual motor unit properties in vivo
Marco Carbonaro, Robin Rohlén, Silvia Seoni, Kristen Meiburger, Taian Vieira, Christer Grönlund and Alberto Botter

Tensor-based morphometry of T1 weighted brain images reveals subtle volume enlargement of temporalis muscles
Assunta Ciarlo, Andrea G. Russo, Andrea Viggiano, Carmine Secondulfo, Francesco Di Salle, Fabrizio Esposito and Antonietta Canna

Pseudo resting-state investigation from task-evoked functional MRI signals
Alice Giubergia, Sara Mascheretti, Valentina Lampis, Tommaso Ciceri, Francesca Maccarone, Martina Villa, Chiara Andreola, Filippo Arrigoni, Alessandra Bertoldo and Denis Peruzzo

Phase synchronization between breathing and ppg signals in sleep events recordings of adult subjects
Alberto Morelli, Leonardo Bocchi and Piergiorgio Francia

Impact of diffusion connectivity metrics on white matter abnormalities in glioma
Maria Colpo, Erica Silvestri, Umberto Villani, Mariagiulia Anglani, Diego Cecchin, Maurizio Corbetta and Alessandra Bertoldo

Millimeter-Waves Imaging for Breast Cancer Detection: Development of Analytical Models
Simona Di Meo, Giulia Bertuzzi, Giulia Matrone, Giovanni Magenes and Marco Pasian

mmWave Radars Data Processing for Gait Parameters Extraction
Antonio Nocera, Federica Verdini, Sandro Fioretti, Gianluca Ciattaglia, Michela Raimondi, Laura Burattini, Linda Senigagliesi and Ennio Gambi

Synthesis of ultrasound images from semantic labels with controllable texture features
Francesco Marzola, Nens van Alfen, Massimo Salvi, Jonne Doorduin and Kristen Meiburger

Myelin quantification in Magnetic Resonance Imaging
Eleonora Lupi, Marta Gaviraghi, Simone Rancati, Fulvia Palesi, Francesco Grussu, Marco Battiston, Carmen Tur, Alberto Calvi, Sara Collorone, Antonio Ricciardi, Ferran Padros, Baris Kanber, Egidio D'Angelo, Rebecca Samson and Claudia Am Gandini Wheeler-Kingshott

Automated quantification of FDOPA PET using XNAT
Giovanna Nordio, Rubaida Easmin, Alessio Giacomel, Ottavia Dipasquale, Daniel Martins, Astrid Schiulaz, Steven Williams, Federico Turkheimer, Oliver Howes and Mattia Veronese

Experimental Microwave Imaging of Human Forearm
Michele Ambrosanio, Martina Teresa Bevacqua, Tommaso Isernia, Joe Lo Vetri and Vito Pascazio

K-medoid clustering of premotor firing patterns supports fine decoding of macaque reach-and-grasp
Elena Hilary Rondoni, Matteo Pizzinga, Francesca Lanzarini, Monica Maranesi, Davide Albertini, Luca Bonini and Alberto Mazzoni

Impact of model selection procedure on Deep Neural Networks ensemble for the Choroid Plexus segmentation in Multiple Sclerosis
Valentina Visani, Valerio Natale, Annalisa Colombi, Agnese Tamanti, Alessandra Bertoldo, Corina Marjin, Giuseppe Kenneth Ricciardi, Francesca Benedetta Pizzini, Massimiliano Calabrese and Marco Castellaro

3D moles mapping and analysis for automatic melanoma detection
Giulia Nanto, Alexa Berto, Luigi Dall'Olmo, Christian Ciolfi, Filippo Scolaro, Mauro Alaibac, Simone Mocellin, Antonio Galgaro and Fabio Scarpa

Error perception in different environments: Monitor vs Augmented Reality
Andrea Farabbi, Luigi Pizzulli, Eleonora Sala, Letizia Santini and Luca Mainardi

Time-frequency analysis of brain response to 3D slant texture and stereo cues
Francesca Peveri, Gabriele Arnulfo, Silvio Paolo Sabatini and Andrea Canessa

Breast Cancer Imaging at Microwave Frequencies via Neural Networks
Michele Ambrosanio, Stefano Franceschini, Maria Maddalena Autorino, Fabio Baselice and Vito Pascazio

On the use of PARAFAC algorithm in group network analysis: a simulation study
Andrea Ranieri, Floriana Pichiorri, Emma Colamarino, Valeria de Seta, Donatella Mattia and Jlenia Toppi

Hidden Markov Models for the identification of fetal phases in CTG recordings
Edoardo Spairani, Giulio Steyde, Beniamino Daniele, Maria Gabriella Signorini and Giovanni Magenes

P300 event-related potential in patients with cognitive decline correlates with task performance
Alberto Arturo Vergani, Carlo Fabbiani, Salvatore Mazzeo, Rachele Burali, Michael Lassi, Giulia Giacomucci, Valentina Moschini, Filippo Emiliani, Maenia Scarpino, Silvia Bagnoli, Assunta Ingannato, Benedetta Nacmias, Sonia Padiglioni, Sandro Sorbi, Antonello Grippo, Valentina Bessi and Alberto Mazzoni

Cortical correlates in upright static balance in adolescent idiopathic scoliosis
Maria Rubega, Matilde Paramento, Stefano Masiero and Emanuela Formaggio

Decoding the interplay between brain structural and functional connectivity in Alzheimer's disease
Virginia Filippi, Edoardo Paolini, Federica Cruciani, Lorenza Brusini, Francesco Dal Santo, Gloria Menegaz, Ilaria Boscolo Galazzo and Silvia Francesca Storti

Closing the loop between neurostimulation and control theory
Roberto Guidotti, Alessio Basti, Giulia Pieramico, Antea D'Andrea, Gian Luca Romani, Vittorio Pizzella and Laura Marzetti

A machine learning approach for stride speed estimation based on a head-mounted IMU
Paolo Tasca, Francesca Salis, Samanta Rosati, Gabriella Balestra and Andrea Cereatti

Differences in cortical reorganization during visuo-motor tasks executed with the dominant and non-dominant hands
Alessandra Calcagno, Stefania Coelli, Federico Temporiti, Manuela Galli, Roberto Gatti and Anna Maria Bianchi

Alteration of muscle recruitment in Parkinson's disease assessed by EMG-based occurrence frequency
Marco Romanato, Francesco Di Nardo, Fabiola Spolaor, Daniele Volpe, Sandro Fioretti and Zimi Sawacha

Altered EEG amplitude coupling correlates to cognitive dysfunction in iRBD patients
Monica Roascio, Rosella Trò, Dario Arnaldi, Francesco Famà, Pietro Mattioli, Ki-Young Jung and Gabriele Arnulfo

Validating biomedical and clinical data via an annotations based framework: experiences within the PON VQA project
Barbara Puccio, Ugo Lomoio, Raffaele Giancotti, Mattia Cannistrà, Sergio Flesca, Francesco Scala, Giuseppe Tradigo, Pietro Hiram Guzzi, Pierangelo Veltri and Patrizia Vizza

Drivers' mental workload assessment based on machine learning applied to multimodal physiological data
David Perpetuini, Daniela Cardone, Michele Tritto, Sergio Nocco, Alessandro Tiberio and Arcangelo Merla

Algorithm based on the "dynamic risk" concept allows ahead-of-time suggestion of corrective insulin boluses in type 1 diabetes therapies employing continuous glucose monitors
Elisa Pellizzari, Francesco Prendin, Giacomo Cappon, Giovanni Sparacino and Andrea Facchinetti

Assessing the impact of brain gliomas on effective connectivity gradients
Giulia Pagnin, Giorgia Baron, Erica Silvestri, Alessandro Chiuso, Diego Cecchin, Maurizio Corbetta and Alessandra Bertoldo

Assessment of the effects of parcellation and frequency band on the definition of functional hubs in rsfMRI
Giulia Vallini, Erica Silvestri, Alessandro Panciera, Marco Aiello and Alessandra Bertoldo

Radiomic analysis of Epicardial Adipose Tissue in cardiac MRI for hospitalization risk assessment
Francesca Lo Iacono, Martina Minotti, Marco Gugliemo, Marco Penso, Maria Ludovica Carerj, Gianluca Pontone and Valentina D.A. Corino

Augmented Reality to Evaluate Temporo-Mandibular Joint Alterations in Orthognathic Patients
Nicolas Emiliani, Federico Babini, Chiara Gulotta, Giovanni Badiali, Emanuela Marcelli and Laura Cercenelli

Transfer learning approaches to classify foetal occiput positions on transperineal ultrasound images
Rocco Morello, Maria Giovanna Di Trani, Andrea Dall'Asta, Francesco Conversano, Paola Pisani, Marco Di Paola, Tullio Ghi and Sergio Casciaro

The hidden structural complexity of the human cerebral cortex
Federica Giorgini, Stefano Diciotti and Chiara Marzi

Track 6 - Neural Engineering and Micro and Nano-technologies

Prediction of injectables' stability leveraging inline analysis and machine learning
Samuele Fiorenza, Paolo Antonio Netti and Enza Torino

A testbed for mechanical and thermal stimulation in studies of somatosensory functions
Marika Sperduti, Nevio Luigi Tagliamonte, Costantino Casale, Paolo Antonio Netti and Loredana Zollo

Engineering of biological entities through dynamic perturbations of lipidic membranes.
Simona Silvestri, Eugenia Romano, Paolo Antonio Netti and Enza Torino

Mechanical validation of an innovative intrafascicular neural interface to restore urinary bladder dysfunctions
Elena Aprea, Alice Giannotti, Outman Akouissi and Silvestro Micera

Development of excitatory neuronal networks derived from human induced pluripotent stem cells
Giulia Parodi, Michela Chiappalone and Sergio Martinoia

A novel microfluidic-based approach to study protein stability behavior in highly concentrated and viscous (HCV) systems
Osvaldo Bortone, Paolo A. Netti and Enza Torino

Towards personalized electroceutical therapy: electrophysiological investigations in a pre-clinical model of ischemic lesion
Marta Carè, Federico Barban, Mattia Di Florio, Rosaria Greco, Cristina Tassorelli and Michela Chiappalone

Boosted transport of Theranostic Angiopep-2 engineered crosslinked Hyaluronic Acid NanoParticles (Thera-ANG-cHANPs) in glioblastoma cells
Angela Costagliola Di Polidoro, Joost Haeck, Laura Mezzanotte, Martine Lamfers and Enza Torino

Integrated sensors for real-time monitoring of biological barriers in engineered cell culture dynamic in vitro models
Simone Perottoni, Alessandro Bonacina, Ruben Dell'Oro, Francesca Donnaloja, Lucia Boeri, Luca Magagnin, Diego Albani and Carmen Giordano

PEDOT:PSS ink-jet printed microelectrodes on paper: towards low-cost and green MEA devices
Fabio Terranova, Andrea Spanu, Annalisa Bonfiglio and Sergio Martinoia

Photosensitive pattern to control geometry and activity of a neural network
Andrea Andolfi, Pietro Arnaldi, Donatella Di Lisa, Monica Frega, Sergio Martinoia and Laura Pastorino

Exposure Assessment of Young People to Wearable Antennas at 5G frequencies
Silvia Gallucci, Martina Benini, Marta Bonato, Emma Chiaramello, Serena Fiocchi, Gabriella Tognola and Marta Parazzini

Interconnected brain regions-on-a-chip: role of connectivity and heterogeneity in the electrophysiological activity
Martina Brofiga, Francesca Callegari, Fabio Poggio, Ilaria Donati della Lunga, Letizia Cerutti, Mariateresa Tedesco and Paolo Massobrio

Comparison of RF exposure levels in 5G-V2X and ITS-5.9 GHz vehicular connectivity
Martina Benini, Marta Bonato, Silvia Gallucci, Serena Fiocchi, Emma Chiaramello, Marta Parazzini and Gabriella Tognola

Profiling of phase-amplitude couplings across sleep for personalized neuroengineering systems
Vinícius Cota, Gianluca Federici, Gabriele Arnulfo and Michela Chiappalone

Day 3

Podium session

Track 4 - Biomaterials, Cell & Tissue Engineering, Biofabrication

Peptide-functionalized chitosan sponges for bone tissue regeneration
Elena Zeni, Paola Brun, Leonardo Cassari, Giovanna Iucci, Antonio Gloria, Annj Zamuner and Monica Dettin

Innovation in neuronal cell culture: from adhesion to maturation, chitosan promotes developing nervous system
Donatella Di Lisa, Lorenzo Muzzi, Elena Dellacasa, Monica Frega, Sergio Martinoia and Laura Pastorino

Development of analytical models to predict self-folding of 4D bioprinted scaffold
Alessio Esposito, Irene Chiesa, Claudia Dell'Amico, Marco Onorati and Carmelo De Maria

Dose-controlled low-intensity pulsed ultrasound and pulsed electromagnetic fields stimulations modulate inflammation in human macrophages
Francesco Iacoponi, Fabio Orlando, Soria Gasparini, Tiziano Pratellesi, Andrea Cafarelli and Leonardo Ricotti

In vitro exposure of endothelial cells to mechanical vibrations
Elena Carrara, Sofia Poloni, Chiara Emma Campiglio, Elisa Riceputi, Michela Bozzetto and Andrea Remuzzi

Vibropolyfection: boosting polymer-mediated gene delivery by mechanical cell loading
Nina Bono, Federica Ponti, Luca Russo, Paolo Bigini, Diego Mantovani and Gabriele Candiani

Track 7 - Biorobotics, rehabilitation & Assistive Technologies

A Reliable User-Independent Motion Intent Detection from Transient EMG Data for Shoulder Joint
Mara Scattolini, Andrea Tigrini, Federica Verdini, Sandro Fioretti, Laura Burattini, Micaela Morettini and Alessandro Mengarelli

Performance Evaluation of the Gloreha Sinfonia Device in Bimanual Modality
Martina Lapresa, Emilio Maria Romano, Loredana Zollo and Francesca Cordella

Poster session

Track 4 - Biomaterials, Cell & Tissue Engineering, Biofabrication

Composite scaffolds based on polyvinyl alcohol and acellular cartilage matrix for hemophilic arthropathy treatment
Marta Confalonieri, Silvia Barbon, Elena Stocco, Veronica Macchi, Raffaele De Caro, Silvia Todros, Andrea Porzionato and Piero Giovanni Pavan

Micropatterned PDMS substrates for cellular mechanotransduction modelling
Elena Bianchi, Cecilia Crescioli, Paola De Stefano, Gabriele Dubini and Alessandro F. M. Pellegata

Cell encapsulation into silk fibroin microgels
Giovanni Perotto, Federica Ponti, Giulio Saroglia, Stefania Marcuzzo, Eleonora Giagnorio, Giuseppe Lauria Pinter, Elena Rosini, Luigi De Nardo, Athanassia Athanassiou, Gabriele Candiani and Nina Bono

Tuning the features of microphysiological systems for biomimetic intestinal in vitro models
Alessandra Maria Anna Rando, Lorenzo Pietro Coppadoro, Sabrina Nicolò, Maria Lombardi, Chiara Foglieni, Gianfranco Beniamino Fiore and Monica Soncini

Injectable gelatin-based photocurable fiber-reinforced hydrogel for the treatment of osteochondral defects
Ignazio Niosi, Lorenzo Vannozzi, Diego Trucco, Silvia Farè and Leonardo Ricotti

Green-Based Anti-Biofilm Nanoformulations Against Bacterial Contaminations In Nosocomial Environments
Giovanni Lo Bello, Roberto Raiteri, Elena Dellacasa, Orietta Monticelli, Maria Luisa Cristina and Laura Pastorino

Near Field Electrospinning Process Using a Multi-Axis Robot
Salvatore D'Alessandro, Andrada Pica, Franco Marinozzi, Fabiano Bini and Gianluca Cidonio

Biological evaluation in vitro and in vivo of hybrid membrane to assess biomedical application
Martina Todesco, Roberto Luisetto, Martina Casarin, Saima Jalil Imran, Gino Gerosa, Chiara Giulia Fontanella and Andrea Bagno

Bio-fabrication of in vitro tissues possessing organ-specific endogenous extracellular matrices
Francesco Urciuolo, Giorgia Imparato, Vincenza de Gregorio and Paolo Antonio Netti

Hydrogel-based photopolymers for 3D printing of scaffolds by bench-top stereolithography
Chiara Merli, Claudia Capitini, Martino Calamai, Gabriele Frediani, Federico Carpi and Caterina Credi

Assessment of printability on autoclaved biomaterial inks for extrusion bioprinting
Eugenia Spessot, Aurora Battistella, Antonella Motta and Devid Maniglio

Intestinal epithelium on chip for absorption studies
Alessandro Cordiale, Mattia Ballerini, Luigi Nezi, Paola Occhetta and Marco Rasponi

Effect of Chitosan coating on PLA electrospun scaffolds for bone tissue engineering
Francesco Lopresti, Vincenzo La Carrubba, Simona Campora and Giulio Ghersi

Microgels as a Biosensing Platform
Edmondo Battista, Sabrina Napoletano, Maria Isabella Maremonti, David Dannahuser, Paolo Antonio Netti and Filippo Causa

Experimental and computational pipeline for identifying oxygen metabolic rate parameters in 2D and 3D in vitro constructs
Ermes Botte, Piera Mancini, Chiara Magliaro and Arti Ahluwalia

Antibacterial activity of bacterial cellulose based wound care paste
Stefania Villani, Sanosh Kunjalukkal Padmanabhan, Mariangela Stoppa, Rossella Nisi, Antonio Licciulli, Pietro Alifano and Christian Demitri

Microfluidic system for a label-free, real-time functional assessment of thrombotic risk
Tatiana Mencarini, Eleonora Puce, Mariagrazia Calogiuri, Mariangela Scavone, Silvia Bozzi and Alberto Redaelli

In-flow viscoelastic compression to probe single-cell biomechanical properties
Maria Isabella Maremonti, David Dannhauser, Valeria Panzetta, Paolo Antonio Netti and Filippo Causa

Mesenchymal Stem Cell Response to Micropatterns and Dynamic Topographies
Chiara Cimmino, Paolo Antonio Netti and Maurizio Ventre

Cell-aware optimization of the extrusion-based bioprinting process
Amedeo Franco Bonatti, Irene Chiesa, Gabriele Maria Fortunato, Aurora De Acutis, Giovanni Vozzi and Carmelo De Maria

3D bioprinting as a tool for the early correction of leather defects in the tanning industry
Costanza Daddi, Matteo Baggiani, Matteo Nicoletta, Simone Micalizzi, Gabriele Maria Fortunato, Aurora De Acutis, Carmelo De Maria, Marco Onorati and Giovanni Vozzi

An engineered breast cancer model on chip for personalized and multiple drug therapy
Giorgia Imparato, Claudia Mazio, Francesco Urciuolo and Paolo Antonio Netti

RNA Sequencing analysis to study Duchenne dilated cardiomyopathy in patient-derived 3D organoid models
Vittoria Marini, Fabiola Marino, Flaminia Aliberti, Maurilio Sampaolesi and Yoke Chin Chai

Hydrogels scaffolds as 2D in vitro models to explore the impact of microenvironmental stiffness on lung adenocarcinoma cells
Valeria Panzetta, Crescenzo Frascogna, Claudia Mazio, Francesco Catuogno, Giorgia Imparato, Francesco Urciuolo and Paolo Antonio Netti

A microfluidic platform to unravel immune cells cross-talk in rheumatoid arthritis
Cecilia Palma, Bianca Aterini, Carlotta Catozzi, Luigi Nezi, Silvia Lopa, Teresa Manzo, Marco Rasponi and Paola Occhetta

Valve-jet technology for robotic-based in situ bioprinting applications
Elisa Batoni, Gabriele Maria Fortunato, Andrea Guerra, Giovanni Vozzi and Carmelo De Maria

Cryopreservation effects on biological tissues: histological and mechanical assessments
Martina Casarin, Martina Todesco, Chiara Giulia Fontanella, Alessandro Morlacco, Fabrizio Dal Moro and Andrea Bagno

Design and fabrication of a novel bioreactor for the engineering of tendon/ligament-to-bone interfaces
Ginevra Pegollo, Simone Micalizzi, Aurora De Acutis, Carmelo De Maria and Giovanni Vozzi

Biological validation of thiolated food grade secondary oil in water nanoemulsions with enhanced mucus-adhesion properties in Intestine-on-a-chip model
Elena Lagreca, Raffaele Vecchione, Raffaele Crispino and Paolo Antonio Netti

Design and fabrication of a micro-dialyser for the study of the gut microbiota-tissues cross-talk
Aurora De Acutis, Costanza Daddi, Francesco Biagini, Emanuele Russello, Marco Calvigioni, Emilia Ghelardi, Carmelo De Maria and Giovanni Vozzi

Natural polymer-based bioinks exploiting internal gelation mechanism for cardiac tissue engineering
Giovanni Paolo Stola, Elena Marcello, Camilla Paoletti, Letizia Nicoletti and Valeria Chiono

Design and fabrication of an intestinal phantom to mimic intestinal tone and motility
Paolo Signorello, Ludovica Cacopardo, Nicole Guazzelli, Irene Nicolai, Federica Viti, Paolo Gandullia, Robert Heuckeroth and Arti Ahluwalia

Nanostructured coatings with bacteria-triggered antimicrobial response for medical devices
Maria Antonia Cassa, Gianluca Ciardelli, Piergiorgio Gentile and Irene Carmagnola

An advanced culture system to investigate electrospun graft biomechanisms for vascular tissue engineering
Elia Pederzani, Chiara Emma Campiglio, Marta Ripamonti, Maichael Esposito, Angela Rizzo, Alice Caldiroli, Stefania Adele Riboldi, Andrea Remuzzi, Gianfranco Beniamino Fiore and Monica Soncini

3D printing of a nanomaterials-embedded gelatin/pectin hydrogel for the development of an in vitro drug testing platform
Lorenzo Guidi, Elisabetta Rosellini, Giovanni Vozzi, Luigi Lazzeri, Maria Grazia Cascone, Carmelo De Maria, Gabriele Maria Fortunato and Anna Lapomarda

Optimization of advanced setups with integrated readouts for evaluation of cardiac toxicity in a heart on chip device
Giacomo Cretti, Marco Rasponi, Roberta Visone, Udo Kraushaar and Paola Occhetta

Peptide anchoring methods for PEEK surfaces
Leonardo Cassari, Annj Zamuner, Grazia Maria Lucia Messina, Martina Marsotto, Hao-Chen Chang, Trevor Coward, Chiara Battocchio, Giovanni Marletta, Lucy Di Silvio and Monica Dettin

Design and validation of a microfluidic cartridge to prepare non-viral gene delivery complexes
Giovanni Protopapa, Nina Bono, Roberta Visone, Fabio D'Alessandro, Marco Rasponi and Gabriele Candiani

Biomimetic platform for investigating in vitro the cell biological response to mechanical stretching – periodontal ligament stem cell application
Beatrice Masante, Giovanni Putame, Andrea Tancredi Lugas, Marta Tosini, Ilaria Roato, Federico Mussano, Mara Terzini, Alberto Audenino and Diana Massai

Evaluation of the optimal pore size for 3D printed bone scaffolds in a perfusion bioreactor
Elisa Batoni, Carmelo De Maria and Giovanni Vozzi

Extrusion control strategy for robotic-based in situ bioprinting
Gabriele Maria Fortunato, Michele Molisani, Giovanni Vozzi and Carmelo De Maria

Effects of different degumming methods on the quality of sericin samples
Ivana Dragojlov, Simone Vesentini and Elisa Fasoli

Engineering the tumor environment in vitro using peptide-enriched, hyaluronic acid-based hydrogels
Annj Zamuner, Leonardo Cassari, Monica Dettin, Maria Teresa Conconi and Elisabetta Sieni

Multiscale computational models for predicting hydrogel viscoelastic properties
Nicole Guazzelli, Ludovica Cacopardo, Valentina Inghirami and Arti Ahluwalia

Engineering of poly(urethane)-based porous constructs for cardiac tissue model design
Andrea Alliaud, Monica Boffito, Rosella Laurano, Susanna Sartori and Gianluca Ciardelli

FRESH approach for the development of 3D channel network in 3D in vitro models
Matteo Pitton, Chiara Liguori and Silvia Farè

Mathematical model of nutrients transport and cell growth in a bioprinted hydrogel
Ilaria Parodi, Silvia Scaglione, Marco Massimo Fato and Rodolfo Repetto

Rapid prototyping of a microfluidic platform for nasal mucosa models
Maria Testa, Francesco Lopresti, Olga Manna, Stefano Burgio, Giorgia Intilli, Alberto Fucarino and Vincenzo La Carrubba

Track 7 - Biorobotics, rehabilitation & Assistive Technologies

Brain-Computer Interface assisted Motor Imagery training in post-stroke rehabilitation: longitudinal study of the EEG sensorimotor rhythms
Elena Mongiardini, Emma Colamarino, Floriana Pichiorri, Andrea Ranieri, Jlenia Toppi, Donatella Mattia and Febo Cincotti

A multimodal wearable system for Human Activity Recognition during daily activities
Pietro Benvenuti, Erika Rovini, Laura Fiorini and Filippo Cavallo

Effectiveness of a home-based tele-rehabilitation program for post-Covid patients: preliminary results
Serena Cerfoglio, Paolo Capodaglio, Paolo Rossi, Federica Verme, Gabriele Boldini, Viktoria Cvetkova, Manuela Galli and Veronica Cimolin

Virtual prototyping of a robotic chess player for play therapy
Mattia Pesenti, Roberto Schinelli, Alberto Antonietti, Marta Gandolla and Alessandra Pedrocchi

A hydraulic implantable artificial detrusor for controlled bladder voiding
Simone Onorati, Federica Semproni, Linda Paternò, Giada Casagrande, Veronica Iacovacci and Arianna Menciassi

Brain signals in semi-immersive and immersive VR environments: a feasibility study
Valerio Antonio Arcobelli, Kevin Marcaccini, Poula Hassaballah, Luca Tonin, Stefano Tortora and Silvia Orlandi

Wearable tactile display of softness for virtual reality
Gabriele Frediani and Federico Carpi

Computational joint action: dynamical models to understand the development of joint coordination
Cecilia De Vicariis, Laura Bandini, Vinil T. Chackochan and Vittorio Sanguineti

Fast path replanning in a dynamic environment in percutaneous cardiac interventions
Angela Peloso, Rossella Damiano, Emiliano Votta and Elena De Momi

An attention classifier for the evaluation of a robotic therapy in children with Autism Spectrum Disorder
Laura Santos, Martina Murgo, Bárbara Silva, Alice Geminiani, Arianna Caglio, Silvia Annunziata, Catarina Barata, José Santos-Victor and Alessandra Pedrocchi

A safe robot control for semi-autonomous pedicle tapping
Clemente Lauretti, Francesca Cordella, Ilenia Saltarelli and Loredana Zollo

Evaluating Spatial Hearing in Virtual Reality Environment
Fulvio Missoni and Andrea Canessa

A cloud-based mobile platform to monitor and counteract cognitive decline
Laura Bandini, Cecilia De Vicariis, Maria Cristina Novello, Carlo Chiorri and Vittorio Sanguineti

Non-linear dimensionality-reduction approach for powered wheelchair control
Elisa Misley, Fabio Rizzoglio, Amy Bellitto, Antonino Massone, Davide Russo, Giorgio Carlini, Maura Casadio and Camilla Pierella

A preliminary test of a novel method for the real time estimation of foot displacement using MIMUs attached to the foot
Ilaria Giuseppina Porco, Sergio Mauro Gavino Solinas, Aldo Lazich and Ugo Della Croce

Understanding user needs for robotics assisted cognitive and physical rehabilitation
Ludovico Ferreri, Enea Parimbelli, Irene Aprile and Silvana Quaglini

Assessment of Balance disorder and vestibular dysfunction using Mixed Reality
Simona Pascucci, Valerio Margani, Michela Franzò, Matteo Curcio, Alberto Polsinelli, Rita Talamonti, Maurizio Barbara, Franco Marinozzi and Fabiano Bini

A Safe Reinforcement Learning platform for Autonomous Robotic Tissue Approaching
Ke Fan, Giancarlo Ferrigno and Elena De Momi

Sensor-based Assessment of Gross and Fine Motor Development in Primary School Children
Maria Cristina Bisi, Alice Masini, Stefania Toselli, Sofia Marini, Laura Bragonzoni, Andrea Ceciliani, Marcello Lanari, Alessandra Sansavini, Alessia Tessari, Davide Gori, Laura Dallolio and Rita Stagni

Personality Traits Influence the Perception of a Robotic Arm endowed with Social Cues
Carlo La Viola, Laura Fiorini, Gianmaria Mancioppi and Filippo Cavallo

A motor-assisted recumbent trike for cycling training in neurological patients
Federica Ferrari, Davide Savona, Eleonora Guanziroli, Franco Molteni, Alessandra Pedrocchi and Emilia Ambrosini

An improved method for the characterization of infants' general movements using a RGB-Depth sensor and a deep neural network tracking processing tool
Diletta Balta, Ilaria Giuseppina Porco, Hsinhung Kuo, Jing Wang, Olga Morozova, Manon Schladen, Andrea Cereatti, Peter Lum and Ugo Della Croce

Track 8 - Design and Validation of Biomedical Devices

Ex Vivo Animal Evaluation of IntraValvular Impedance Sensing Applied to Biological Heart Valve Prostheses
Camilla Gironi, Laura Cercenelli, Barbara Bortolani, Nicolas Emiliani, Lorenzo Tartarini and Emanuela Marcelli

Wearable sensor for in-vivo skin hydration monitoring
Andrea Cataldo, Raissa Schiavoni, Antonio Masciullo and Christian Demitri

Establishing Computational Modeling Credibility in Patients Undergoing TAVI
Chiara Catalano, Stefano Cannata, Caterina Gandolfo and Salvatore Pasta

Mechanical Properties of Polyamide 12 for the use in Balloon-Expandable Transcatheter Heart Valves
Omar Zahalka, Chiara Catalano, Tahir Turgut, Nils Gotzen, Stefano Cannata, Caterina Gandolfo and Salvatore Pasta

Patient-specific phantom for home haemodialysis
Gabriele Maria Fortunato, Francesca Tonelli, Alberto Greco, Nicola Carbonaro, Aldo Casani and Carmelo De Maria

A response surface-based approach to predict spinal rod contouring parameters
Francesca Berti, Linda Carpenedo, Camilla Boldrin and Luigi La Barbera

Highly controlled ultrasound-mediated drug delivery experiments: an in vitro set-up
Sofia Sirolli, Leonardo Ricotti and Andrea Cafarelli

Exposure set-up for assessing the far-field electromagnetic immunity levels of active implantable medical devices
Cecilia Vivarelli, Rosaria Falsaperla, Giancarlo Burriesci, Federica Censi, Giovanni Calcagnini and Eugenio Mattei

Temperature influence on reflectance photometers for bilirubin measurement
Lorenzo Zucchini, Milos Ajcevic and Agostino Accardo

Combination of VR and manikins to improve medical training
Mara Coduri, Andrea Calandrino, Giulia Addiego Mobilio, Elisa Grasso, Matteo Pescio, Paolo Rossi, Giorgio Carlini, Marco Chirico, Fabio Solari, Manuela Chessa, Maura Casadio and Serena Ricci

Usability of a multi-sensor array for the application of electro-phonocardiography in home care
Noemi Giordano, Gabriella Balestra, Samanta Rosati and Marco Knaflitz

Physiologically relevant in vitro experiments: degradation kinetics of a pool of enzymes
Cristina Oldani, Nina Bono, Alice Caldiroli, Stefania Adele Riboldi and Gabriele Candiani

Multiscale Modelling of Platelet Activation in Membrane Oxygenation Systems
Marta Baccarella and Salvatore Pasta

Engineering a smart intrauterine device based on pH-controlled copper release.
Greta Bertola, Ludovica Cacopardo, Florinda Coro, Carmelo De Maria and Arti Ahluwalia

Circulating tumour cells deformability measurement in microfluidics
Maria Isabella Maremonti, David Dannhauser, Paolo Antonio Netti and Filippo Causa

Open-source as an enabling approach for the introduction of artificial intelligence in healthcare
Florinda Coro, Amedeo Franco Bonatti, Gabriele Maria Fortunato, Ilenia Gulino, Lucia Arcarisi, Maria Elena Lippi, Valentina Calderai, Gionatan Gallo, Maurizio Palmieri, Pietro Ducange, Cinzia Bernardeschi, Gabriele Tomei, Paolo De Simone, Arti Devi Ahluwalia and Carmelo De Maria

A method for the evaluation of cervical surgical instrumentation reliability through a computational and experimental approach
Luca Ciriello, Alessandro Belluzzo, Andrea Grassi and Tomaso Villa

Microfluidic platform for cell classification from optical signatures via machine learning
David Dannhauser, Maria Isabella Maremonti, Paolo Antonio Netti and Filippo Causa

Remote In-Bed Monitoring of Vital Signs Using Radar Technology
Marco Mercuri, Ilde Lorato, Tom Torfs and Felice Crupi

A novel concept of steerable catheters actuated by muscle cells: the BioMeld project
Carlotta Salvatori, Leonardo Ricotti and Lorenzo Vannozzi

Development of a computational model to estimate the hemolysis risk associated with hemodialysis catheters
Ilaria Guidetti, Francesco De Gaetano, Diego Gallo, Umberto Morbiducci and Maria Laura Costantino

Author Index

Accardo Agostino	Discriminatory power of Global Longitudinal Strain and Left Ventricular Ejection Fraction for Identification of Dilated Cardiomyopathy
–	Estimating the degree of Non-Alcoholic Fatty Live Disease (NAFLD) from ultrasound images: preliminary results
–	Temperature influence on reflectance photometers for bilirubin measurement
Agnifili Mauro Luca	Lumped-parameter hemodynamic model as a non-invasive tool to assess coronary blood flow in AAOCA
Ahluwalia Arti Devi	A computational platform to assess the metabolic-electrophysiological behaviour of neurons cultured in monolayers
–	Design and fabrication of an intestinal phantom to mimic intestinal tone and motility
–	Early stages of cognitive decline are characterized by different EEG microstates dynamics
–	Engineering a smart intrauterine device based on pH-controlled copper release.
–	Experimental and computational pipeline for identifying oxygen metabolic rate parameters in 2D and 3D in vitro constructs
–	Genetic Algorithms for the identification and design of physiologically relevant 3D constructs
–	Multiscale computational models for predicting hydrogel viscoelastic properties
–	Open-source as an enabling approach for the introduction of artificial intelligence in healthcare
–	Oxygen metabolism in in vitro ecosystems
Aiello Marco	Assessment of the effects of parcellation and frequency band on the definition of functional hubs in rsfMRI
Ajcevic Milos	Discriminatory power of Global Longitudinal Strain and Left Ventricular Ejection Fraction for Identification of Dilated Cardiomyopathy
–	Estimating the degree of Non-Alcoholic Fatty Live Disease (NAFLD) from ultrasound images: preliminary results
–	Temperature influence on reflectance photometers for bilirubin measurement
Akouissi Outman	Mechanical validation of an innovative intrafascicular neural interface to restore urinary bladder dysfunctions
Alaibac Mauro	3D moles mapping and analysis for automatic melanoma detection
Albani Diego	Integrated sensors for real-time monitoring of biological barriers in engineered cell culture dynamic in vitro models
Alberti Giosuè	A dexterous hand prosthesis based on additive manufacturing
Albertini Davide	Development of predictive models for short-term prediction of disability progression in multiple sclerosis
–	K-medoid clustering of premotor firing patterns supports fine decoding of macaque reach-and-grasp
Albites-Sanabria Jose	Wearable-based Sit-to-Stand transfers in Older Adults: context differences between in-lab and home-based assessments
Alfano Caterina	Network-based integration of clinical, imaging and molecular biomarkers of dementia

Aliberti Flaminia	RNA Sequencing analysis to study Duchenne dilated cardiomyopathy in patient-derived 3D organoid models
Alifano Pietro	Antibacterial activity of bacterial cellulose based wound care paste
Alliaud Andrea	Engineering of poly(urethane)-based porous constructs for cardiac tissue model design
Aloisi Marta	EEG-based quantitative measures to support the clinical diagnosis of disorders of consciousness
Altieri Manuela	XGBoost vs. TabPFN in Neuroimaging Machine Learning-based analysis
Amato Francesco	A Distributed Multi-Centric Application for the Analysis of Cardiac Biomarkers
–	A Multiparameter Statistical Approach for Cardiotocographic Signals Analysis
–	A preliminary version of a Genome-Scale Metabolic Model for Induced Human Pluripotent Stem Cells (hiPSCs)
–	Control Theory Measures for Dynamic Analyses of Human Functional Connectome Data
–	Evaluation of breast density variability between right and left breasts
Amato Lorenzo Gaetano	Network model accounts for evolution of EEG functional connectivity in patients with cognitive decline
Ambrosanio Michele	A Novel Authentication System Based on Hand Gesture Ultrasound Signatures
–	Breast Cancer Detection via Two-dimensional Ultrasound Tomography
–	Breast Cancer Imaging at Microwave Frequencies via Neural Networks
–	Experimental Microwave Imaging of Human Forearm
–	A deep learning approach for the analysis of voxel composition in magnetic resonance imaging
Ambrosini Emilia	3D upper limbs tracking through inertial sensors: calibration, methodology, and validation
–	A motor-assisted recumbent trike for cycling training in neurological patients
–	Automatic extraction of acoustic features to predict Alzheimer's disease among English-speaking subjects
Andolfi Andrea	Photosensitive pattern to control geometry and activity of a neural network
Andrean Daniele	Modeling Doxorubicin Treatment Effect in Multiple Myeloma
Andreola Chiara	Pseudo resting-state investigation from task-evoked functional MRI signals
Andreoni Giuseppe	Quantifying the contribution of single joint kinematics to the overall ergonomic discomfort
Angelone Francesca	Evaluation of breast density variability between right and left breasts
Anglani Mariagiulia	Impact of diffusion connectivity metrics on white matter abnormalities in glioma
Anglese Serena	Biomechanical assessment of the anomalous coronary compression by patient-specific finite element analysis
–	Development of novel computational tool to support surgical planning for the treatment of Anomalous Aortic Origin of the Coronary Arteries (AAOCA)
Annunziata Silvia	An attention classifier for the evaluation of a robotic therapy in children with Autism Spectrum Disorder

Antelmi Luigi	**Soft-tissue alterations identified with a CNN trained with simulated ultrasound images integrating expert knowledge**
Antenucci Pietro	**How to assess vascular dysfunction during septic shock and resuscitation**
Antonello Riccardo	**Automated control of bioreactors: An hardware-in-the-loop proof of concept test towards an experimental facility**
Antonietti Alberto	**A multiscale computational approach to replicate the full-scale mouse striatum model**
–	**Virtual prototyping of a robotic chess player for play therapy**
Aparo Anonino	**Exploring the potential of MCVAE for patients stratification and skewed data compensation across the AD continuum**
Aprea Elena	**Mechanical validation of an innovative intrafascicular neural interface to restore urinary bladder dysfunctions**
Aprile Irene	**Understanding user needs for robotics assisted cognitive and physical rehabilitation**
Arcarisi Lucia	**Open-source as an enabling approach for the introduction of artificial intelligence in healthcare**
Arcobelli Valerio Antonio	**Brain signals in semi-immersive and immersive VR environments: a feasibility study**
Arnaldi Dario	**Altered EEG amplitude coupling correlates to cognitive dysfunction in iRBD patients**
Arnaldi Pietro	**Photosensitive pattern to control geometry and activity of a neural network**
Arnulfo Gabriele	**Altered EEG amplitude coupling correlates to cognitive dysfunction in iRBD patients**
–	**Profiling of phase-amplitude couplings across sleep for personalized neuroengineering systems**
–	**Time-frequency analysis of brain response to 3D slant texture and stereo cues**
Arrico Lorenzo	**Zwitterionic coatings for an implantable artificial pancreas**
Arrigoni Filippo	**Pseudo resting-state investigation from task-evoked functional MRI signals**
Aterini Bianca	**A microfluidic platform to unravel immune cells cross-talk in rheumatoid arthritis**
Athanassiou Athanassia	**Cell encapsulation into silk fibroin microgels**
Atzeni Michele	**Assessing Personal Exposure to Airborne Particulate Matter with Wearable Sensors and Ventilation Rate Models**
Atzori Manfredo	**A dexterous hand prosthesis based on additive manufacturing**
Audenino Alberto L.	**Biomimetic platform for investigating in vitro the cell biological response to mechanical stretching – periodontal ligament stem cell application**
–	**Mechanical evaluation of synthetic meshes: definition and verification of a rigorous test protocol**
–	**Reducing bone plates standard fatigue test time with an analytical runout load prediction**
–	**The effect of CFR-PEEK cross-link in short fixation for the stabilisation of lumbar metastasis: an in-vitro comparative study**.
Autorino Maria Maddalena	**A Novel Authentication System Based on Hand Gesture Ultrasound Signatures**
–	**Breast Cancer Detection via Two-dimensional Ultrasound Tomography**
–	**Breast Cancer Imaging at Microwave Frequencies via Neural Networks**

–	**A deep learning approach for the analysis of voxel composition in magnetic resonance imaging**
Avanzini Pietro	**Quantifying the contribution of single joint kinematics to the overall ergonomic discomfort**
Babini Federico	**Augmented Reality to Evaluate Temporo-Mandibular Joint Alterations in Orthognathic Patients**
Baccarella Marta	**Multiscale Modelling of Platelet Activation in Membrane Oxygenation Systems**
Bäckström Mikael	**Advances in the development of a instrumented head surrogate for brain injury investigation**
Badiali Giovanni	**Augmented Reality to Evaluate Temporo-Mandibular Joint Alterations in Orthognathic Patients**
Baggiani Matteo	**3D bioprinting as a tool for the early correction of leather defects in the tanning industry**
Baggio Giacomo	**Single region contribution to the brain dynamic (in)stability**
Baglio Francesca	**Development of a novel surface-based approach to quantify fNIRS-fMRI spatial correspondence**
Bagno Andrea	**Biological evaluation in vitro and in vivo of hybrid membrane to assess biomedical application**
–	**Cryopreservation effects on biological tissues: histological and mechanical assessments**
–	**Mechanical characterization of hybrid membrane suitable for biomedical application**
Bagnoli Silvia	**Early stages of cognitive decline are characterized by different EEG microstates dynamics**
–	**P300 event-related potential in patients with cognitive decline correlates with task performance**
Bagshaw Andrew	**fMRI characterization of intrinsic brain networks relevant for motor control with and without visual feedback by fractal dimension**
Baldan Matteo	**Model Assessment of Doxorubicin Pharmacokinetics in Multiple Myeloma**
Baldazzi Giulia	**A novel tool for the annotation of bipolar electrograms for cardiac electrophysiology**
–	**Abnormal Ventricular Potentials Identification Using a Siamese Neural Network**
Baldoin Elisa	**Advances in the development of a instrumented head surrogate for brain injury investigation**
Baleani Massimiliano	**Development of a contrast-enhanced micro tomography protocol for human meniscus: a pilot study**
Balestra Gabriella	**A machine learning approach for stride speed estimation based on a head-mounted IMU**
–	**Usability of a multi-sensor array for the application of electro-phonocardiography in home care**
Ballardini Giulia	**Zwitterionic coatings for an implantable artificial pancreas**
Ballerini Mattia	**Intestinal epithelium on chip for absorption studies**
Balsamello Carlo	**The prediction of the patient's response to hemodialysis treatment: DialysIS vs InterACTIVE-HD 2.0 experience**

Balta Diletta	An improved method for the characterization of infants' general movements using a RGB-Depth sensor and a deep neural network tracking processing tool
Bandini Laura	A cloud-based mobile platform to monitor and counteract cognitive decline
–	Computational joint action: dynamical models to understand the development of joint coordination
Barata Catarina	An attention classifier for the evaluation of a robotic therapy in children with Autism Spectrum Disorder
Barbacane Sara	Analysis of an Elite Amputee Paralympic Sprinter in Track Running Pilot Tests
–	Comparative Analysis of Steady and Resisted Accelerated Treadmill Running of an Elite Amputee Paralympic Sprinter
–	Towards a Wearable System for Complete Collection of Clamp Loads in Transfemoral Paralympic Sprinters
Barban Federico	Towards personalized electroceutical therapy: electrophysiological investigations in a pre-clinical model of ischemic lesion
Barbara Maurizio	Assessment of Balance disorder and vestibular dysfunction using Mixed Reality
Barbieri Riccardo	Decoding Emotions through Music: A Physiological Analysis of Emotion Recognition
–	Effects of State Representation on a Reinforcement Learning Based Decision Support System
–	Quantitative validation of an automatic videoPPG technique during autonomic elicitations
Barbon Silvia	Composite scaffolds based on polyvinyl alcohol and acellular cartilage matrix for hemophilic arthropathy treatment
Barcali Eleonora	Optimization of a cardiac tissue segmentation pipeline in murine whole-heart reconstructions
Barcillesi Matteo	Inertial measurements unit validation for countermovement jump (CMJ) tests in athletes
Bardi Elena	3D upper limbs tracking through inertial sensors: calibration, methodology, and validation
Bari Vlasta	Assessment of cerebral autoregulation in patients undergoing anaesthesia with propofol: a comparison among spontaneous variability methods
Barni Luca	Inertial measurements unit validation for countermovement jump (CMJ) tests in athletes
Baron Giorgia	Assessing the impact of brain gliomas on effective connectivity gradients
–	Single region contribution to the brain dynamic (in)stability
Barone Ylenia	Brain-heart interaction: an ECG-fMRI integrated study in physiology and major depressive disorder
Baselice Fabio	A Novel Authentication System Based on Hand Gesture Ultrasound Signatures
–	Breast Cancer Detection via Two-dimensional Ultrasound Tomography
–	Breast Cancer Imaging at Microwave Frequencies via Neural Networks
–	A deep learning approach for the analysis of voxel composition in magnetic resonance imaging
Baselli Giuseppe	Development of a novel surface-based approach to quantify fNIRS-fMRI spatial correspondence
Bassetto Franco	A dexterous hand prosthesis based on additive manufacturing

Basti Alessio	Closing the loop between neurostimulation and control theory
–	Disclosing brain functional connections with multi-dimensional approaches
Batoni Elisa	Evaluation of the optimal pore size for 3D printed bone scaffolds in a perfusion bioreactor
–	Valve-jet technology for robotic-based in situ bioprinting applications

***Abstract*— The ability to complete sit-to-stand (STS) transfers has a significant impact on a person's functional mobility. Wearable sensors allows for objective, long-term monitoring of STS transfers under home-based conditions. However, despite some recent initiatives assessing STS transfers in home-based settings, the majority of STS transfer algorithms have primarily been used for assessment during the execution of prescribed activities in a lab setting. More research is also required to comprehend the distinctions between in-lab and home-based measurements, as well as their relationship to clinical outcomes. The current study compared STS features identified in 20 older adults performing activities in-lab and at home. Our results showed that duration, peak acceleration, and smoothness of STS transfers performed in the lab versus at home differed significantly. The duration of STS transfers at home was 30% longer on average than in the lab. Furthermore, because they are natural rather than instructed actions as in lab settings, the number of STS per hour was significantly lower in home-based conditions. Understanding the distinctions highlighted is critical for the successful incorporation of home-based mobility assessments into prospective clinical trials.**

***Keywords*—wearable sensors, sit-to-stand, home-based, in-lab.**

I. Introduction

Wearable sensing technology advancements have increased interest in objective, home-based measurement of health and well-being [1]. Because they can be packaged into small, power-efficient devices that can be discretely worn at various locations on the body, inertial measurement units (IMUs) are particularly well-suited for continuous movement measurements. Recent research has shown that IMUs can be used to identify sit-to-stand (STS) transfers. Approaches that use multiple IMUs across multiple body locations [2], [3] can detect STS transfers and measure STS kinematics with reasonable accuracy. However, because of the poor wearability and high patient burden associated with the use of these multi-sensor systems, they are unsuitable for long-term monitoring in home-based conditions and have limited application in clinical research. To address these limitations, several attempts have been made to detect and assess STS transfers using a single IMU located somewhere on the torso (typical locations: chest, waist, lower back) or thigh/upper leg [2]–[5].

While the majority of the research to date has focused on the evaluation of prescribed STS transfers performed in the lab, some recent efforts [6], [7] have examined data collected under home-based conditions. The findings show that STS transfer features derived from IMU data collected during home-based conditions can detect differences in age, fall risk, and disease severity (e.g., mild vs. severe Parkinson's disease). Furthermore, multi-parametric approaches [7] that rely on features extracted from STS transfers such as duration, smoothness, variability or peak acceleration have been shown to be more sensitive for detecting clinically meaningful differences than single-parametric approaches.

The research presented herein focuses on evaluating quantity and quality features extracted from STS transfers in lab and home-based settings using data from a single inertial unit worn on the lower back. To understand the contextual differences between in-lab and home-based assessments, descriptive analysis, correlations, and percentual changes on identified STS transfers were performed.

II. Methods

A. Study Participants

The current study is based on the ADAPT study dataset, which included 20 older adult participants recruited from a senior citizen center in Norway's Trondheim area [8]. Participants included in this study were over the age of 65, able to walk 100 meters without a walking aid, and able to follow oral instructions, and living independently.

The ADAPT study was approved by the Regional Committee on Ethics in Medical Research in Central Norway. Table I displays the participants main characteristics.

TABLE I: Cohort characteristics

	Participants (N=20)
Gender (M/F)	5/15
Age (years)	76.4 ± 5.6
Height (cm)	167 ± 7.2
Weight (kg)	73.7 ± 11.4

B. Wearable sensor characteristics and setup

The ADAPT dataset includes a diverse set of sensors on various body locations, motivated by the potential for algorithm development from popular activity monitoring device attachment locations [3], [9]–[11] and existing large datasets recorded from independent living older adults in previous projects focused on fall detection and risk assessment. In our research, we focused the analysis on a single wearable sensor located on the lower back. The sensor was a tri-axial accelerometer and gyroscope sensor with a sampling frequency of 100 Hz and a measurement range of

±2g.

C. *In-lab and Home-based protocol*

All subjects in the ADAPT study completed two task-based protocols: a supervised semi-structured protocol (in-lab) and a home-based unsupervised protocol (home-based). Walking, shuffling, stairs (ascending/descending), standing, postural transfer, sitting, lying, leaning, picking, and kneeling were the general purpose categories for all activities.

The in-lab protocol was carried out in a smart-home environment in the Usability Laboratory at the Norwegian University of Science and Technology's Faculty of Medicine in Trondheim, Norway. This laboratory is made up of three rooms and an observation room. The three rooms featured various types of furniture as well as ceiling-mounted cameras that were monitored and controlled from an observation room. The subjects were given a task-based protocol to follow in a specific order [8].

The home-based protocol was recorded in the participant's home environment with inertial sensors and a GoPro Hero3+ (GoPro, Inc., San Mateo, CA, USA) body-worn camera at the chest and pointed towards the feet. The performed activities were identified using video data, and the sensor data was labelled accordingly. Five experts labelled the data according to the general activity categories.

D. *Sit-to-stand identification*

To identify STS transfers, a previously validated algorithm [6] was implemented in Python 3.8.

The method relies on a single 3-axis accelerometer data and works in any device orientation, performing a calibration step each time the device is worn. The method is divided into two parts: (1) acceleration filtering with potential STS identification, and (2) STS transfer confirmation.

The first step starts by removing high frequency components. The acceleration vector magnitude is first zero-phase filtered with a fourth order Butterworth filter with a cutoff frequency of 5 Hz. The resulting signal is smoothed by taking a rolling mean (RM) with a 0.25 s window and equal weighting, resulting in the RM acceleration. The RM acceleration is subjected to a continuous wavelet transform (CWT), with coefficients in the 0-0.5 Hz band summed at each time point to yield the CWT 'power'. Potential STS transfer time points are identified as peaks in the CWT power with a minimum time difference of one second and a minimum amplitude greater than the standard deviation of the power.

Following what was defined in previous studies, we calculated quantity and quality sit-to-stand parameters associated with movement disorders and the risk of falling [3], [6], [7]. Sit-to-stand quantity was characterized by the number of sit-to-stand transfers per hour (SPH). Sit-to-stand quality was characterized by the duration (s), maximum and minimum acceleration (m/s^2), spectral arc length (SPARC) and jerk (associated with smoothness), and vertical displacement (m).

For each parameter, the average from all sit-to-stand transfers was computed for each participant.

E. *Statistical analysis*

Correlation matrices were computed during laboratory and home-based assessments to investigate the relationships between the different features. Wilcoxon signed-rank test was performed to analyse differences between lab and home-based assessments, adjusted p-values (Benjamini-Hochberg) were computed to account for false discovery rate. Analyses were performed using the SciPy and Scikit-learn libraries in Python 3.8.

III. Results

A. *Sit-to-stand transfers*

A total of 8.9 and 36.3 hours of recording were analysed, allowing the identification of 416 and 318 STS transfers for all participants during in-lab and home-based conditions, respectively. To account for the differences in the number of recording hours, the number of sit-to-stands was divided by the number of recording hours (Sits per hour, SPH). Figure 1 shows the distribution of SPH under both settings. In-lab recordings show a higher number of SPH. The logic behind this is that in lab settings, a specific number of STS transfers must be completed by a participant which is dependent on the specific laboratory protocol, whereas in home-based settings, a person's day-to-day pace may reflect a more natural number of STS transfers.

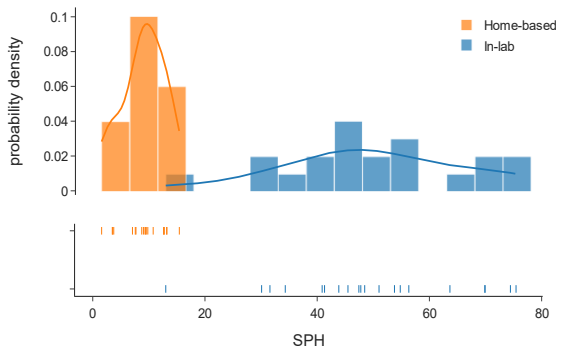

Fig. 1: Histogram distribution of the identified sit-to-stand per hour (SPH) during in-lab and home-based recordings per participant

A similar trend was observed when analysing subgroups based on gender. Participants performed less sit-to-stand transfers ($p<0.05$) in home-based conditions for both subgroups (Figure 2).

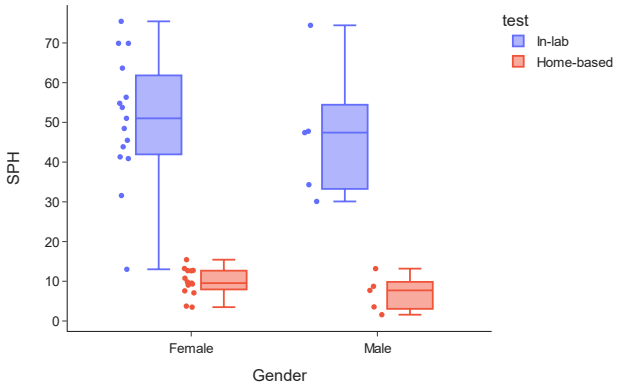

Fig. 2: Lab and home-based SPH differences by subgroups

Figures 3 shows a moderate correlation (r=0.6) for sit-to-stand per hour computed for lab and home-based assessments.

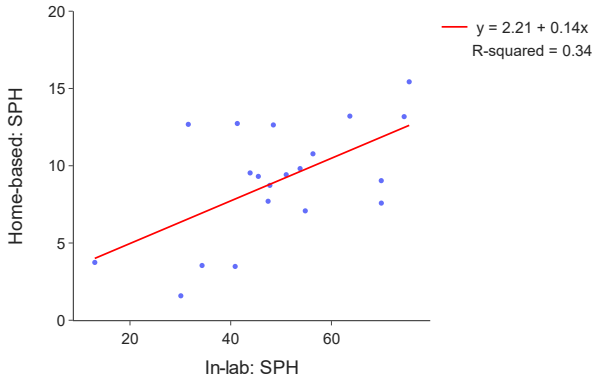

Fig. 3: SPH correlation identified in in-lab and home-based settings

Despite the fact that more SPH were performed under in-lab conditions than under home-based transfers, a moderate correlation was observed. However, no significant correlations were found for some quality features (e.g. Duration, Figure 4).

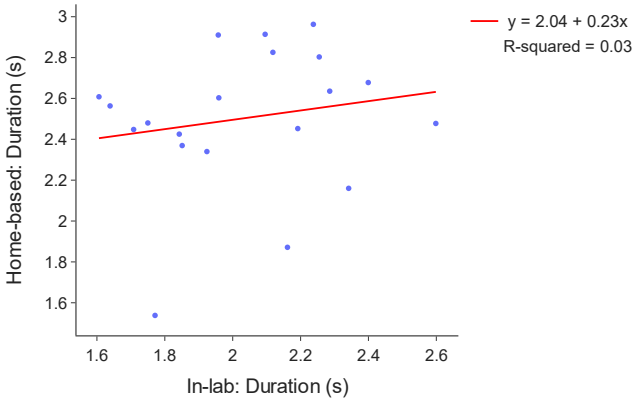

Fig. 4: STS duration correlation identified in lab and home-based settings

Table II shows the mean and standard deviation (SD) for all extracted features under in-lab and home-based assessments. Only SPH (p=0.007) and Max Acc. (p=0.02) were found to be significantly correlated.

TABLE II: SIT-TO-STAND BASED MEASURES

	In-lab		*Home-based*		*Correlation*	
	Mean	*SD*	*Mean*	*SD*	*r*	*p*
SPH	49.7	15.6	9.1	3.7	0.6	0.007
Duration	2.03	0.27	2.5	0.3	0.18	0.44
Max Acc.	11.8	0.5	11.4	0.5	0.52	0.02
Min Acc.	7.53	0.46	8.13	0.5	0.36	0.12
SPARC	-2.3	0.05	-2.38	0.04	0.39	0.09
Jerk	-3.8	0.56	-3.81	0.53	0.21	0.36
Vertical Disp.	0.63	0.16	0.55	0.12	0.38	0.1

To assess the differences between in-lab and home-based measurements, the percentage change from home-based parameters was calculated from the mean values obtained from in-lab assessments (Figure 5). The number of sit-to-stand transfers performed during home-based assessments was 80% lower than the number of sit-to-stand transfers performed during in-lab assessments. Furthermore, the duration of STS transfers at home was 30% longer on average than in the lab. Finally, the Wilcoxon signed-rank test (p-values adjusted) showed significant differences between lab and home-based measurements for SPH (p<0.0001), duration (p=0.0003), max. Accel. (p=0.004), min. Accel. (p=0.0004), SPARC (p=0.0003), and vertical displacement (p=0.025). No significant differences were found for jerk.

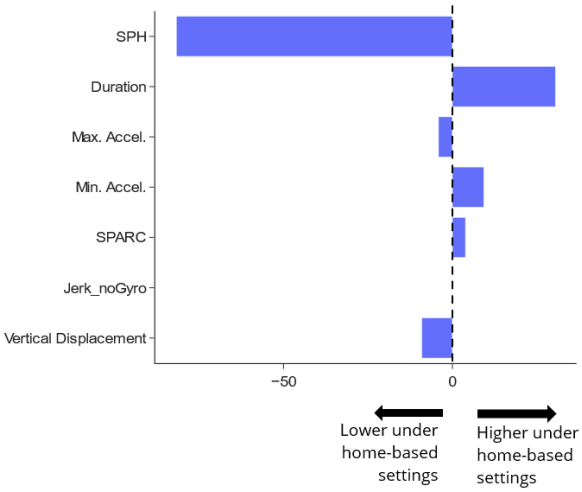

Fig. 5: Percentage change from parameters measured under home-based conditions compared with in-lab conditions

IV. CONCLUSION

The present study aimed to assess the differences between in-lab and home-based sitting transfer measurements. Our results showed that features extracted from home-based measurements significantly differ from in-lab measurements. The duration of sitting transfers was longer under home-based conditions, suggesting that home-based STS transfers may be more demanding than in-lab assessments. Several factors could explain the significant differences in the analysed. Home-based behaviours are usually self-initiated, embedded in a rich behavioural context, and goal directed. In contrast, actions in a more supervised setting, are typically triggered by a command and performed in an isolated, standardised setting with limited ecological validity. Performance can be influenced by a variety of psychological and physiological processes that vary depending on the context. These include attentiveness, motivation, fatigue, pain, and stress.

On the other hand, while in our study the number of sitting transfers per hour was lower under home-based assessments, wearable-based monitoring at home opens the possibility to extend the recordings for days/weeks allowing to potentially identify a greater number of sitting transfers than in laboratory assessments.

A current limitation of the present study, lies in the number of participants and recording hours. In addition, the home-based assessments were not completely unsupervised as there were some tasks that participants had to complete, though at their own choice of order and preference. We must note that to better evaluate home-based events reliably, future studies need to measure patients inconspicuously and for longer periods of

time, while they move freely and fully unsupervised in their daily living environment.

Overall, the differences found in lab and home-based assessments in this study aims to raise the attention on the need to move from traditional laboratory assessments. Clinicians and researchers should consider these disparities and the multiple factors that contribute to them in order to successfully integrate home-based mobility assessments into clinical practice.

ACKNOWLEDGEMENT

This study was partially funded by the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 820820 (Mobilise-D). This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and EFPIA.

***Abstract*—Nowadays, some solutions based on automatic approaches to identify, characterize, and delineate abnormal potentials in post-ischemic ventricular tachycardia bipolar electrograms have been proposed in the literature. However, while a significant amount of annotated data is required for these purposes, no open annotated dataset is currently available. Furthermore, there is also a lack of freely available and open-source software to enable collaborative clinical annotation. In particular, for post-ischemic ventricular tachycardia electrograms, the presence of such tools and dataset could significantly foster the research in the field of computer-aided minimally disruptive ablation procedures.**

This paper proposes a tool entirely developed in MATLAB, which allows clinical experts to annotate post-ischemic ventricular bipolar electrograms by labelling them as physiological or not and delineating the abnormal potentials. The proposed interface embeds several features, beyond the annotation options, such as the electroanatomic map display, electrogram spatial localisation, the twelve surface ECG representation and QRS delineation, and several graphical facilities.

In upcoming works, we aim to use the proposed graphical user interface to conduct intra- and inter-annotator studies and produce a validated and trustworthy annotated dataset to be publicly released according to the open data initiative.

***Keywords*—Ventricular tachycardia, cardiac electrophysiology, open data, dataset annotation**

I. Introduction

THE most widely used approach for the treatment of post-ischemic ventricular tachycardias is trans-catheter radiofrequency ablation [1], [2]. This technology is mainly based on the identification of target areas to be ablated in order to completely suppress the arrhythmia. Such areas are commonly characterized by local bipolar electrograms (EGMs), also known as abnormal ventricular potentials (AVPs), that exhibit late activations with high-frequency fractionated components [3]–[5].

Nowadays, the process of identifying AVPs and, consequently, targeting ablation zones, is performed during substrate mapping by the electrophysiologists, who visually analyse the morphology of each recorded EGM, in a very time-consuming procedure. Some solutions based on automatic approaches to identify ablation sites are being proposed in the literature [6], [7], with the aim of shortening the procedure time and possibly improve its effectiveness.

In addition to the use of substrate maps to distinguish physiological EGMs and AVPs, the characterization of the late activations in the AVPs is also of great interest to better understand the behaviour of wavefronts activation in correspondence with the post-ischemic scar, as also the re-entry circuit pathways. The latency identification, often investigated in the literature [8]–[10], actually represents a signal delineation problem.

Unfortunately, the data from post-ischemic ventricular tachycardia procedures that can be collected in a single hospital are often limited and not readily available. However, solutions based on supervised learning for the development of accurate AVP identification and delineation, require large and annotated datasets for a proper training.

To the best of the authors' knowledge, no such kind of public dataset currently exists. Moreover, there is also a lack of freely available and open-source software tools enabling collaborative clinical annotation of post-ischemic VT EGMs.

On these premises, this research was aimed at designing and developing a graphical user interface (GUI) that allows clinical experts to annotate post-ischemic ventricular bipolar EGMs, with the final aim of creating a reliable multi-annotated dataset to be released. Specifically, the dataset will contain information regarding both the type of each EGM and the delineation of the late activation in the case of AVP. This solution could solve the lack of a public dataset in the field of post-ischemic VT, thus enabling the effective development and benchmarking of algorithms for arrhythmogenic sites detection and characterisation, as also to facilitate collaboration across the research community.

II. Methods

The GUI has been entirely developed in MATLAB R2022b (MathWorks Inc., MA, USA) and provides a user-friendly tool for the annotation of post-ischemic VT bipolar EGMs. For the time being, the development of the tool is directed at reading export files of mapping procedures performed using the CARTO®3 system (Biosense Webster, Inc., Diamond Bar, California), but it will be further extended in next versions.

The tool consists of two windows: the **Start Window**, which is the initial window used to launch the annotation while providing a summary of the annotation progress, and the **Annotation Window**, which includes all the functionality to fulfil the annotation. The tool analyses each procedure independently and provides a .mat file as output.

A. Data loading

The software loads the data from a folder containing all the procedures that the user must annotate, each one contained into a dedicated folder. The folders do not report any personal data of the patient they refer to, but only the procedure data useful

to perform the annotation. The four types of files used by the software are described in Table 1.

TABLE I: FILES USED BY THE ANNOTATION GUI

Files	*Content*
[MapIndex-MapName]_car.txt	Summary of values recorded for each point
[StudyName]_[StudyDate].xml	Summary of the entire mapping study
[MapIndex-MapName].mesh	Geometry data of 3D images
[MapIndex-MapName]_P[Point#]_ECG_Export.txt	2.5 seconds of intracardiac and body surface ECG signals

On the left, the format of file contained in each procedure folder; on the right, the content of each file type.

In particular, the .mesh file is the main file used for the reconstruction of the ventricle map with the corresponding voltage or local activation time (LAT) information. The .xml and car.txt files are used for data extraction to locate the bipolar EGM on the map. Finally, the folder contains multiple ECG_Export.txt files, one for each recorded bipolar EGM. These files are taken as input for the extraction of all the recorded signals, both the EGM and the 12-lead superficial ECG. The procedure file also contains other types of data that are not used by the current version of the annotation tool.

B. *Start window*

The "Start window" it's the first window that is displayed every time that to tool is launched. When a user runs the tool for the first time, the system requests the name and surname initials, which will be used as a reference to save the output data and keep track of who performed that annotation. This information is then stored and is no longer requested. Finally, as shown in Figure 1, the "Start Window" contains the start button and a counter that displays the progress made in the annotation by the user.

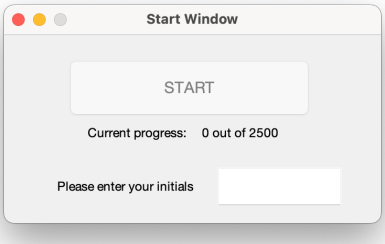

Fig. 1: Start window of the developed annotation GUI for post-ischemic VT bipolar EGMs. Here the current number of annotated EGMs with respect to the overall dataset is displayed, along with an editable text field for input of annotator initials.

C. *Annotation window*

The main window of the GUI is designed to be an intuitive, user-friendly environment that provides simple tools for the visualization, annotation, and delineation of physiological EGMs and AVPs. The window can be conceptually divided

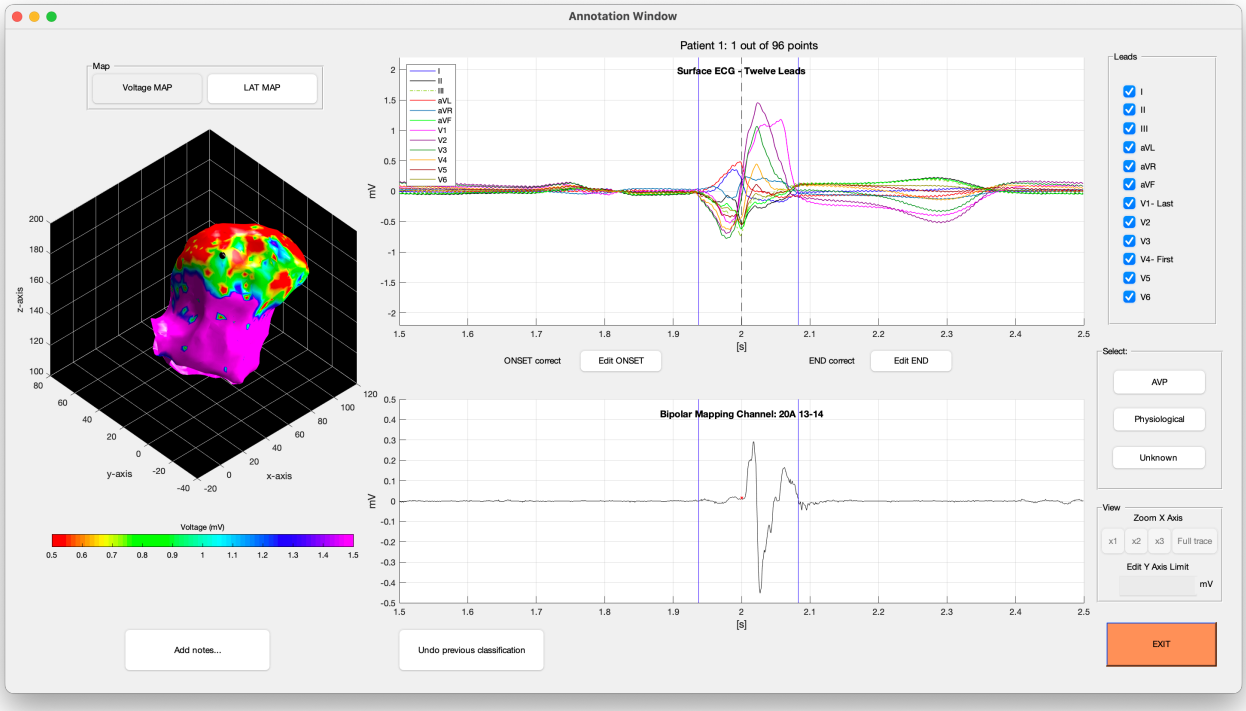

Fig. 2: Annotation window of the GUI developed for the annotation of post-ischemic VT bipolar EGMs. The plot on the left represents the bipolar voltage/LAT map which the current bipolar EGM refers to. On the right, the 12-lead surface ECG (on top) and the bipolar EGM (on bottom) to be annotated. Below the plot of the 12-lead surface ECG, the "Edit ONSET" and "Edit END" buttons enable the editing of the onset and end of the QRS complex automatically detected by the system. On the right side of the ECG plot, the "Leads" panel is available, which contains a check box for the selection of the surface leads to be plotted; below, the "Select" panel is introduced to annotate the bipolar EGM, along with the "View" panel, in which the user can modify the zoom settings on the bipolar EGM plot both on the x and y axis. Finally, at the bottom, there are the buttons to add notes and go back to the previous point, and, in orange, the button to close the tool.

into three plots: a 12-lead ECG plot, a bipolar mapping channel EGM plot, and a 3D colour-coded cardiac chamber map.

The ECG and EGM signals from the dataset are automatically and sequentially loaded onto the window to be displayed on the two 2D plots, as shown in Figure 2. Their default view displays only a segment of the signal, centred on the recorded beat.

An underlying algorithm detects the two superficial ECG leads that exhibit the earliest activation and the latest end of the QRS complex. These fiducial points are indicated by the two blue lines in the upper plot; if needed, the user can change their location simply through the dedicated buttons (i.e., the **Edit ONSET** and **Edit END**) and by clicking on the graph for repositioning. Any edit is saved, thus allowing for further statistical analysis and annotation validation. The user can also choose which of the 12-lead surface ECG wants to display, using the checkboxes in the **Leads** panel.

The lower section is the one aimed at the EGM classification and delineation. After observing the bipolar signal morphology, the user is expected to choose among the three classes in the **Select** panel: AVP, Physiological and Unknown. The last two options automatically save the selection, whereas the AVP class requires the user to mark both the onset and end of the abnormal potential in the current signal. The AVP button also enables the tool on the **View** panel, allowing the user to access the zoom option and modify the view, freely switching from the default focus view to the full view (i.e., the entire 2.5 s long EGM recording) or to focused views on x and y axis, and vice versa. Once the selection is performed the annotation automatically moves to the next signal annotation.

Furthermore, the user is presented with another information to further enhance task performance: the 3D colour-coded cardiac chamber map. This remarkable feature is based on the data from the CARTO®3 mapping system procedure, which contains both the voltage map and the LAT map. By simply clicking on the dedicated upper buttons (i.e., **Voltage MAP** and **LAT MAP**), the user can switch between these two representations, displayed on the left side of the window. In Figure 3, an example of the two maps is proposed. In addition to the information given by the colour coding, the localization of the current point is also shown to the user, marked on the ventricle map by a black sphere.

Additional features are the option to add notes, which will be later saved into an additional file, the **UNDO** button, which allows the user to delete the previous signal annotation, and the **EXIT** button, which allows the annotation process to be stopped and to resume it later.

Furthermore, to avoid affecting any reliability of data gathering, some strategies have been implemented to prevent users from altering the desired running condition, such as granting full view accessibility only during the AVP delineation and enabling the undo action no more than once in a row.

D. Data saving

During the annotation process, a cell array named "datamatrix" is updated in all its fields by adding an item each time a new annotation is carried out. Once the annotation is completed on the entire procedure, the interface returns a .mat file containing the datamatrix. In addition, the .mat file reports in its name the initials of the annotator, so that this information can be used for future analyses, label voting and annotation validation. The saved cell array consists of nine fields, one per column, labelled as follows:

- Folder Name: the path of the patient folder.
- File Name: the name of the analysed .txt file is

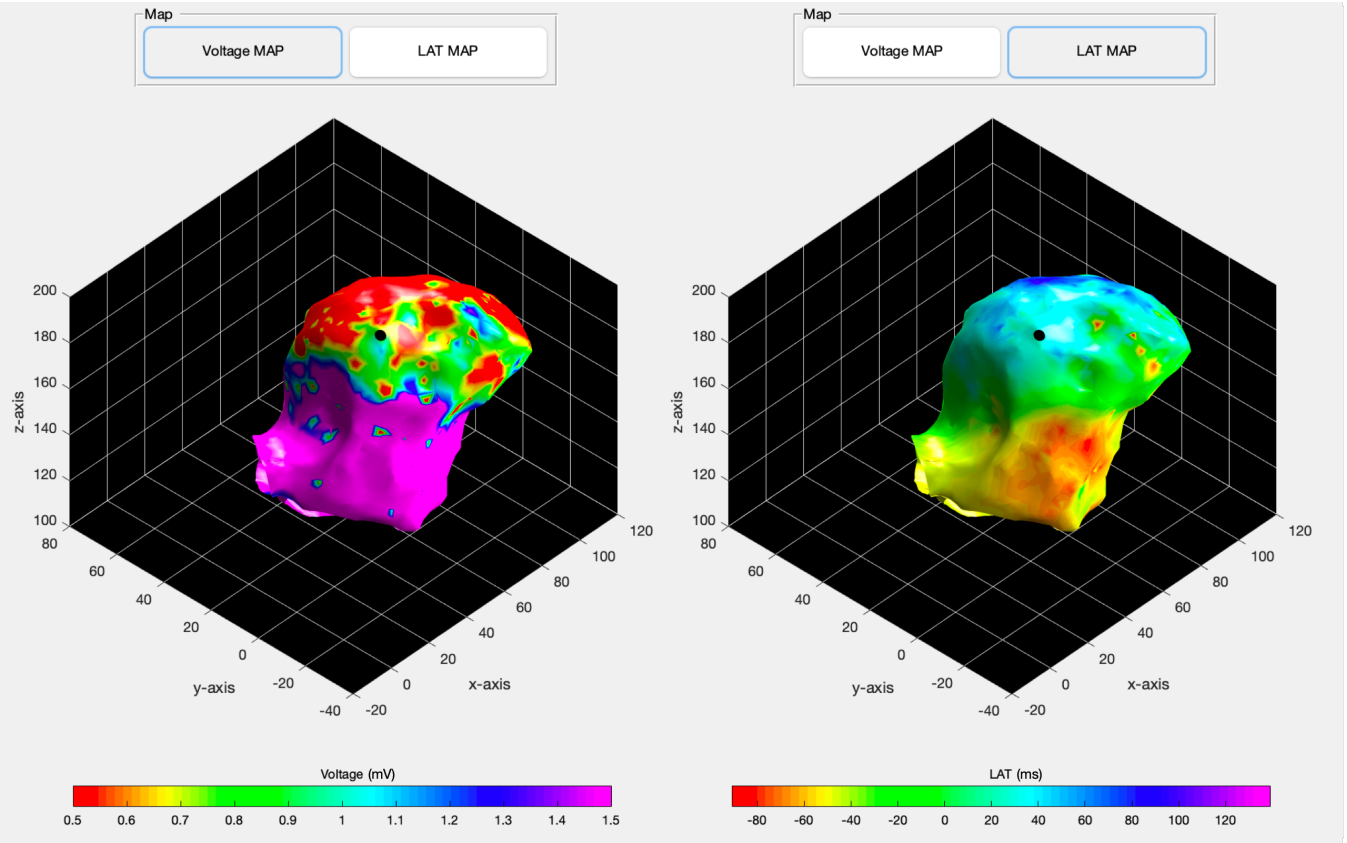

Fig. 3: The 3D color-coded ventricle maps. On the left, the voltage map, and on the right, the LAT map representation of the same ventricle.

saved.

- Onset/End Number: the samples that the annotator marked as the onset and end points of the AVP. For the “Physiological” and “Unknow” classes, this value is set to NaN.
- Class: the manual annotation. To facilitate the creation and subsequent management of the datamatrix, each class has been saved as a number: 2 for AVP, 1 for Physiological, and 0 for Unknown.
- QRS Onset/End: the samples corresponding to the onset and end of the QRS complex automatically computed by the algorithm embedded in the annotation tool.
- QRS Onset/End Modified: the samples selected by the annotator as the actual QRS onset and end points, if the expert needs to modify the ones proposed by the system; in case of no modification, these values are set to NaN.

In addition to the datamatrix, eventually, the interface also returns .txt files that carry notes entered by the operator during the annotation phase.

III. Discussion and conclusions

This work proposes the first tool for the annotation of post-ischemic ventricular bipolar EGMs and the delineation of AVPs. The proposed solution is a user-friendly GUI currently dedicated exclusively to procedures performed and exported through the CARTO®3 mapping system (Biosense Webster, Inc., Diamond Bar, California). However, future versions will also allow annotating data from multiple electroanatomic mapping systems.

This tool is currently being used to present the same dataset to multiple expert electrophysiologists to investigate inter-annotator variability in the manual annotations, and for the construction of a validated annotated dataset to be released as open data. This would fill the gap in the literature about the existence of freely accessible and public datasets of AVPs and physiological post-ischemic VT electrograms. In addition, because of the interface input structure required, it is also possible to create mini-batch of a repeated set of data to be submitted to the same annotator to conduct intra-annotator variability analyses, useful to identify the expected precision of the automatic tools.

Currently, multiple expert annotators are being enrolled to access to a multi-procedure dataset containing a mini-batch of repeated signals. From this, we aim to conduct intra- and inter-annotator analysis and produce a validated and trustworthy annotated dataset that may be exploited to design automated classification and annotation systems in order to develop and benchmark computer-aided systems to support clinicians during such electroanatomic mapping and ablation procedures.

Design and Evaluation of an Intuitive Administration Dashboard for a Platform used to Monitor Clinical Trials

L. Cossu[1], L.C. Causin[1], A. Facchinetti [1] and G. Cappon[1]
[1] *Department of Information Engineering, University of Padova*

***Abstract*—The IMPACT platform, an integrated mobile solution for simplifying the conduct of clinical trials, has recently been developed. To enhance the platform, a new administrative dashboard was designed and developed with the goal of ensuring the quality of data collected during the trial and facilitating the necessary actions for its conduction. To improve accessibility, a role-based access policy was implemented during the design and development of the dashboard, with different roles such as data and study administrators granted access to the newly developed dashboard. Usability of the dashboard was evaluated through task-based sessions with 14 participants, and the results were analyzed using custom-defined metrics. The analysis revealed that the dashboard was well-received and highly usable, as participants were able to complete tasks with minimal errors and a reasonable amount of time, after an initial period of acclimation to the layout of the dashboard.**

***Keywords*—Administrative dashboard, clinical trial management, platform, usability**

I. INTRODUCTION

Clinical trials play a vital role in advancing medical technology by providing a means to evaluate the effectiveness of new therapies and technologies in real-world conditions. However, these trials come with a host of challenges, one of which is effective subject and data management. Data collection from various sources such as sensors, questionnaires and patient diaries can be in various formats and must be effectively integrated into the trial framework. This data may also need to be made available to clinicians and other trial operators to monitor patients' conditions and ensure safety during the trial.

To address the challenges of clinical trial management, we have indeed developed IMPACT [1], an Integrated Mobile Platform for Automated Clinical Trials. This mobile platform automates the processes of data collection, organization, and display for monitoring, allowing for a predefined and modular approach. Currently, IMPACT consists of three components that communicate via a secure ad-hoc web API: a mobile application for use by trial participants to collect data during the trial, a website for clinicians to monitor all enrolled patients in real time, and a cloud database that stores all collected data and allows remote monitoring via the website. The schema of the platform structure and components is illustrated in Figure 1.

The mobile application component of IMPACT is designed to function as an electronic diary for trial participants, allowing them to log and track all events relevant to the study.

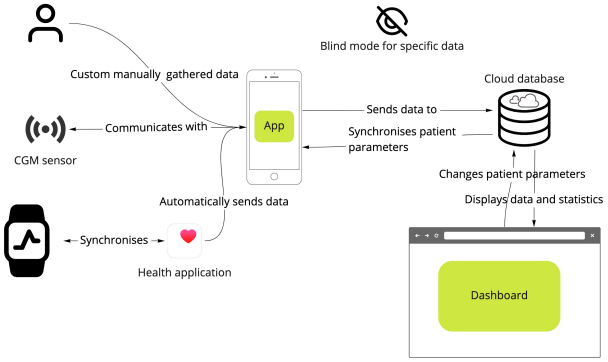

Fig. 1: Overview of the current structure of the IMPACT platform, illustrating the main components and data flow.

The application is able to automatically collect data without requiring any input from the user, reducing the burden of manual data entry. The modular approach of the application allows it to be adapted to the specific requirements of each trial, implementing solutions to collect all necessary data in the most reliable and least burdensome way for the patient.

The web application component of IMPACT is intended for use by clinicians to monitor patients' status and data in real-time, ensuring their safety and enabling them to make adjustments to trial parameters as needed.

Currently, the only way to verify the status of data collection and address potential issues is through the clinical web application, this method however is not ideal as it requires clinicians and data managers to share login credentials, which can lead to exposing personal information to data managers who may unintentionally modify data parameters. A more efficient approach is to clearly differentiate the responsibilities of data management and clinical tasks, ensuring that clinicians are only responsible for clinical duties and data managers are responsible for verifying the integrity of the data.

In this work, we present how we have implemented a solution to address this issue by implementing role-based access to the data and dividing tasks among different roles. This approach allows us to thoroughly verify the integrity of the trial conduction while also safeguarding the privacy of participants by clearly differentiating the responsibilities of data management and clinical tasks, and ensuring that only

authorized personnel have access to sensitive data.

II. MATERIAL AND METHODS

On the IMPACT platform, several new roles have been implemented, each with specific functions and permissions. These roles are:

- Superuser
- Data administrator
- Study administrator
- Researcher

The superuser role serves as the primary system administrator and is responsible for the technical management of the platform. This role has the authority to carry out any action within the system, including accessing all system data, registering any type of user, and creating new studies. Below the superuser in terms of privileges and permissions are the data administrator and the study administrator. The data administrator has almost the same privileges as the superuser, including access to all system data and the ability to register any type of user except for the superuser. However, the data administrator is not able to delete another data administrator or a superuser. This role is responsible for managing the data and ensuring its integrity. The study administrator, who is ranked below the data administrator, has access to all data related to a specific study. However, its authority is limited to only registering new clinicians. Overall, the study administrator has similar privileges to the data administrator, including the ability to create and modify details for patients, clinicians, and clinical centers within the study, as well as delete them. However, the main limitation for both the study administrator and the data administrator is their inability to enroll patients, a task that is reserved for clinicians. The researcher role has access to all data related to the specific study they are a part of, but cannot access data from other studies. A researcher is able to view the complete list of patients within their study, but can only see the clinicians who have access to the data of the study and are considered active, rather than those who do not have access and are inactive. Only data administrators have the ability to create a researcher and give it access to a study.

Access rules for the platform are directly implemented and can be managed through an administrative interface. This interface allows the study and data administrator to view all relevant information for their role and perform all actions they are authorized to take. The access rules are deeply integrated into the platform server, ensuring that all requests and actions made by each user are authorized by the platform based on their role. In this way, the system ensures that all access and permissions are granted to the right person and with clear limits and responsibilities, thus allowing for a thoughtfully secure, efficient and user-friendly management of the clinical trial data.

The mobile application and clinician dashboard have been developed using Flutter [2], a cross-platform framework that allows for the creation of a single codebase that can be deployed on mobile, desktop, and web platforms. This capability enabled the reuse of most features and design elements from the clinician dashboard for the administrative interface.

The administrative dashboard allows study and data administrators to log in and access a version of the dashboard that is tailored to their privileges i.e., the study administrator does not have access to the researchers and administrators management pages. The other main pages of the dashboard include the study overview, enrolments, clinicians, patients, and clinical centers management pages. These pages provide an overview of the trial characteristics and personnel and allow for various actions such as adding, modifying, or deleting users. For example, the patients page, shown in Figure 2, lists all patients in the study with their study-related information such as the clinical center responsible for their care and whether the patient has requested to be removed from the system in accordance with GDPR [4] regulations. Each row also includes buttons to perform relevant actions for each patient, such as modifying their information, transferring them to a new clinical center, deleting the patient from the system, and accessing a page with information on the patient's data quality and details.

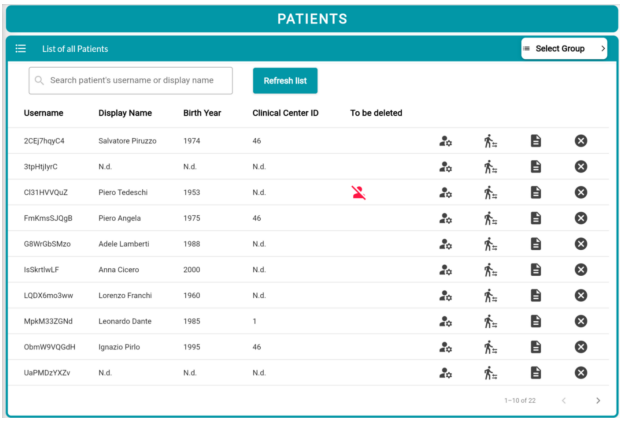

Fig. 2: Patients page of the administrative dashboard.

III. USABILITY ASSESSMENT

Usability is a crucial aspect of any tool as it directly impacts the effectiveness and efficiency with which tasks can be completed. A user-friendly dashboard that allows administrators to easily navigate and access the necessary features and functions can significantly reduce the time and effort required to perform their duties. Therefore, ensuring the usability of an administrative tool is crucial for its success and widespread adoption.

To assess the usability and ease of use of the IMPACT platform's administrative dashboard, we conducted a task-based testing session. Participants were asked to perform 10 different tasks, designed to simulate common actions that an administrator would take on the dashboard. These tasks were carefully crafted to evaluate the usability of the tool and identify any potential issues or areas for improvement. This task-based testing approach allows for an in-depth evaluation of the tool's usability, by providing insights on the participants'

experience and perception of the interface, and providing valuable feedback on how to improve it. Furthermore, this methodology is a trustable and efficient way to evaluate the user interface usability as it allows to measure the performance, satisfaction, and error rate of the tasks assigned to the participants. The 10 different tasks have been designed as follows:

1) Starting from the "Log In" screen, perform the log in and read the clinical study report on the main page, called "Study Overview." On this page, the user must then change the name of the clinical study to "Type 2 Diabetes Study," save the preferences, and log out.
2) Starting from the "Log In" screen: perform the log in and go to the "Enrollments" section. Here, the user must pause enrollment number X and then terminate enrollment number Y, entering a date of their choice and the end-of-enrollment reason "Adverse event."
3) Starting from the homepage, find the identification number (ID) of the Clinical Center associated with Padova.
4) Starting from the homepage, find the clinician "USERNAME," assign them the name "Mario Rossi" and the ID of the Clinical Center in Padova, and save the changes.
5) Starting from the homepage, the user has to find the patient "USERNAME," change their Display Name to "Mario Rossi" and their date of birth to "DATE OF BIRTH".
6) Starting from the homepage, the user must transfer patient "USERNAME" to the Clinical Center in Padova.
7) Starting from the homepage, grant researcher "USERNAME" access to study data until December 15, 2023.
8) Starting from the homepage, the user must find and view all patients enrolled with clinician "USERNAME."
9) Starting from the homepage, the user must create a new study administrator, find it, and delete it. The user must then log out.
10) Log in as a study administrator. Starting from the homepage, the user must create a new clinician and assign them to the center in Padova, giving them the Display Name "FIRST AND LAST NAME." The user must then delete the clinician.

To evaluate the ease of use, efficiency, and subjective satisfaction with the administrative dashboard, we considered a comprehensive set of evaluation metrics. These metrics, including the Task Success Rate (TSR), Time on Task (ToT), Number of Clicks, Difficulty Rating and Errors, were carefully selected to provide a thorough understanding of the performance of the dashboard from various perspective.

- Task Success Rate (TSR): Defined as the normal rate of task completion, TSR is calculated by dividing the number of users who successfully completed a task by the total number of subjects who attempted the task. A high TSR indicates that most users were able to complete the task successfully. Additionally, to evaluate the number of errors made during the task completion, the error-free task success rate (ef-TSR) was also calculated, which is defined as the number of people who completed the task without making errors divided by the total number of people who attempted the task.
- τ: the normalized increase in percentage of time required to complete the task in relation to the minimum task time (MTT)
- χ: percentage increase in clicks compared to the minimum number of clicks required to complete the specific task. Similarly to the previous metric, after defining the minimum number of clicks (MC), we have normalized the number of click done above the minimum by the minimum number of cliks.
- Difficulty: at the end of each task, users were asked to rate the difficulty of the task as low, medium, or high (corresponding to values 1, 2, and 3, respectively). The average rating was then calculated using the arithmetic mean.
- Errors: these are defined as the number of incorrect clicks made per task (as opposed to clicks, which refer to the total number of clicks made per task). The number of critical errors, or errors that resulted in the failure of a task, was also taken into account. The average number of errors and critical errors per task was also calculated using the arithmetic mean.

Furthermore, to evaluate the overall satisfaction with the administrative dashboard, participants were asked to complete the System Usability Scale (SUS) questionnaire [3] at the end of the tasks. The SUS is a widely-used tool for efficiently evaluating the usability of websites and other systems. The SUS provides a single score between 0 and 100, the higher the score, the more usable is considered the system.

IV. Results

The usability and ease of use of the administrative dashboard were rigorously evaluated through a task-based testing session with 14 volunteers (8 males, with an average age of 33 ± 13.5 years). The participants were selected to ensure a diverse range of expertise and familiarity with telemedicine, with 9 of the participants reporting low levels of knowledge, and half reporting some prior experience with telemedicine platforms.

The tests were conducted using the Zoom online video conference software, with the participants sharing their screens as they logged into the administrative interface with provided credentials and completed the tasks. Table I shows the reference values for the τ and χ metrics, which are the minimum time (MTT) and minimum number of clicks (MC) required to complete each task.

The findings of the experiments are documented in Tables II and III. The results of the task-based testing session indicate that the administrative dashboard has a high level of usability and ease of use.

TABLE I: Reference values for each task in minimum number of clicks and time of task

Task	MTT [s]	MC
1	25	8
2	27	13
3	11	3
4	19	5
5	29	5
6	13	4
7	23	7
8	19	5
9	36	12
10	51	19

The overall success rate for completing tasks was high, with the exception of one participant who made an unintentional error in one task, which resulted in a critical failure and prevented the completion of the task. Despite this, the overall success rate is commendable, particularly in light of the fact that many of the participants reported minimal prior experience with telemedicine and a significant proportion had not previously utilized a telemedicine interface.

TABLE II: Numeric results on the average success rate, time on task and clicks

Task	TSR	ef-TSR	τ	χ
1	100%	79%	195,90%	12,14%
2	93%	79%	262,50%	27,32%
3	100%	71%	332,47%	63,31%
4	100%	100%	196,70%	26,20%
5	100%	100%	59,93%	30,25%
6	100%	71%	201,25%	47,19%
7	100%	79%	240,51%	57,54%
8	100%	29%	496,17%	116,81%
9	100%	43%	360,62%	82,13%
10	100%	100%	94,18%	8,58%

TABLE III: Numeric results on average self-reported difficulty, errors and critical errors for each task

Task	Difficulty	Errors	Critical errors
1	1,00	1,00	0
2	1,50	1,79	1
3	1,50	1,36	0
4	1,14	0,50	0
5	1,00	0,43	0
6	1,21	0,93	0
7	1,64	2,50	0
8	2,21	3,21	0
9	2,36	4,93	0
10	1,21	2,36	0

From the results, it can be concluded that the dashboard is characterized by high usability and great intuitive use. Test users, who did not have much familiarity or expertise with similar sites, needed more time to become familiar with the interface. This is evident from the results presented in the τ and χ columns of Table II. While these metrics show that participants required more time and clicks than the minimum needed to complete the tasks, they also demonstrate that once participants were familiar with the interface, they were able to complete tasks with ease. However, it is worth noting that, notwithstanding the aforementioned results, only two tasks (8 and 9) presented more challenges for participants in terms of time taken, clicks, difficulty and errors. Specifically, the τ parameter shows a time increase of 500% and 360% respectively for tasks 8 and 9, compared to the minimum time required to complete the same tasks. The χ parameter also reports an increase, respectively for tasks 8 and 9, of 116% and 82% of clicks compared to the minimum number of clicks necessary to complete them. Moreover, these tasks were rated by participants as harder than the others. These results indicate that there may be room for improvement in these specific tasks, devising ways to make them less cumbersome for users and making them more trustworthy.

Nevertheless, aside from these two tasks, the metrics used to evaluate the usability of the dashboard, such as task success rate, time on task, number of clicks, and user ratings of task difficulty, generally showed low levels of difficulty and errors for the majority of tasks. Notwithstanding this, the results of the System Usability Scale (SUS) questionnaire were favorable, with a mean score of 89.3 and a standard deviation of 5.5, which indicates that the dashboard is considered to be highly usable, versatile, and user-friendly.

V. Conclusion

In conclusion, this study has presented the results of a usability evaluation of a telemedicine administration interface, which was developed to support a real clinical study. Overall, the findings of the experiments indicate that the dashboard is an easy-to-use, intuitive and reliable tool. Nonetheless, the difficulties encountered in tasks 8 and 9 should be taken into account and further research could be done to address any seasonality issues with the use of the platform, in order to ensure a thorough user experience.

Automatic extraction of acoustic features to predict Alzheimer's disease among English-speaking subjects

C. Giangregorio[1], E. Ambrosini[1], and S. Ferrante[1]
[1] *Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy*

***Abstract*—Dementia is a disease characterized by the decline of cognitive function. Previous studies have shown that speech conveys information about health and cognitive status. The current work aims at validating the capability of a set of acoustic features automatically extracted from voice recordings to classify the level of cognitive decline. To reach this aim, the Pitt Corpus, a dataset of 458 recordings of English-speaking subjects, has been exploited. A Support Vector Machine classifier achieved the best classification performance, with an F1-score of 78% to distinguish people with a diagnosis of Alzheimer's Disease (AD) from non-AD subjects. An improvement of the classification performance was achieved by two gender-based classifiers, which obtained an F1-score of 83% and 88% for female-based and male-based classifiers, respectively. The results of this study confirmed the possibility to predict AD based on acoustic features automatically extracted from voice recordings. Since no manual intervention was required in data processing, the proposed algorithm is a good candidate for being implemented on a mobile application so as to implement an ecological momentary assessment of people at risk of cognitive decline.**

***Keywords*—Alzheimer's Disease, speech processing, machine learning**

I. INTRODUCTION

Dementia is a category of neurodegenerative diseases defined by a gradual long-term decrease in cognitive function. It is characterized by a set of symptoms including memory loss, poor executive functions (e.g. problem-solving, decision-making), language impairment, motor problems, and emotional distress. This category comprises different forms, the most common one being Alzheimer's disease (AD) which represents up to 75% of total cases [1]. It is important to stress that this pathology starts silently for up to 20 years before there are clear and observable cognitive symptoms, thus there is a need to find strategies to detect the problem as early as possible, to enhance therapy effectiveness and quality of life. Since speech and language capacity is a well-established early indicator of cognitive deficits, speech-processing methods may offer the possibility of automatically screening for prototypical indicators in real-time. Indeed, in recent years, voice has been one of the most studied digital biomarkers [2], being widely employed since it allows an ecological and rapid assessment of several aspects linked to the health status of a subject that would usually be assessed in presence of clinicians.

The use of voice to detect cognitive decline from the analysis of acoustic features has been eased by the advent of artificial intelligence. Indeed, several studies have been reported in the literature on the recognition of cognitive decline from spontaneous speech, thanks to the availability of already existing datasets such as the Pitt Corpus, the largest public corpus of speech tasks from elderly subjects and those with dementia (AD). For example, Fraser et al. exploited the Pitt Corpus to distinguish healthy control and AD, based on linguistic variables derived from transcripts, achieving an accuracy of 81% [3]. Other studies have used linguistic features derived from the manual transcriptions to classify the recordings: Ammar et al. obtained 79% of accuracy [4] by considering linguistic, syntactic and pragmatic features; while Orimaye et al. considered n-grams, i.e. collections of *n* successive words, along with the linguistic and syntactic features, reaching an AUC of 0.93 [5]. Nevertheless, the main disadvantage of transcription-derived features is that they are language-dependent and rely on the information content. Therefore, to comply with the privacy issue, they could be employed only when the recordings do not involve sensible data, making them not suitable for ecological assessment in a domestic environment. Other works have focused on the prediction of AD subjects relying only on acoustic features [6–10]. Warnita et al. for example used the features extracted through OpenSMILE, an open-source toolkit for audio feature extraction, usually employed in speech emotion recognition, to distinguish controls from AD subjects using a gated Convolutional Neural Network, obtaining an overall accuracy of 73.6% [7].

The aim of this work is to develop a classification model based only on automatically extracted acoustic features for the prediction of AD in English-speaking subjects. In a previous study, currently under evaluation, the same acoustic features have been employed in Latin-derived-language speaking subjects, Italian and Spanish; in that work, an overall accuracy of about 70% has been achieved in distinguishing people with mild impairment of cognitive function from healthy controls. This study aims therefore at validating the transferability of these features on subjects with a diagnosis of AD and on a different language.

II. METHODS

A. Dataset

The current work was developed by exploiting the recordings contained in the Pitt Corpus, an existing dataset of 458

TABLE I: Demographic characteristics of the two groups of the dataset. (*): mean (standard deviation); (†): median (interquartile range).

	AD (n=237)	non-AD (n=180)
Age, years*	71.6 (8.4)	64 (7.8)
Gender (Female / Male)	163 / 74	113 / 67
YoE, years†	12 (3)	13 (4)
MMSE†	19 (8)	30 (1)

recordings of English-speaking subjects, a part of which with a diagnosis of Alzheimer's Disease (AD) [11]. Each recording, acquired through an air microphone, contains the description of the *Cookie Theft picture* of the Boston Diagnostic Aphasia Examination [12]. From the AD group, MCI subjects and those that were not classified as probable or possible AD were discarded. In particular, 180 non-AD and 237 AD recordings were selected for the purpose of this work, maintaining the classes unbalanced. The demographic characteristics of the selected subjects are described in Table I.

B. Feature extraction

Features extraction was performed via an automatic algorithm implemented in MATLAB, which has been previously described in detail in [13]. A summary of these features, grouped by domain, is reported in Table II. Before the extraction, recordings were standardized by removing the mean value for each recording and by dividing them by their standard deviation. To evaluate the robustness of the features in an uncontrolled environment, no manual pre-processing was performed to clean the recordings from possible interruptions by the interviewer. Features extraction was repeated three times for voice segments lasting respectively 5s, 10s, and 15s to assess whether specific patterns can be captured by different time lengths. Moreover, to reduce noise among the segments, each feature with a normal distribution has been substituted by its mean and standard deviation, while the remaining ones with their median and interquartile range, thus extracting a total of 138 features.

TABLE II: Summary table of extracted features

Domain	Feature	
Voice periodicity	Unvoiced percentage	F1
	Unvoiced and voiced parts (and related statistics)	F2-F9
	Total voice breaks	F10
Shimmer	Shimmer	F11
Syllables	Speech Rate	F12
	Phonation Percentage	F13
	Articulation Rate	F14
	Intersyllabic time	F15
	Intrasyllabic time	F16
	Pauses	F17
	Duration of pauses	F18
Spectral features	Pitch (mean, standard deviation)	F19, F20
	Standard deviation of the 3rd formant	F21
	Speech Temporal Regularity	F22
	Centroid	F23

C. Feature selection and classification

Binary classification was performed on the selected recordings of the Pitt Corpus, to discriminate between healthy control (non-AD) and Alzheimer's disease (AD).
Moreover, classification was also carried out on two separate subsets, composed by Female-only and Male-only subjects, respectively, since it has been shown how some acoustic features, such as pitch, are highly affected by gender [14].

1) Classifiers: To perform the classification, support vector machines (SVM), CatBoost classifier (CAT), and Logistic Regression (LR) were compared. The first two classifiers were chosen since SVM is robust to noise in training data, while CatBoost is the state of the art of boosting algorithms, and it has been proven to be effective with small datasets. Finally, LR was taken into account for its simplicity and computational speed. Each classifier was implemented in Python using the Scikit-learn libraries and the Catboost library. In order to achieve robust estimations the performance of each classifier was evaluated using repeated 10-fold cross-validation. Indeed, for each model, cross-validation was repeated 10 times, each time with a different random seed and the reported performances are the overall mean and standard deviation. Due to the unbalanced nature of the dataset, Precision, Recall and F1-score were computed as performance metrics. The choice of the best model was based on the F1-score.
Since the number of features is high with respect to the dimension of the dataset, it was decided to reduce the computational cost of the problem, by carrying out the analysis and selection of the most informing features through SHAP [15].

2) Model explainability: To understand the impact of the acoustic features in the prediction of AD, a ranking of the most informing features has been implemented by summing up the unweighted mean of the Shapley values obtained at each cross-validation.

III. RESULTS

Results obtained on the whole Pitt Corpus dataset are reported in Table III. The best model, chosen in terms of the highest F1-score, is support vector machine which yields a mean F1-score of 78% and both Precision and Recall of 79%. Table IV reports instead the classification performance of the gender-based classifiers. In this task, the classification performances highly improve for all the machine learning models. In particular, support vector machine achieves a mean F1-score of 83% and 88%, respectively for the Female-only and the Male-only dataset.
To analyze the impact of features, the rankings for the overall dataset and the two subsets are reported in Figure 1 and 2, respectively. The features have been grouped in the four domains defined in Table II, according to their information content: spectral (in red), syllabic (in blue), those related to voice periodicity (in green), and shimmer (in yellow). Figure 1 shows that features related to the periodic nature of the voice hold great relevance in the prediction of cognitive decline, with the unvoiced percentage and the voice breaks in the first positions, followed by the syllabic and spectral features, such

TABLE III: Performance of the classification models obtained on the whole dataset

Model	Precision	Recall	F1-score
CAT	0.77 (0.02)	0.79 (0.02)	0.77 (0.01)
SVC	0.79 (0.01)	0.79 (0.01)	0.78 (0.01)
LR	0.73 (0.01)	0.80 (0.01)	0.76 (0.01)

TABLE IV: Performance of the classification models obtained on the Female-only (F) and Male-only (M) dataset

Model	Gender	Precision	Recall	F1-score
CAT	F	0.81 (0.02)	0.84 (0.02)	0.82 (0.01)
	M	0.83 (0.02)	0.80 (0.02)	0.81 (0.02)
SVC	F	0.82 (0.02)	0.85 (0.02)	**0.83 (0.01)**
	M	0.90 (0.02)	0.87 (0.01)	**0.88 (0.02)**
LR	F	0.75 (0.01)	0.85 (0.02)	0.79 (0.01)
	M	0.77 (0.02)	0.75 (0.02)	0.75 (0.01)

as the duration between syllables and pitch. The importance of the voice periodicity is confirmed in Figure 2a and 2b, although some differences can be observed. Indeed, for the Female-only dataset, shimmer is shown to have an important role in the prediction of AD, being in the top 5 features after the features related to the unvoiced parts of speech, whereas for the Male-only dataset, spectral features, i.e. pitch and the standard deviation of the 3^{rd} formant, are in the first positions of the ranking along with those related to voice periodicity.

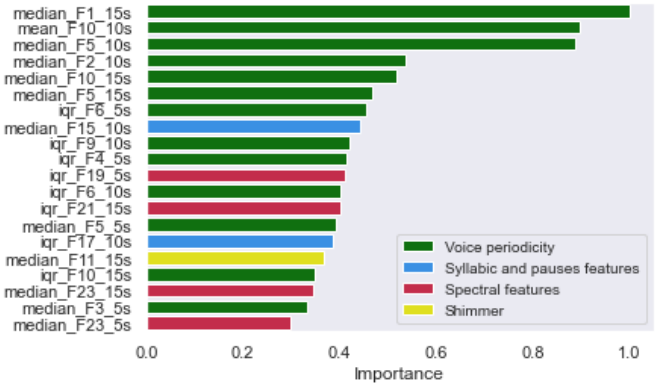

Fig. 1: Feature ranking of the complete dataset

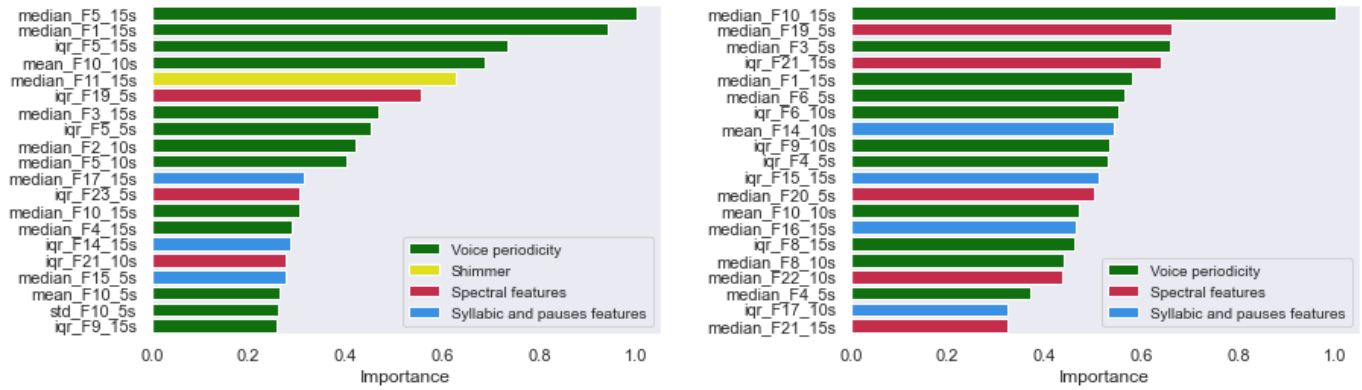
IV. DISCUSSION



An automatic classification algorithm has been implemented for the detection of AD among English-speaking subjects of the Pitt Corpus, by considering it all together and then dividing the subjects by the reported gender. For the overall dataset, the best performance of the classification model was 78% with support vector machine, whereas for the Female-only and Male-only subsets an F1-score of 83% and 88% was achieved, respectively. The metrics obtained in the classification task of the complete dataset are slightly lower than those obtained with the gender-based classifiers, probably due to the intrinsic different acoustic characteristics of the two genders that may act as confounding factors in the prediction. Nevertheless, the feature ranking obtained from the overall classification in Figure 1 showed in the first places voice periodicity features, which are strictly correlated with cognitive decline. Indeed, in past studies, it has been shown that unvoiced percentage and number of voice breaks tend to increase with AD [16]. However, the feature rankings of the gender-specific classifiers highlighted that also different sets of features are relevant for AD detection, depending on gender. For example, shimmer appeared among the top features of the female-based classifier whereas spectral features, such as pitch and the third formant, highly contribute to the prediction of AD in the male-based classifier.

These performances were obtained by considering only acoustic features, to determine whether the identified features can be used to define a screening tool, with the possible aim of longitudinal monitoring of cognitive decline among elderly people. Other studies have classified the Pitt Corpus dataset by considering only speech features. Kumar et al. achieved an F1-score of 87.5% by computing acoustic features such as MFCCs, and formants [8]. Triapthi et al. obtained an F1-score of 85.7% by employing acoustic features derived from subsampled signals [9]. Finally, Liu et al. achieved an F1-score of 82.9% after data augmentation [10]. The aforementioned classification performances have all been obtained after a manual cleaning of the recordings in which silences and the possible interruptions of the interviewer were removed. In the current work, this step was ignored since the objective was to validate the features in a context as similar as possible to real life, in which it is highly probable that the speaker is interrupted by other people or has long periods of silence. Nevertheless, the performances obtained when building the two different gender-based classifiers were comparable with those obtained in literature, with the male-based classifier even reaching a higher F1-score with respect to the aforementioned works, suggesting that our automatic feature extractor and classifier can be robust in monitoring elderly people in an uncontrolled environment.

The same starting set of features was previously successfully employed to classify Italian and Spanish people with the earliest symptoms of cognitive decline, defined in the previous study by a low Mini-Mental State Examination score, i.e. less than 26. The good performances obtained in a non-Latin-derived language prove the cross-language potential of this set, which might be exploited for a mass screening of symptoms of cognitive decline in elderly people.

V. CONCLUSION

The Pitt Corpus was analyzed to distinguish AD subjects from the control subjects, by automatically extracting acoustic features. The analysis was fully automatic, without further manual cleaning of the recordings to test the robustness of the features in a completely uncontrolled scenario. The good performances achieved, mainly on gender-based classifiers, are promising for the employment of this set of features in the development of a cross-language screening tool for symptoms

***Abstract*— In recent years, the increasingly widespread use of medical equipment has revolutionized the way in which clinical practice is performed and made their management increasingly complex. The Clinical Engineering of the Spedali Civili Hospital in Brescia decided to develop a medical equipment management software with the aim of digitalize and optimize its own processes. The objective of the present study is to share the methodology used for the implementation of a tailor-made software for medical equipment management throughout the entire device's life cycle.**

***Keywords*— Clinical Engineering, digitalization, Medical Equipment Management Software**

I. INTRODUCTION

Nowadays, health technology is an integral part of clinical workflow and play a central role in everyday practice. However, the complexity of electromedical equipment, in terms of number and differentiation, is reflected in the complexity of managing these medical devices [1].

To satisfy this increasing need, clinical engineering departments (CEDs) adopts management software systems that enable safe and optimized management of the hospital's medical equipment [2].

Many benefits are provided by the use of Medical Equipment Management Software (MEMS), compared to paper-based management: easier storage and faster retrieval of information, more efficient maintenance management, greater patient safety [2], reduction in working time and workload [3], minimize human error [4], facilitate the tracking of medical equipment during the entire life-cycle [5].

The idea of using management software also responds to the need, increasingly common in all sectors, to collect structured data that can be processed, analyzed and exchanged between operational units. [6,7]. To understand this necessity in CEDs it is important to consider the quality ISO 9001 standard - which requires that the main actions performed within a complex structure (CS) have to be tracked - and the Medical Device Regulation 2017/745 which states that the recalls of devices from the market have to be done using the UDI or serial number. So, it is important to have this data available and to be able to retrieve them in a quick and easy way.

According to literature [3, 5], since 90s CEDs has been developed or adopted different modalities of MEMS: Integrated Software System for Medical Equipment Management (ISSMEM) that provides useful tools for all the management activities range; Computerized Maintenance Management System which operates for gathering, storing and analyzing data on the maintenance performed on the medical devices; discrete component that targets one function of the health technology management.

The ready-made software already available in the market are solutions that concentrate on only equipment maintenance management. For this reason, most of these software systems have been designated based on the specified needs of the CEDs [3].

In this pilot study it is presented the pathway elaborated by the CS[1] Clinical Engineering of the Spedali Civili Hospital in Brescia to develop an ISSMEM. The final aim of this system is to digitalize and optimize all the processes managed by this CS. Furthermore, the MEMS offer to the CS Clinical Engineering the possibility to monitor the quality and the cost-effectiveness of the service through the use of quality and cost KPIs.

Another objective of this work is to compare the new software to the previous situation in which the CS Clinical Engineering of the Spedali Civili Hospital had a software (provided by the global service), that doesn't allow the management of all the activities, so part of the tasks was done using paper.

Lastly, the aim of this study is to share the methods and the preliminar results about the work done by CED of the Spedali Civili Hospital to develop a tailor-made software for medical equipment management throughout the entire device's life cycle.

II. MATERIALS AND METHODS

For the realization of the software the CS Clinical Engineering of the Spedali Civili Hospital selected, through open tender procedure, a technological partner identified in the company ELLF S.r.l. This partner is involved in the project for the development of the coding part of the software. Additionally, it was deemed appropriate to form a multidisciplinary team involving the research university Politecnico of Milan and the CS ICT of the Hospital, required

[1] A complex structure is an operational unit, endowed with autonomous resources, which performs major functions in support of corporate management and performs activities primarily related to the planning and organizational growth of the company.

for the integration with other application tools and for IT security problems.

With this team a series of multidisciplinary working meetings have been carried on for one year in which the software system development follows the phases of *requirement analysis, analysis* and *optimization of processes, software design, implementation* and *evaluation*.

To understand the general requirements and specifications to be developed within the portal, the technology partner asked a series of questions to the CS Clinical Engineers. In addition, to find a solution to these requirements, a number of solutions were proposed by all team members and discussed and selected through common brainstorming techniques.

Regarding process analysis, Clinical Engineering described in detail all phases and steps of the current procedures carried out within the CS. Each step was examined to understand how the software could be used within the flow of activities, with the aim of simplifying and optimizing them. Then the functions that the application must perform within the procedure were identified. Subsequently, the data involved within a given process and their flow between the different functions were defined: each function was matched with the data that it uses as input and the data it produces as output. To carry forward this process analysis, User Stories and Use Cases Diagrams were developed.

The software evaluation was conducted as a Beta Testing activity developed through two different operations:

- The use and the test of the software by the final user with the goal to determine the proper functioning of the system, to monitor problems and to find bugs.
- The distribution of a questionnaire that could assess the first use of the Beta version of the software. The questionnaire was designed by the authors following the steps described below. The decision to implement a questionnaire and not to use an already validated one is due to the consequent possibility of greater customization of the questions. Initially, the Clinical Engineers of the CS were identified as the recipients of the survey, because they are professionals with significant knowledge of the software structure. In a second moment the questionnaire was deliver also to the Technicians as external end-users that didn't participate to the development phase.

  After this step, investigation areas were defined: they correspond to the different sections of the software and an additional section for the general evaluation of the usability.

  Then questions and rating scale have been defined. Lastly, the questionnaire was implemented online with *Google Forms* and then it was distributed to the recipients through a link shared via e-mail.

III. Results

In this paragraph it is reported the result obtained for each development phase.

A. Requirements analysis

The fundamental objective of a ISSMEM is to support the CEDs in the management activities of the entire medical equipment's life cycle. The discussion led to the definition of the needs of the Clinical Engineering and to the drafting of general technical specifications that the software must have or allow to do. The following are the main ones:

- ability to use the core functionality of the platform without the need for installation/setup on users' computers;
- user friendly interface;
- user authentication and user profiling;
- modular access permission management;
- management of users and user licenses;
- storage management;
- system configuration managed by the user;
- management of the device entry process;
- creation of a tender documents' repository;
- portals monitoring of external companies;
- calculation of ISO 9001 process indicators;
- importing data from Excel;
- modular dashboards;
- generation of reports;
- alerts and notifications;
- computerization of backup equipment management;
- monitoring of effectiveness and efficiency indicators through the creation of a management dashboard;
- management of requests for action by business units through a prioritization algorithm;
- monitoring of major maintenance activities;
- monitoring of equipment utilization and development of indicators to support HTA;
- compilation by suppliers of a dedicated form to collect input data for all equipment;
- tracking of major actions carried out using the software.

B. Analysis and optimization of the process

At this stage, the different types of software users were defined. They are shown below:

- manager of the CS Clinical Engineering;
- clinical engineers;
- clinical engineering technicians;
- clinical engineering warehouse workers;
- clinical engineering secretaries;
- coordinators of hospital departments;
- clinical engineering suppliers.

Next, all processes to be digitized were identified:

- Scheduling of technology equipment purchases, in collaboration with the corporate biomedical technology committee;
- Tenders for maintenance services and technology purchases, in coordination with the Procurement Unit;
- Definition of the technical specifications of biomedical and technical-economic technologies, verifying with departmental referents the specific needs to be met.
- Installation, testing, inventory of new equipment;
- Preventive maintenance;
- Corrective maintenance in case of failure, with backup equipment inventory management;
- Electrical and functional safety controls according to current CEI standards;
- Decommissioning of medical equipment;

- Development of HTA studies, in connection with regional organization.

Each of these processes was analysed and digitalized through the use of the software.
Using the Uses Cases Diagram (one example reported in Fig. 1), it is possible to observe all the actors involved and the main activities that will be carried out with the new management software.

In particular, some elements that have been derived from this analysis are the simplification and optimization of processes due to automatic actions and controls performed by the software. This results in significant time savings, and in a higher efficiency compared to the current situation where CS Clinical Engineering has to perform these tasks.

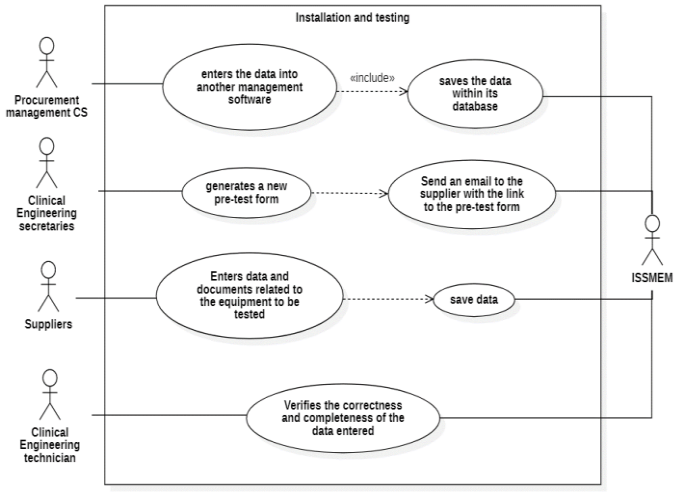

Fig. 1: Use Case Diagram Installation and Testing process

C. Software design

First of all, a modular design has been chosen because it offers many advantages in terms of upgradability, system efficiency, and the ease of maintenance. The system architecture is based on a central module which carries out the main tasks of the CS Clinical Engineering, while each peripheral module performs a more specific function.
Other design characteristics are defined by the multidisciplinary group: single page application usable through all modern browsers, both PC and mobile, cloud hosting that ensures data security and scalability, integrated authentication with enterprise Active Directory on Premise, simplified software update process that does not require desktop client installation and upgrade, user friendly and customizable interface.

The programming language used is C# associated with Angular and NodeJS for the web interface part; the DB used is SQL Server on Microsoft Azure cloud.

D. Software implementation

This system has been implemented to manage all the aspects related with Clinical Engineering technical management, so the main modules developed in the Beta-version are:

- Contract management section;
- Testing and installation section;
- Medical equipment section that contains inventory, classification, technical specification, warranty (Fig. 2)
- Personnel management section;
- Maintenance management section (in which is possible to manage the preventive and corrective maintenance);
- Biomedical gas management section;
- Master data and element type tables management section;
- Modular dashboards to set the KPIs.

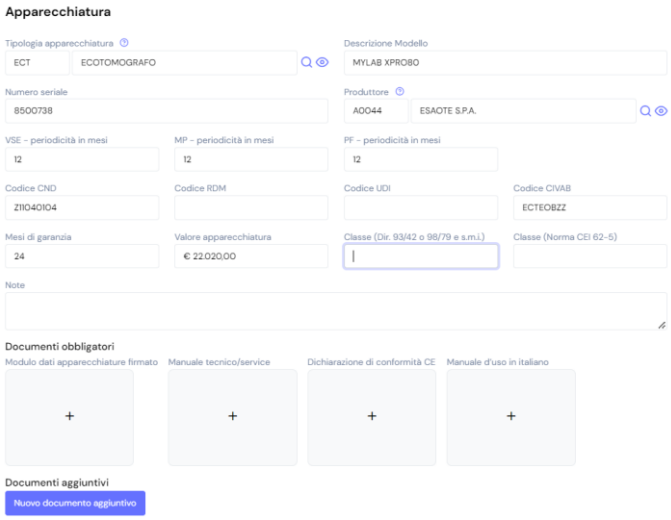

Fig. 2: Screen showing the registry of an equipment

E. Evaluation

Initially, the Beta testing activity was characterized by performing several operations on the software to test the Beta version and check for bugs. In this version, a database extrapolated from the previous management software was used, so test operations were carried out using real data.
Problems were found about the user access to the software and related to what different types of users can edit and fill out in the different modules.
The critical issues were discussed and resolved with the technology partner, and then the satisfaction questionnaire was developed and distributed.

Submitting the questionnaire to the clinical engineers who participated in the design of the software itself certainly poses a very high risk of bias, but it was necessary to involve them in this evaluation as experienced users who were in a position to determine whether what was required was implemented correctly by the developers.
In a second step, the questionnaire was submitted to the clinical engineering engineers, who reported ratings in line with those of the engineers.

All respondents felt that the software was extremely simple and intuitive. 100% of users think that the new Software is intuitive, user-friendly, and comprehensive, and that not many steps are needed to achieve the goal.
Concerning the comparison with the previous software, all engineers agreed that the new management software was more efficient and user-friendly.
Lastly, on a scale of one to five all users are more than satisfied

with the overall use of the new software, as shown in the chart below (Fig. 3).

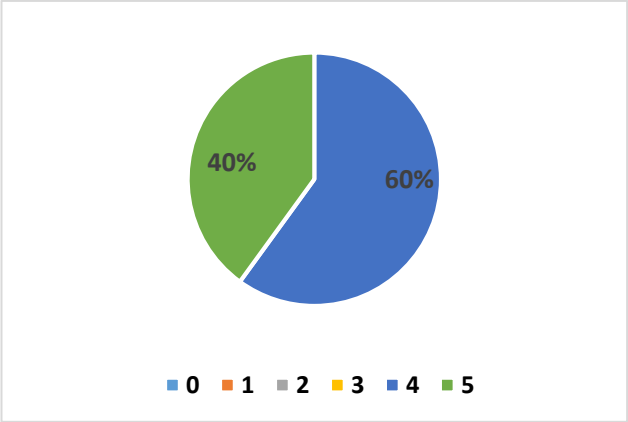

Fig. 3: answers to the question: "How much satisfied are you with the overall use of the new management software?"

IV. Discussion and conclusion

The results reported in the previous paragraph are preliminar and the pathway to obtain the final version is still long and complicated, but many advantages are already appreciated by the final user.

An important element is the constant monitoring of the progressive implementation status of the software in order to supervise the functional and coordinated integration of the final system into the operational reality.

In any case, having defined the technical specifications in detail at the beginning made possible to develop software that fully reflected the needs of the Clinical Engineering. With the flow analysis, it was possible to think in depth about the processes in place in the CS: this activity allowed not only to implement the paper forms in digital format, but also to revise the processes in order to make the most of digitization as a tool for simplification and data analysis.

The entire specification and flow analysis phase led to the development of the most important sections of the new software. From the first use of the Beta version and subsequently from the positive feedback gathered from the analysis of the questionnaire data, it was found that the new software is more simple, intuitive and functional than the one in use.

The latter considerations lead to the possibility of conducting a constructive reasoning about the contextualization of development technology in the hospital setting. On the one hand, the innovation brought by software brings to a change in work mentality, revolutionizing the current method of parceled work, reorganizing and facilitating the ordinary activities of the Clinical Engineering into a single digitized working solution. However, on the other hand, it is also true that this aspect has to be accompanied by the development of an appropriate digital culture in the system in which it is integrated. In this sense, the business managements effort in appropriate digital training plays a role of primary importance.

Consequently, process digitalization must be flexible and able to modulate itself to the needs of the realities in which it is structured, and not vice versa. Only in this way it is possible to create value for the citizen.

In this context, the software developed by CED of Spedali Civili Hospital has the greatest strength of being a customized platform, which adapts to the needs of the specific context, in a simple and intuitive way.

***Abstract*—Measuring both electrical and mechanical activities of the heart has gained success thanks to technologies able to measure them. Heart electrical activity is measured by means of Electrocardiography which generate Electrocardiographic (ECG) signals. The automatic analysis of ECG signals by means of algorithms and tools may help to detect anomalies and automatically annotate them. Recently, a particular type of network architecture, referred to as Autoencoder (AE), has been used for similar tasks in many fields, both biomedical and not. Nevertheless, using an AE for the analysis of ECG signals can still provide improvements to clinicians. We here present a tool that can be used by clinicians for the semi-automatic identification of anomalous windows in ECG signals. Moreover, the tool allows signal visualization, manual annotation, and measuring.**

***Keywords*—ECG, anomaly detection, signal annotation, autoencoder**

I. INTRODUCTION

Biomedical signals are related to the investigation of neural activity, cardiac rhythm and other physiological activities. Biomedical signal processing involves the acquisition, management and analysis of such signals to extract meaningful information to identify patterns and trends within the signals.

ECG signals measure the rhythmic electric activity of the heart and can be composed of one up to fifteen channels. The standard number of channels of an ECG signal is typically twelve.

One ECG signal has a variable duration ranging from 10 seconds for a standard clinical ECG up to 24/72 hours for a cardiac holter.

Cardiac diseases, such as arrhythmia, represent a disturbance in the normal heart rhythm resulting in an irregular heartbeat, which is responsible for the addition of irregular patterns to the ECG signal. Visual inspection of ECG signals with the aim of annotating possible cardiac arrhythmias events is time-consuming, thus software tools able to automatically analyze heart-related signals could be a valuable help as a clinical decision support system.

AEs are relatively new types of neural network architectures that have increasingly been used to detect anomalies in signals. An AE uses a feedforward approach to reconstruct its input in the output. The comparison between the reconstructed output and input data allows to detect possible anomalies in the input. [6]

AE is usually trained on data without anomalies. After the training phase, an AE model is able to reconstruct signals without anomalies but fails to perform well with signals containing anomalies. The reconstruction error, which is the error measured between the input signal and its low dimensional reconstruction is used to detect anomalies. We used root mean square error (RMSE) as the reconstruction error metric.

We here describe the development of a tool, based on an AE model, able to perform the unsupervised anomaly detection task on 15 lead ECG signals.[5] The proposed system is able to perform semiautomatic identification and annotation of anomalies on ECG signals having 15 channels, 12 standard ECG leads and 3 Frank leads.[2]

II. Methods

The proposed tool has been implemented in the Python 3 programming language and it uses the following Python libraries:

- *Tkinter*, a library used to build the Graphical User Interface;
- *Pytorch*, a largely adopted library for creating and training deep learning models;
- *dash* and *plotly*, used for plotting signals;
- *neurokit2*, an open-source library for the analysis of biomedical signals, used in our tool to perform R-peaks detection in ECG signals.

A. Dataset

Synthetic ECG signals were generated using the SIMARR3 arrhythmia simulator [3]. This software can simulate both normal signals and signals with atrial fibrillation, tachycardia, and bradycardia events at a given sam-

pling rate. It is also possible to generate signals containing one or a mix of the most common types of artifacts in ECG signals such for example, electromyography (EMG) noise, baseline wander caused by respiration, and electrode movement artifacts.

We generated:

- 500 ECG signals with no arrhythmia events (labelled as *normal*) sampled at 500 Hz and with a duration of at least 60 seconds;
- 290 ECG signals with atrial fibrillation events (labelled as *anomaly*), sampled at 500 Hz and with a duration of at least 60 seconds.

For each signal, a windowing algorithm has been applied to extract 281 three-seconds windows of the signal.

We split the windows data into training and test set like the following:

- the training set contains 100500 normal windows with no atrial fibrillation events;
- the test set contains 81490 windows with atrial fibrillation event and 40000 normal windows.

B. Tool

Our tool is composed of a Graphical User Interface (GUI), depicted in Figure 1, for signal loading, visualization, manual annotation, and semiautomatic annotation performed by our AE.

The proposed AE, called DPNet depicted in Figure 2, is a convolutional autoencoder (CAE), i.e an AE composed only of convolutional 2-dimensional layers. The model input consists of a 3-second signal window of 15 lead ECG sampled at 500 Hz. The workflow used to perform the anomaly detection is depicted in Figure 3, the overall workflow of our tool represented in Figure 4. By using this software, the clinician is able to:

- identify, visualize and annotate abnormal portions of the signal;
- visualize a single channel or all 15 channels of the signal;
- zoom on the signal;
- visualize singularly each heart beats;
- visualize a specific time window of the signal;
- visualize the distance between two successive R peaks of the ECG signal;
- click on a specific point of the signal to insert a text annotation;
- visualize the heart rate, in beats per minute;
- make textual and/or geometric (rectangles, lines) annotations on the signal.

C. RESULTS

For the evaluation of the AE model, we computed the reconstruction error on the test set. Then, the model has been evaluated in terms of the AUC metric score (Area Under Curve) on the test set. AUC is the area under the ROC (Receiver Operating Characteristic) curve

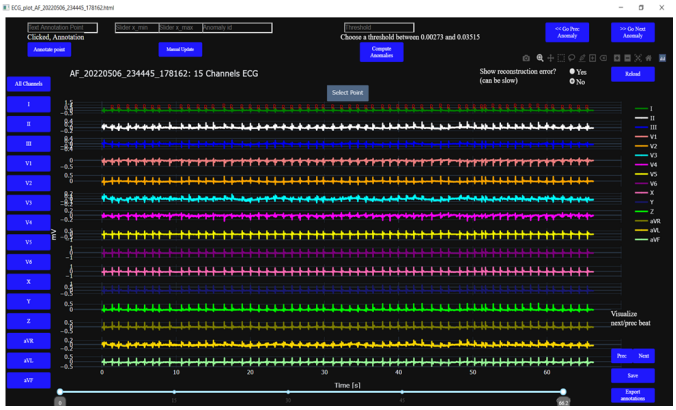

Fig. 1: ECG anomaly detector and annotator tool initial interface.

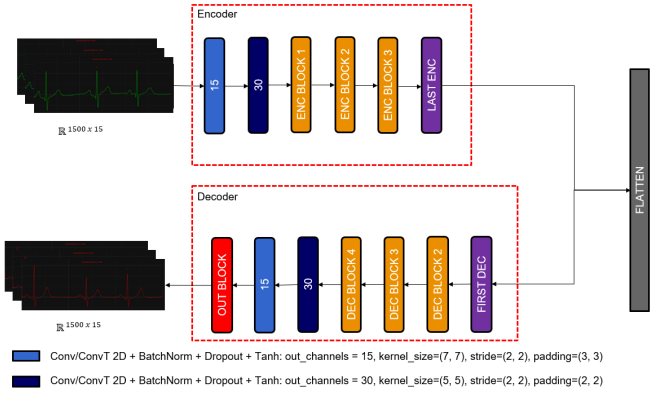

Fig. 2: The DPNet architecture.

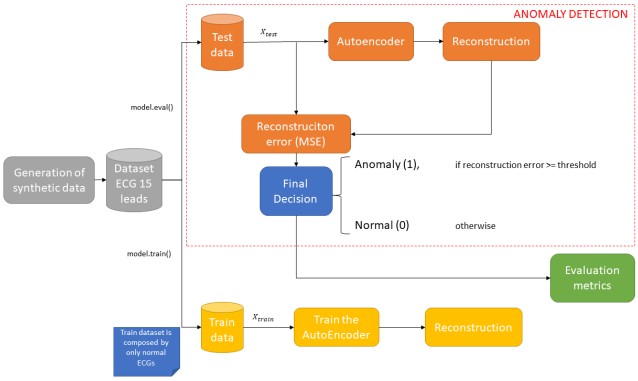

Fig. 3: Workflow for anomaly detection.

and represents the degree of separability between the two classes, i.e. normal and abnormal, providing an indicator of how well the model is able to distinguish between two classes. The model marked an AUC score equal to 0.925 on the test set. In figure 5 we show an example of a real window with a cardiac arrhythmia event correctly detected using our tool.

In table I we report some classification performance

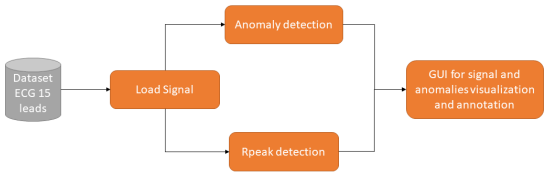

Fig. 4: Workflow of our proposed tool.

Metric name	Metric value
Accuracy	0.9257
F1 score	0.9204
Sensitivity	0.9124
Specificity	0.9376
ROC AUC	0.925

TABLE I: Performance metrics of our AE in the anomaly detection task with a threshold parameter equal to 0.0073 (optimized).

metrics of our AE in the task of anomaly detection. Those metrics were obtained using only the test set of our dataset and by optimizing the threshold parameter for the anomaly detection task. The optimized threshold found is equal to 0.0073.

Fig. 5: An example of a corrected identified atrial fibrillation event found using our tool with a threshold of 0.0073.

III. Conclusion

In this work, we presented an AE model that can be used to automatically identify anomalies in ECG signals. We trained the AE using synthetic normal ECG windows, then we evaluated the model using synthetic normal and abnormal ECG windows (with atrial fibrillation events). In these steps, synthetic signals were generated using the SIMARR3 software. We measured the performance of the AE in the anomaly detection tasks obtaining an AUC score of 0.925.

We then developed a tool for the loading, analysis, visualization, manual and semi-automatic annotation of ECG signals.

Our tool can, with good precision, automatically identify and send to the clinician the portions of the signal that are considered anomalous because correlated, for example, with atrial fibrillation events, cardiac arrhythmias, or noise presence.

The main problem with the AE is due to the fact that it has been trained using 15 lead ECG signals. In clinical reality, however, there are few hospital centers that perform this type of measurement (12 lead ECG is the standard). Also, the signals used to train and test the model are synthetically generated and not real human signals.

One possible future work can be, for example, retraining the model using only the 12 channels related to the ECG signal.

ACKNOWLEDGEMENTS

PNG, PV and UL were partially funded by the MISE PON-VQA project. UL Ph.D. fellow is partially supported by Relatech S.p.A. Authors thanks Elena Succurro for suggestions on ECG signals.

***Abstract*—The clinical heterogeneity that characterizes Amyotrophic Lateral Sclerosis (ALS) makes its diagnosis, prognosis, and care difficult. In this context, characterizing patients based on their clinical features or progression patterns is crucial, allowing a deeper understanding of the disease and the planning of more effective treatments. In this work, we employ Archetypal Analysis for studying a real-world ALS population based on their characteristics at diagnosis. First, we derive a set of extreme clinical types (archetypes) whose combination describes the study population, and analyze their differences in terms of clinical characteristics. Then, we cluster patients according to their similarity to the archetypes and we investigate how the so-obtained groups differ in terms of time to life-support interventions and survival.**

***Keywords*—Amyotrophic Lateral Sclerosis, Archetypal Analysis, patient stratification, unsupervised clustering.**

I. Introduction

Amyotrophic lateral sclerosis (ALS) is a progressive and degenerative disease that affects the nerve cells that control voluntary muscle movement. ALS progression impairs motor neurons in the brain and spinal cord, wasting the muscles and leading to the inability to control movements; sometimes it is also accompanied by cognitive and behavioural symptoms. ALS aetiology is still unknown, with some genetic and environmental factors possibly triggering the disease onset. The mean life expectancy is 3-5 years from onset, with death usually occurring from respiratory failure. Despite a relative uniformity during the late stages of the disease, the symptoms at the onset and the timing of the clinical manifestations are highly variable among the patients [1].

Related to this heterogeneity, one of the major needs is the identification of groups of patients with similar characteristics (*i.e.*, patient stratification), to be able to effectively predict the course of the disease in terms of speed of worsening, symptom occurrence, and the need for life-supporting interventions. For a deep understanding of this rare and incurable disease, it is also essential to investigate which are the main markers that determine its different manifestations. Clinically, patients can be stratified into phenotypes based on their characteristics or by observing their clinical progression. Alternatively, it is possible to automatically stratify patients using a data-driven approach: recently, clustering algorithms such as k-means, dimensionality reduction methods such as Uniform Manifold Approximation and Projection (UMAP), and network-based approaches were employed for this purpose [2], [3].

Archetypal Analysis (AA) is an alternative unsupervised computational approach that allows to discern a specific number of extreme and not necessarily observed points called archetypes (i.e. ideal, prototype patients), such that each archetype is constrained to be a mixture of points in the dataset and such that each point can be well represented as convex mixtures of the archetypes [4]. AA can be used on multivariate datasets as an exploratory tool since, analyzing the characteristics of each archetype, allows for highlighting the differences among groups of patients.

In this work, we aim at stratifying ALS patients by employing AA and considering the variables collected at the diagnosis of a real-world ALS cohort. First, we derive the archetypes and analyze their differences in terms of clinical features. Then, we associate each patient with their closest archetype. Finally, we investigate how the identified patients' groups differ in terms of clinical outcomes, considering: the need for non-invasive ventilation (NIV), percutaneous endoscopic gastrostomy (PEG), tracheostomy, and death.

II. Materials and methods

A. Dataset

The dataset used in this work was extracted from the Piemonte and Valle d'Aosta ALS register (PARALS) [5]: selecting the patients with the first visit from January 1st, 2007 to December 31st, 2015, we identified 924 ALS subjects. For each patient, we collected features to characterize their condition at the time of diagnosis, including:

- demographics and lifestyle: sex, marital status, educational level, smoke habits;
- dates of: birth, onset, diagnosis, PEG, NIV, tracheostomy, death;
- ALS-related variables: onset site, phenotype, mutation in ALS-linked genes (C9orf72, SOD1, TARDBP, FUS, OPT, TUB);

- comorbidities: psoriasis, epilepsy, stroke, rheumatic diseases, poliomyelitis, obstructive sleep apnea syndrome, monoclonal gammopathy of undetermined significance;
- other health-related variables: frontotemporal dementia (FTD), forced vital capacity (FVC), first/second tumour, thyroid impairments, psychiatric diseases, hypertension, diabetes, chronic obstructive pulmonary disease (COPD);
- a panel of 39 different blood exams, covering general health analysis, heart problems, and organ function.

B. Data preprocessing

A preprocessing phase was necessary to solve some typical issues that may arise with real-world data. First, we aggregated the variables presenting low occurrences and belonging to the same category, creating the binary variables: "genetics", which indicates if a mutation occurs in at least one tested gene; "comorbidities", indicating that at least one of the concurrent conditions listed above occurs; "tumour", which indicates that the patient had at least one cancer. Other more frequent and already binary conditions, such as hypertension or diabetes, were not aggregated. Variables assuming multiple possible values were either converted into binary features, if their occurrence had low frequency in the data (such as psychiatric diseases, that were transformed into new features indicating the presence/absence of at least one psychiatric disease), or coded as dummy features (such as FTD and smoke habits).

Then, we derived some variables coding the time passed from the ALS onset to the other clinical events for which a date was available, obtaining the following new features: age at onset, diagnostic delay, and time to PEG/NIV/tracheostomy/death. Next, we filtered out the blood test variables presenting more than 30% of missing values. In total, 16 of the 39 available tests were removed, 10 of which had more than 50% missing values. We imputed the remaining missing values in the preprocessed data using the *mice* R package [6] with default parameters. To check the robustness of the imputation process, we compared the distribution of each variable before and after the imputation.

Tables I and II provide an overview of the data after these preprocessing steps. Lastly, we scaled all variables in the range [0,1] to balance the contribution of features to the analysis.

C. Method

The goal of the analysis is the unsupervised stratification of the patients according to their clinical characteristics at diagnosis and the comparison of the obtained groups in terms of clinical outcomes, namely time to NIV, time to PEG, time to tracheostomy, and time to death. The analysis consists of three steps: (1) the identification of a number of archetypes from the data, using all the available variables except those corresponding to the outcomes; (2) the unsupervised classification of the subjects into different clusters according to their similarity to the archetypes; (3) the comparison of the clusters in terms of the four outcomes of interest.

1) *Archetypal Analysis.* Given an $n \times m$ matrix X representing a multivariate dataset, where n is the number of observations, m is the number of variables, and k is the number of archetypes chosen by the user, AA allows determining a $k \times m$ matrix Z of archetypes such that:

a) the data are best approximated by convex combinations of the archetypes Z, *i.e.*, they minimize the residual sum of squares (RSS):

$$RSS = ||X - \alpha Z^T||_2, \quad \alpha_i \geq 0, \quad \sum\nolimits_i \alpha_i = 1 \qquad (1)$$

b) the archetypes are convex combinations of the data points:

$$Z = X^T \beta, \quad \beta_i \geq 0, \quad \sum\nolimits_i \beta_i = 1 \qquad (2)$$

where α are the coefficients of the archetypes and β are those of the dataset, respectively.

Since the identification of the archetypes is based on an iterative process that, starting from a set of *k* randomly chosen points in the features' space, minimizes the approximation error between the original data points and those reconstructed as a combination of the archetypes, it is recommended to repeat the identification algorithm several times to avoid falling into local minima [4]. Here, we tested a number of archetypes *k* from 2 to 8, repeating the procedure 15 times for each *k*. The optimal number of archetypes was chosen by detecting the elbow in the scree plot reporting on the x-axis the value of *k* and on the y-axis the RSS. To reinforce the choice of the best *k*, we also analyzed the minimum, mean and standard deviation of the RSS over the 15 repetitions for each *k* [7].

The archetypes, by construction, lie on the boundary of the convex hull of the data and can be therefore easily influenced by outliers. Thus, to avoid incorrect or skewed results, we employed the identification method of *robust archetypes*, which reduces the influence of outliers by using M-estimators instead of least squares estimators when performing the optimization procedure [8]. All analyses were performed using the *archetypes* R package [9].

For the sole purpose of visualizing the data and archetypes in two dimensions, principal component analysis (PCA) was used. The two-dimensional representation allows to easily check the position of the archetypes with respect to the data and to verify that they are actually on the convex hull. Radar plots were used to investigate the characteristics of each archetype individually; for a more effective rendering, we computed for each variable its standard deviation (sd) across the *k* archetypes and then only included in the radar plots those with sd>0.13 (sd_{min}=0.00004679, sd_{max}=0.4158768), i.e. those variables that differentiate the most among archetypes.

2) *Subject clustering based on archetypes.* As mentioned, AA allows representing the data as a linear combination of archetypes, each multiplied by a non-negative coefficient α_i. We decided to assign each subject to the archetype with higher α_i, following the rationale of the nearest prototype classifier [7], to inspect how patients cluster based on their extreme behaviours, obtaining *k* distinct clusters.

3) *Comparison of the cluster in terms of clinical outcomes.* Finally, we compared the different clusters using the Wilcoxon test to assess any statistically significant differences in terms of

TABLE III: Minimum, mean, and sd of the RSS computed over 15 repetitions, for a number of archetypes k from 2 to 8.

Archetypes	k=2	k=3	k=4	k=5	k=6	k=7	k=8
min	0.0531	0.0504	0.0495	0.0475	0.0470	**0.0461**	0.0470
mean	0.0531	0.0511	0.0502	0.0482	0.0479	**0.0474**	0.0476
sd	<0.0001	0.000642	0.00045	0.001264	0.000715	**0.00064**	0.000426

Fig. 2 shows how the archetypes (in red) are positioned amongst the subjects (in green): as expected, they position

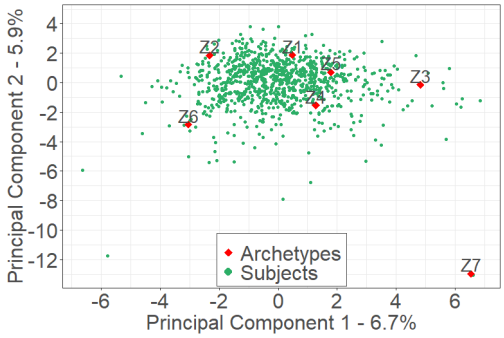

Fig. 2: Two-dimensional representation of the subjects (green dots) and archetypes (red diamonds) using PCA.

on the borders of the dataset, identifying types who are not necessarily observed in the data but who are extreme in their characteristics.

The 7 mined archetypes are reported in Fig. 3 as radar plots. The variables were filtered according to their standard deviation, ultimately retaining 24 features out of a total of 44.

By analyzing the resulting archetypes Z_i, we can describe the extreme behaviors characterizing the data. Z_1 represents a male subject with non-bulbar onset and medial age at onset, as well as Z_2, which is a female subject almost free of other diseases. Z_3 delineates an individual who is living alone, with mainly no FTD issues and high bilirubin values. Z_4 represents a subject with rather advanced age at onset and FTD at diagnosis. Z_5 outlines an ex-smoker subject, with older age at onset and affected by hypertension; this is, in general, also the

archetype placing greater emphasis on the presence of other comorbidities, such as diabetes. Z_6 is mainly similar to Z_1, presenting in addition relatively high values of triglycerides and cholesterol. Finally, Z_7 describes a female subject, ex-smoker, with pronounced cognitive FTD impairment and with high ESR and albumin values; this is also the only archetype with a low chlorine value.

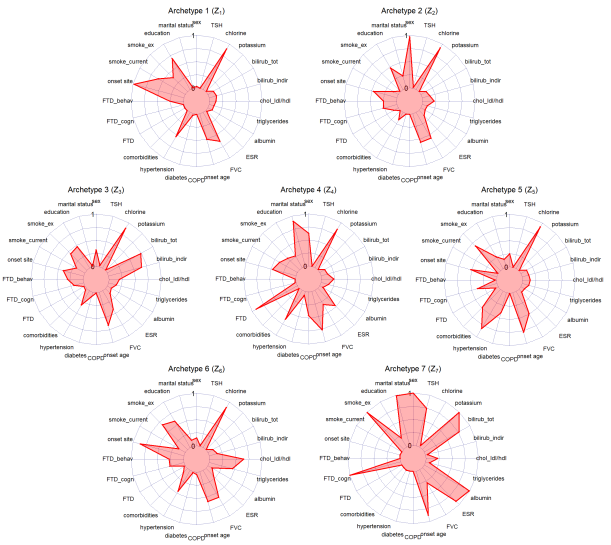

Fig. 3: Radar plots representing the archetypes, including the 24 variables with sd>0.13 only. For each variable, the innermost circle represents a standardised value equal to 0, the outermost circle equal to 1. The levels of the categorical variables correspond to those of Tab. I, then normalized in the range [0,1].

We then assigned each subject to their most representative archetype, getting seven clusters C_i with 60 subjects in C_1, 286 in C_2, 59 in C_3, 79 in C_4, 259 in C_5, 180 in C_6, and only 1 subject in C_7. Based on this, we decided to perform the following analysis only considering clusters C_1-C_6.

Fig. 4 reports the comparison of the time of occurrence of the four considered outcomes in the different clusters. The clusters differ in terms of mean time as well as in the order of occurrence of the outcomes. Clusters C_1 and C_3 have time-to-event values comparable with those of the other clusters, for all outcomes but tracheostomy, where C_3 has the shortest time of occurrence among all clusters. Statistically significant differences are observed in C_2 vs C_4, C_2 vs C_5, and C_4 vs C_6 for PEG, NIV and death (all p-values<0.015). This confirms that archetypes-based clustering can be a useful tool to identify groups of patients with different characteristics both in terms of covariates at diagnosis and clinical outcomes.

IV. Conclusion

In this work, we applied AA to a multivariate dataset of ALS patients to study disease heterogeneity and outline extreme behaviors at diagnosis. We identified 7 archetypes that were first compared in terms of clinical characteristics, and then used to define 7 clusters of patients. By analyzing their distributions in terms of time to PEG, NIV, tracheostomy, and death, we assessed how stratifying patients based on their similarity to the mined archetypes can be a valid criterion to identify groups characterized by different progression timing and patterns. In future works, we aim to further characterize the identified clusters to explore intra-cluster variability (e.g. by comparing the characteristics of the subjects belonging to the same cluster) and inter-cluster variability (e.g. considering the differences in progression patterns and comparing the archetypes with the clinical phenotypes described in the literature).

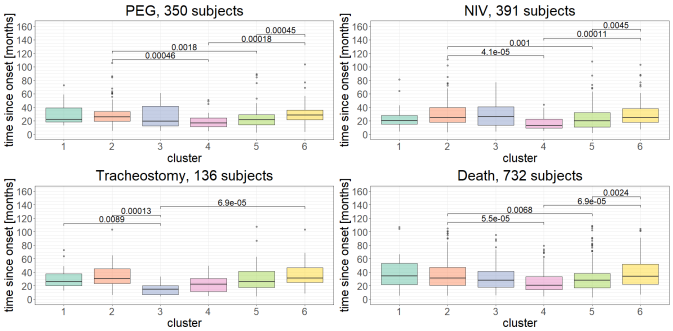

Fig. 4: Box plots comparing the times of occurrence of the outcomes (PEG, NIV, tracheostomy, and death) among the clusters. For each outcome, the number of subjects who experienced the event and statistically different p-values (Wilcoxon test, threshold = 0.01) are reported.

Assessing Personal Exposure to Airborne Particulate Matter with Wearable Sensors and Ventilation Rate Models

***Abstract*—Air pollution is a major contributor to global morbidity and mortality. Accurate assessment of individual's exposure to air pollution is important to quantify the impact of air pollution on human health. Historically, human exposure to air pollution has been quantified using pollutant concentrations from fixed air quality monitoring stations. This approach does not consider the subject's activities and the differences between indoor and outdoor air pollution; however, these limitations can be overcome using wearable sensors.**

In this work, we propose a new approach to measure personal exposure to airborne Particulate Matter (PM) that consists in using a wearable/portable air quality sensor to measure air quality at the subject's location, a wearable Heart Rate (HR) sensor to collect HR timeseries, and a ventilation rate (VE) model to estimate the volume of inhaled air per minute (L/min) based on HR and other subject's covariates. Finally, VE and PM timeseries are combined to estimate the inhaled pollutant doses over time, as a measure of personal exposure. To model VE as a function of HR, 4 literature models are considered. The estimates obtained with the 4 models are compared in 3 representative subjects. Initial data analysis showed that the 4 models may drive to statistically significant differences in exposure estimates, thus the choice of the model can be a critical aspect of this approach. Regardless of the model used, timeseries of inhaled PM revealed significant daily variations in pollutant exposure, highlighting the importance of methodologies for accurate personal exposure assessment.

***Keywords*—Personal Exposure, Air Pollution, Wearable Sensors, Respiratory Rate Estimation.**

I. Introduction

Air pollution is a significant contributor to global morbidity and mortality. Nearly 90% of the global population is exposed to air that exceeds the WHO's guideline limits for pollutants [1]. One of the major air pollutants is particulate matter (PM), i.e., a mixture of solid particles and liquid droplets in the air generated by sources such as road dust, construction debris and fuels burned in automobiles. The small size (1, 2.5 and 10 μg) of PM allows it to penetrate the lungs upon inhalation, leading to respiratory illnesses [2].

Air pollution is not solely an outdoor phenomenon, as indoor air quality can also be affected by the infiltration of outdoor air into buildings. This means that indoor air quality can have a significant impact on human health. As a result, it is essential to accurately quantify total exposure to poor-quality air, which has been identified as a major health hazard.

Exposure assessment refers to the process of estimating or measuring the magnitude, frequency, and duration of an individual's exposure to a particular agent. Accurate quantification of everyday human exposure to air pollution is necessary for health risk assessments. However, exposure is the result of complex interactions between environmental and human systems, making it challenging to assess. Ideally, the assessment has to be based on measuring the concentration of a pollutant within the person's breathing zone for a defined time. Historically, approaches to quantify human exposure have relied on pollutant concentrations from fixed outdoor air quality monitoring stations linked to subject's residence or workplace. Fixed sensors generally give accurate measurements, but, because air quality monitoring sites are often spaced far apart, their location rarely coincides with the places where people experience the majority of their exposure (e.g., at home, work, or school). As a result, it is necessary to use spatial interpolation techniques or statistical methods to indirectly measure a subject's exposure to air pollution.

Environmental parameters, such as pollution, can vary significantly over short distances (e.g., a few meters) [3] and short time intervals [4]. Given the rapid proliferation of mobile devices, as well as the different types of advanced sensors being embedded, there is high interest in exploring the feasibility of using wearable sensors to quantitatively define an individual's exposure to environmental pollution.

Numerous research studies have been conducted to investigate the feasibility of assessing exposure levels in various circumstances by integrating air quality data with wearable devices and/or location data, the latter of which can be obtained through Global Positioning System (GPS) or Time Activity Diary (TAD) [5][6]. For instance, a study [7] compared residence-based monitoring station assessment, mobility-based monitoring station assessment, and mobility-based real-time sensing assessment. The findings revealed that monitoring station assessment may lead to substantially biased estimates due to potential under- or overestimation of individual exposure levels at indoor locations. However, these methods lack precision in measuring the inhaled pollutant dose, which is crucial in transit environments where physical activity can rise inhalation rates.

In this work, we propose a new approach for monitoring

the personal exposure to air pollution using wearable sensors of air quality and activity, and some literature models for the estimation of ventilation rate to compute the inhaled pollutant dose. For estimating ventilation rate, 4 candidate models are considered. The feasibility of the proposed approach is tested on 3 healthy subjects. The exposure estimates obtained with the 4 candidate models on the 3 subjects are finally compared.

II. Estimation of Personal Exposure to Airborne PM using Wearable Sensors

A. Overview of the proposed approach

The proposed approach integrates the measurements collected by a wearable/portable air quality sensor and a wearable heart rate sensor, using a ventilation rate model and an inhalation model. Wearable/portable air quality sensors can measure pollutant concentration (e.g., PM) at the subject's location at almost continuous time (e.g., every 1-5 min).

It is well established that the pollutant amount inhaled is not only influenced by an individual's location (i.e., the level of pollution they are exposed to) but also by their activity level (as the intensity of activities affects the respiration rate and, therefore, the amount of contaminants ingested).

According to Borghi et al. [8], the amount of inhaled dose over a certain time of exposure can be estimated as:

$$I_{pollutant} = C_{pollutant} * VE * t \tag{1}$$

where $I_{pollutant}$ is the dose of pollutant inhaled by a subject in μg; $C_{pollutant}$ is the concentration of pollutant measured in μg/m^3; VE is the ventilation rate in m^3/min and t the time of exposure in minutes.

Measuring Ventilation Rate (VE) in daily life is challenging, because it requires the use of a face mask with an airflow sensor, which can obstruct the intake of air pollution and obstacle the daily activities. Therefore, VE estimation methods are often used in field studies. In some cases, the VE of the subject is derived from literature population values and adjusted based on physical effort intensity during measurements.

In the proposed approach, VE timeseries are estimated starting from almost continuous-time heart rate (HR) timeseries collected by a wearable smartwatch, using some literature models of VE that have HR as main predictor. In particular, the 4 candidate models described below are considered.

B. Ventilation rate models

Several solutions were proposed in the literature for the estimation of VE starting from HR, which is easy to measure in the field using portable and inexpensive equipment. Although HR is affected by various factors, it is mainly influenced by oxygen consumption, which is strongly correlated with respiration. The following subsections describe some literature models to estimate VE starting from HR.

a) Model A

Zuurbier et al. [9] proposed 3 different models for estimating VE in individuals, one for both males and females, one for males, and one for females. Volunteer subjects (N = 34) performed submaximal tests on bicycle ergometers. HR was recorded every second and VE was measured using a pneumotach. Regression equations between HR and the natural log-transformed VE were calculated:

$$VE_{overall} = e^{0.89+(0.022*HR)} \tag{2}$$

$$VE_{men} = e^{1.03+(0.021*HR)} \tag{3}$$

$$VE_{women} = e^{0.57+(0.023*HR)} \tag{4}$$

b) Model B

In a study published by Guo et al. [10], 80 volunteers underwent incremental tests on a bicycle ergometer. HR was continuously measured with a chest strap and VE was measured with a facial mask and a portable gas analyzer. The investigators proposed 3 exponential models, one for both men and women, one for men, and one for women, in which the exponent is a regression of HR:

$$VE_{overall} = 10^{0.585+(0.007*HR)} \tag{5}$$

$$VE_{men} = 10^{0.559+(0.007*HR)} \tag{6}$$

$$VE_{women} = 10^{0.647+(0.006*HR)} \tag{7}$$

c) Model C

In a study conducted by Good et al. [11], 35 volunteers were provided with an Oxycon Mobile indirect calorimetry system that measured breath-to-breath VE and HR in a laboratory setting. The volunteers performed 9 or 11 prescribed tasks (6 min each). Predictive models for VE were developed based on multiple linear regression. The resulting model equation is:

$$\begin{aligned} VE = {} & 0.99 - 27.41 * sex + 50.24 * \frac{HR}{100} \\ & + 15.73 * \frac{age}{100} - 43.65 * \frac{HR_{rest}}{100} \\ & - 7.02 * \frac{hip}{100} + 23.02 * sex * \frac{HR}{100} - 10.34 * sex * \frac{age}{100} \\ & - 26.21 * sex * \frac{HR_{rest}}{100} + 38.78 * sex * \frac{hip}{100} \end{aligned} \tag{8}$$

where HR_{rest} is resting HR and hip is the hip circumference.

d) Model D

Greenwald et al. [12] conducted a pooled-data analysis that included 8 datasets for a total of 471 individuals. The study protocols included measures of Forced Vital Capacity (FVC), VE, HR and physical activity. The data analyzed included subjects performing sport or routine activities. The models developed in this study were based on log-transformed generalized linear mixed models. The resulting model equation is:

$$VE = e^{-9.59} * HR^{2.39} * age^{0.274} * sex^{-0.204} * FVC^{0.520} \tag{9}$$

Three models out of four (A, B, D) were not validated, except from the model C which has been validated on the same subjects performing different physical tasks.

III. Feasibility Study of the Proposed Approach

A. Data collection

The feasibility of the proposed approach was tested with data collected from 3 healthy volunteers. Upon recruitment, each volunteer completed a questionnaire that included information about their gender, age, hip circumference, FVC, and resting HR. Each participant was provided with a personal air quality monitor, i.e., the Atmotube PRO (Atmotech Inc., San Francisco, CA), and a smartwatch, i.e., either a Fitbit Charge 5 (Fitbit Inc., San Francisco, CA) or an Apple Watch (Apple Inc., Cupertino, CA) to gather HR data.

The Atmotube PRO is a wearable/portable air quality monitoring device. It is equipped with sensors that measure the concentrations of PM of different sizes (PM1, PM2.5, PM10), total volatile organic compounds (VOCs), temperature, humidity, and pressure. The sensors are calibrated automatically and do not require any input from the user beyond placing the device in its charger as needed and synchronizing data through the proprietary app installed on the user's smartphone. Participants in this study were asked to wear the Atmotube PRO and the smartwatch continuously for a period of 4 weeks.

B. Statistical analysis

The inhaled doses of PM1 were estimated using the 4 models of VE (Eq. 3-6-8-9) presented in subsection II-B combined with Eq. 1. Descriptive statistics, such as mean and standard deviation (SD), maximum and minimum values, median and percentiles (5% - 95%), were calculated for each inhaled dose timeseries to provide a comprehensive overview of the data. Moreover, the average daily sum of inhaled dose was computed for each signal, to obtain an index of the average daily exposure over the 4-week period.

To determine if there were significant differences between the daily sum of inhaled dose estimated with the different VE models, a Kruskal-Wallis H Test (1% significance level) and multiple pairwise Wilcoxon test were conducted for each subject independently, after checking the normality assumption (Lilliefors test) and the homogeneity of variance (Levene test).

IV. Results

The mean age of the study participants at the time of recruitment was 27.7 years, and all subjects were male. The average resting HR and hip circumference were 55.7 beats/min and 98.5 cm, respectively. The FVC of all participants was set to 5 L, based on the normal range for healthy males between the ages of 20-60 (4.75-5.5 L). The study dataset included 94 person-days of data collected from May to December 2022, with an average follow-up period of 31.5 days. Figure 1 shows the average daily VE timeseries provided by the 4 VE models (top panel), the average daily PM1 concentration timeseries (middle panel), and the daily mean profiles of inhaled PM1 dose (bottom panel), for Subject 1. We can observe that the estimates of Model C (Good, violet curve) are systematically higher than those of the other models, while the other three models provide estimates closer to each other.

TABLE I: Descriptive statistics of PM1 inhaled doses [μg] estimated with the 4 VE models.

	Subject 1	*Subject 2*	*Subject 3*
Model A			
Mean±SD	0.88±1.33	1.08±2.38	0.54±0.56
min-max	0.04-20.14	0.04-69.4	0.09-17.7
median (5^{th} - 95^{th})	0.55 (0.08-2.37)	0.67 (0.1-3)	0.41 (0.17-1.3)
Model B			
Mean±SD	0.78±0.93	0.97±2	0.34±0.4
min-max	0.04-12.77	0.04-61.1	0.04-15.5
median (5^{th} - 95^{th})	0.53 (0.07-2.14)	0.63 (0.09-2.6)	0.24 (0.06-0.88)
Model C			
Mean±SD	1.44±1.92	1.25±3.2	0.46±0.75
min-max	0.02-26.41	0.05-98.1	0.5-22.7
median (5^{th} - 95^{th})	0.85 (0.12-4.42)	0.63 (0.08-3.9)	0.23 (0.01-1.56)
Model D			
Mean±SD	0.72±1.25	0.9±2.1	0.29±0.44
min-max	0.02-20.01	0.02-61.5	0.01-12.5
median (5^{th} - 95^{th})	0.4 (0.06-2.10)	0.51 (0.09-2.67)	0.17 (0.04-0.9)

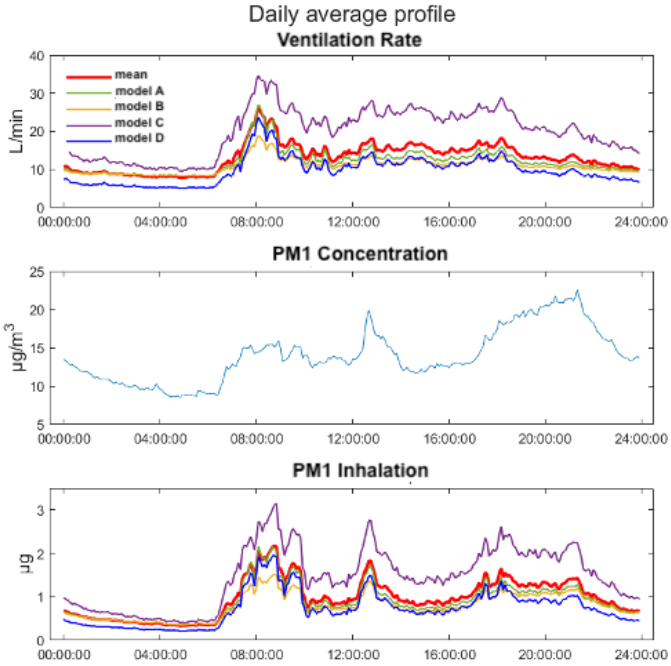

Fig. 1: Subject 1 daily average profile. From the top: VE computed using all the models (A - Zuurbier, B - Guo, C - Good, D - Greenwald), PM1 concentration measurements, Inhalation rate computed using each VE estimations. In the top and bottom panels, the red profile represents the mean of the profiles obtained with the 4 models.

The descriptive statistics calculated for each timeseries of PM1 inhaled dose are reported in Table I. The Model D estimation is typically lower, while Model C results in higher PM1 inhaled dose estimates. SD and the minimum-to-maximum interval show that Model C has a larger level of variability than the other models. Then, Model C appears to overestimate the inhalation of pollutants and to be more

sensitive to changes in the independent variables. Regarding the differences among subjects, we shall consider that the measurements of Subjects 1 and 2 were collected in the autumn, while the measurements of Subject 3 were collected during the spring. While air pollution is a problem throughout the year, some pollutants tend to be more prevalent during certain seasons due to a variety of factors like temperature, environment, and human activity. Pollution levels generally decline during the warmer and more sunny seasons, with consequent lower individual exposure. This likely explains the lower inhaled doses of Subject 3 compared to the others.

TABLE II: Average daily sum of inhalation [μg].

Model	*Subject 1*	*Subject 2*	*Subject 3*
A	245.7 $\pm$144.6	244.8$\pm$170.7	76.8$\pm$45.4
B	217.9 $\pm$121.6	217.8$\pm$150.3	70.2$\pm$40.5
C	399.5 $\pm$224.8	280.7$\pm$214.8	93.9$\pm$57.5
D	200.6 $\pm$124	203.4$\pm$146.4	59.7$\pm$36.6

TABLE III: Kruskal-Wallis H and Multiple Comparison Tests for the daily sum of inhalations timeseries.

	Subject 1	*Subject 2*	*Subject 3*
Kruskal-Wallis H Test (p-value < 0.01)			
P-Value	<0.01	0.54	0.1
Multiple Comparison Test (p-value < 0.05)			
P-Value (Model A vs B)	0.91	0.93	0.94
P-Value (Model A vs C)	<0.05	0.99	0.77
P-Value (Model A vs D)	0.54	0.7	0.45
P-Value (Model B vs C)	<0.05	0.82	0.42
P-Value (Model B vs D)	0.9	0.97	0.8
P-Value (Model C vs D)	<0.05	0.54	0.07

Table II shows the average daily sum of inhalation. In accordance with Table I results, the average daily sum of PM1 inhalation calculated using Model C has generally higher values, whereas that calculated using Model D has generally lower values. Regardless of the model used, the inhalation time series showed a large daily variation in exposure to contaminants to which subjects may be exposed.

The Lilliefors and Levene tests indicated that the assumptions of normality and homogeneity of variance were not met. Therefore, a Kruskal-Wallis H Test and subsequent Multiple Comparison Test were conducted. The findings from the Kruskal-Wallis analysis (Table III) revealed a statistically significant difference in the average daily sum of inhalation estimates among the four models (p-value < 0.01) for Subject 1, but not for Subjects 2 and 3 (with p-values of 0.54 and 0.1 respectively). Further pairwise comparison tests showed that Model C was significantly different from the other models for Subject 1. As expected, there were no significant differences between the models for Subjects 2 and 3. These results are consistent with the mean values presented in Table II. This behavior could be attributed to the inherent characteristics of Model C, which uses a linear regression model with a greater number of factors and interaction terms compared to simpler exponential models.

V. Conclusion

We proposed a new approach to assess the personal exposure to airborne PM using wearable sensors of air quality and HR, and models of VE and inhalation. Four literature models for estimating VE starting from HR were used for this purpose in a feasibility study conducted in 3 subjects.

A preliminary data analysis revealed that there might be significant differences between the inhalation estimates obtained by the 4 models. This suggests that the choice of the VE model may be a critical aspect of the proposed approach. Regardless of the model used, inhalation timeseries revealed significant daily variations in exposure to pollutants that a subject may experience, which cannot be captured by traditional approaches based on fixed monitoring stations. This encourage future research studies to enhance approaches, like the one proposed in this study, to assess personal exposure using wearable sensors.

Future work includes the assessment of the proposed approach on a larger population. Moreover, given the significant differences between the estimates obtained in this study, a benchmark study to validate VE models against standard methods (e.g., pneumotach) on a large population is needed to enable robust choice of VE models for future projects.

***Abstract*— In 2017, the European Medical Device Regulation 2017/745 made official and effective the implementation of a unified European database on medical devices, EUDAMED, and stated the need to adopt a medical device (MD) nomenclature to support its functioning. Registries are a fundamental tool to evaluate MD long-term safety and to contribute to its traceability. To achieve these goals, the MD Library embedded in the Registry framework plays an important role as it contains all information useful to identify the implanted medical devices and to compare their performance. Similarly to EUDAMED, MD Registry Libraries are based on a detailed and defined MD taxonomy that allows a correct MD categorisation on the basis of a selected set of technical features. The aim of this study is to propose a generalised approach to build a MD taxonomy to be implemented in a MD Registry Library starting from the experience gathered in the implementation of the MD Registries included in the Italian Implantable Prostheses Registry (RIPI).**

***Keywords*— medical devices, nomenclatures, registry, RIPI**

I. INTRODUCTION

IN 2017, the European Medical Device Regulation (MDR) 2017/745 made official the implementation of a unified European database on medical devices, EUDAMED, and stated that a medical device (MD) nomenclature should be made available to facilitate the functioning of EUDAMED [1]. In 2021, the Regulation (EU) 2021/2078 was issued providing all the rules for EUDAMED implementation and use [2]. Accordingly, all medical devices marketed in Europe should be collected in the single database EUDAMED and identified by a unique number, the Unique Device Identifier (UDI).

The selection of a MD nomenclature was fundamental to the functioning of EUDAMED in order to classify all medical devices into macroscopic and homogeneous classes. The European Medical Device Nomenclature (EMDN) was adopted by the European Commission (EC) on March 4th, 2019 taking as a reference the Italian national MD classification (Classificazione Nazionale dei Dispositivi medici, CND) [3],[4]. In 2021, WHO analysed different nomenclatures concluding that CND was the one that complies with the WHO principles for international classification, coding and nomenclature of medical devices. [5]. Moreover, WHO and EC have recently been collaborating in view of adopting an international standardised nomenclature [6].

Besides its role in EUDAMED, EMDN is also a useful tool for other purposes, representing a 'classification root' from which other systems can be developed [4]. Among them, MD Registries can benefit from more detailed and specific classifications, or taxonomies, to classify the implanted devices [7]. Indeed, in depth device knowledge allows a more complete, consistent and informative interpretation of the clinical data collected from the Registry, helping to obtain information on device usage and performance and to compare similar devices [8]. A medical device Registry is defined as an "organized system that continuously and consistently collects relevant data in conjunction with routine clinical care, evaluates meaningful outcomes, and comprehensively covers the population defined by exposure to particular device(s) at a reasonably generalizable scale (e.g. international, national, regional, and health system) with a primary aim to improve the quality of patient care" [9]. Since it represents a fundamental tool to contribute to the traceability of the device and to improve patient safety [10], its establishment is encouraged by MDR especially for class III MDs [1]. Certainly, a Registry should rely on a MD Library based on a defined taxonomy, classification or nomenclature to ensure MD traceability and monitoring,[11]-[13].

The aim of this study is to describe the methodology set up by the Italian Implantable Prostheses Registry (RIPI) [14] to design a taxonomy specific for a class of medical devices. The final scope of the taxonomy design is to complement the existing nomenclature, providing more detailed technical features of the device, and to set up the basis for the development of a dedicated MD Registry Library, essential to promptly identify and characterise the implanted device [8], [15], [16].

This work has been conducted for the purposes of the development of the MD Libraries for the Italian National Registries of spinal implants (RIDIS) and of cardiac devices, defibrillators and pacemakers, (RIDEP). Both RIDEP and RIDIS are included into RIPI.

II. STATE-OF-THE ART

A. The Italian Implantable Prostheses Registry (RIPI)

RIPI was established by law at the Italian National Institute of Health in 2017 (Istituto Superiore di Sanità, ISS) (DPCM 03/03/2017). It is organised as a cross coordination structure of individual registries of implantable devices divided by subject: joint prostheses like hip, knee, shoulder, and ankle (Italian Arthroplasty Registry, RIAP); spinal implants (Italian Spinal Implants Registry, RIDIS); implantable cardioverter defibrillator and pacemaker (Italian Implantable Cardioverter-defibrillator and Pacemaker Registry (RIDEP); artificial heart valves (Italian Heart Valves Registry, RIVAC) and implantable hearing devices (Italian Implantable Hearing

Device Registry, RIDIU) (https://ripi.iss.it/ripi/en/). Currently, RIAP is already active and collects data routinely; RIDIS and RIDEP have been completely designed while design of RIVAC and RIDIU is ongoing.

B. The MD Library

The Library is the database of all implantable devices collected by a specific Registry included in RIPI. Each device contained in the Library is described by a set of technical features. The Library is designed to be directly fed by manufacturers, according to the rules stated by a high-specific taxonomy.

C. The agreement with NJR to adopt the NJR-EPRD classification and share the MD Library

Most of the existing implant registries collect only the device ID or its barcode, which provide only market data for traceability but not specific device information [17]-[19]. However, the Dutch registry LROI [8], the English National Joint Registry (NJR) (https://www.njrcentre.org.uk/njr-annual-report-2022/) and the Endoprothesen Register Deutschland (EPRD) (https://www.eprd.de/de/downloads-1/berichte) have defined their detailed taxonomies to classify the registered devices. Remarkably, in 2018, NJR and EPRD, in the absence of a universally recognised and shared nomenclature for joint prostheses, agreed in developing and continuously updating over the years an internationally shared taxonomy [13],[16],[20]. This collaboration is the first example of an inter-registry international cooperation for classifying medical devices. For joint prostheses, ISS has recently signed an agreement with NJR in order to adopt the already defined NJR-EPRD classification and set up a shared international MD database linking both RIAP and NJR Libraries.

III. Materials and Methods

1) Materials

The taxonomy is a structured list including device-specific variables, properly grouped and described by a minimum core set of technical and identification features.

To set up the RIDIS and RIDEP taxonomies, the following sources of information were considered:

- CND nomenclature: a hierarchical classification organised in 22 anatomical/functional categories that characterise devices by homogeneous properties. Each category is organised in groups and sub-groups structured in different levels (up to 7) and identified by a correspondent alphanumeric code [21];
- Medical Devices Database of the Italian Ministry of Health (BDRDM): a database that contains all medical devices marketed in Italy, together with their technical datasheets (the registration is mandatory) [22];
- Medical Devices datasheets: technical documents available on the manufacturers websites;
- Literature review: analysis of studies concerning survival and/or failure of the specific implantable devices;
- Opinions of experts: clinicians and specialists, members of the registry technical panel.

In particular, the following CND classes (version 2022, January 26) were considered:

- RIDIS:
  i. “P0907. Prostheses and Stabilisation Systems of the Vertebral Column”, i.e., systems for interbody fusion, cages or cages and disc prostheses;
  ii. “K0103. Devices for Minimally Invasive Spinal Surgery”, i.e., devices used for kyphoplasty, vertebroplasty and products for cementation;
  iii. “J020202 Totally implantable spinal neurostimulators”;
- RIDEP:
  i. “J01. Cardiac Function Devices”, i.e., pacemakers, implantable defibrillators and leads;
  ii. “C02Devices for Arrhythmology”, i.e., leads and cardioversion devices.

2) Methods

A technical expert panel composed by clinicians nominated by the involved scientific societies and by researchers of ISS was established to define a first draft of the taxonomy structure, organised in groups and sub-groups. Both engineering and clinical aspects were considered to define the taxonomy: the first ones due to the fact that they are more closely related to the technical features of the devices, the last ones as they are associated to the device intended purpose.

The items included in the first structure were then weighed by associating the number of devices registered in BDRDM in order to have an overview of all specific devices actually marketed in Italy, selected on the basis of the proper CND code.

A set of technical features was then selected from the technical sheets, the manufacturers' manuals and catalogues, and associated to each item included in the first version of the taxonomy. To ensure device identification and traceability, the following information were selected and included in the taxonomy for each device: CND, manufacturer, product catalogue code, lot, barcode, UDI, ID registration in BDRDM.

The taxonomy was then shared and discussed with the clinical experts: only the technical features deemed as most useful to characterise the device and to carry out future analyses were retained. Subsequently, the taxonomy was shared with the manufacturers covering the highest portion of the spinal device market in Italy and was then finalised in a consensus meeting aimed at refining and making the taxonomy feasible and functional.

The final version of the taxonomy was then made suitable to fit into formal XML (eXtensible Markup Language, lit. “extensible markup language”) and XSD (“XML Schema Definition”) schemas, useful for the subsequent implementation of the MD Library in the RIPI platform. To perform this step, the names of the identified variables were translated into English, according to the specifications provided by RIPI-IT group. Moreover, specific business rules were introduced, namely syntactical and semantic rules providing a set of variable combinations which help avoid mistakes in compilation and ensure data coherency.

IV. Results

The designed methodology is structured in the following six steps (reported in Table I):

1. The CND (EMDN) codes of medical devices matching the registry area of interest are identified;
2. The first minimum core set of technical and functional features essential to assess the MD performance is defined on the basis of the information available from different sources (technical datasheets, institutional MD Database, EUDAMED, commercial catalogues, scientific publications);
3. The draft of the core set is discussed with the clinicians in order to check completeness of the list of variables useful to assess the performance of the devices from the clinical perspective;
4. The taxonomy is shared with the representatives of the industries to verify its feasibility and functionality at industrial level. To quantify the characteristics that they could easily routinely upload in the Library, manufacturers are required to classify the information requested on the taxonomy as "available", "not available" and "searchable". To ensure the consideration of all crucial technical features of the selected devices, it is advisable to include the highest number of manufacturers, if possible all, in this process;
5. Specific business rules are introduced to enter only valid combinations of values into the web-based platform in order to reduce compilation errors. The rules are defined using both manufacturers' datasheets and surgeons' opinions;
6. The taxonomy is converted into XML and XSD schemas to allow its implementation in the Registry Library. When feeding the MD Library, manufacturers are required to structure their data by using the XML format in accordance with the XSD schemas.

TABLE I
SUMMARY OF THE METHODOLOGY TO SET UP A MD TAXONOMY

step	*description*
1	*Identification of CND classes of Medical Devices that match Registry area*
2	*Definition of a first core-set of technical features*
3	*Proactive discussion of taxonomy draft within the multidisciplinary team of the Registry technical panel*
4	*Sharing of the taxonomy draft with the leading industries to verify its feasibility*
5	*Definition of business rules*
6	*Adaptation of taxonomy in XML and XSD schemas for subsequent implementation of the Registry MD Library*

Table II shows the macro categories of the taxonomies developed for the RIDIS and RIDEP registries.

V. Discussion

The methodology to design a taxonomy for a specific MD registry was abstracted from the processes developed in the implementation of two Italian implantable prostheses registries: RIDIS and RIDEP.

TABLE II
MACRO CATEGORIES OF MD TAXONOMIES DEVELOPED FOR RIDIS AND RIDEP REGISTRIES

categories	*RIDEP*	*RIDIS*
MD Identification	*Manufacturer, product code, CND/EMDN, UDI, lot number*	
Type of device	*Defibrillator, Pacemaker, catheters and loop recorder*	*Spinal fixation system, cages, disc prostheses, cements*
Technical and functional features	*Chambers connector, remote control, MRI conditional, sensors*	*Geometry, type, materials, spine level, mechanics or physics properties*

Implantable prostheses registries have become increasingly widespread in recent decades [10],[23] because of the highest economic impact on healthcare and invasiveness for the patient (risk class III) of the devices they monitor [24],[25].

This study highlighted some essential features that should be accomplished when designing a specific MD taxonomy: 1) to select only properties actually bringing information and knowledge when comparing devices' performance and their effects on patients, avoiding excessive details unnecessary to reach registry's aims; 2) to involve all actors (clinicians and manufacturers) dealing with the device within the Registry to collect their opinion and retain only the essential characteristics. Indeed, it is crucial to consider all the stakeholder perspectives in the decision-making process of inclusion and exclusion criteria; 3) to share the design of the taxonomy with the largest number of manufacturers to verify that they are able to provide all the selected information because are either available or collectable and not confidential, thus making the feeding of the Library feasible.

The availability of BDRDM was very helpful to draft a first list of medical devices marketed in Italy. However, the integration with other sources, such as literature and catalogues, was necessary to have a global perspective by including also the devices not marketed in Italy.

Hopefully in the near future, EUDAMED could fulfil at least at European level the same role BDRDM has at the Italian level; indeed, it includes information relating both to the economic operator and to the device (Annex VI, Part A) [1].

However, Registries need more specific information regarding the implanted medical devices to perform statistical analyses on their performance. Therefore, MD Libraries represent an important source of long-term data when the Registry goes live [11]. By following the methodology presented in this study, it is possible to implement a MD Registry Library and support health operators in data collection, without asking them to manually input MD codes, thus dramatically reducing identification errors. Moreover, each device is described by a set of technical features useful to conduct analyses on its use and performance over time according to the diseases or conditions of the patients [26]. Accordingly, manufacturers can also receive valuable information on how their devices are performing and they might possibly correct the focus for a safer device design.

A limit of the proposed methodology is related to the possible biased exclusion of selected MD properties in the taxonomy.

Indeed, some technical information characterising the device, that might be important to be studied, may be confidential as protected by patents and therefore not sharable by the manufacturers, thus preventing the Registry to perform subsequent complete statistical analyses.

VI. Conclusion

In this paper, starting from the experience gathered in Italy in the framework of RIPI, a methodology to implement a MD Library functional to achieve the MD Registry goals is presented. In a worldwide context, where safety and traceability of medical devices are considered a priority and data exchange and statistical results are crucial for social and scientific growth, the implementation of MD Libraries and MD taxonomies might be an essential step. Due to its generalisation and its easy use, the presented methodology might represent a first useful reference to set up taxonomies not only for other implantable prostheses, but also for other categories of devices.

Acknowledgements

This study was coordinated by the Italian National Institute of Health and supported by the General Directorate of Medical Devices and the Pharmaceutical Service at the Ministry of Health. We acknowledge the RIPI team (M. Masciocchi and A. Cornacchia) for the administrative management and for the preparation of the database. Also, we acknowledge the experts participating in the RIDIS (G. Barbagallo, P. Berjano, A. Piazzolla, L. Sampaolo, V. Vitiello, G. Zanoli) and RIDEP (G. Calcagnini, F. Censi, M. Ghidina, A. Proclemer, G. Zanotto, M. Zecchin) technical panels.

***Abstract*— This paper relates to projects that are being carried out at the Health Informatics section of the Bioengineering laboratory of the DIBRIS (University of Genoa). The main and unifying aspect of the work in this section is the treatment of clinical data in order to achieve data sets characterized by high quality to support medical research. Specifically, the presented examples are about: an infectious disease network, a natural language processing based pipeline for microbiology and an electronic health record system for cardiology. Methodologically, an attempt has been made to make extensive use of specific standards in order to collect data already widely available the digital format on various platforms, both those already analytically organized and those dispersed in natural language pieces.**

***Keywords*— Standards, Interoperability, Natural language processing, Electronic Health Record.**

I. Introduction

THE work described here relates to projects that are being carried out at the Health Informatics section of the Bioengineering laboratory of the DIBRIS (University of Genoa). The main and unifying aspect of the work in this section is the treatment of clinical data in order to achieve data sets characterized by high quality to support medical research. Specifically, the presented examples are about: an infectious disease network [1], a natural language processing based pipeline for microbiology [2] and an electronic health record system for cardiology [3].

In the last decades evidence-based medicine has emerged as an important aspect of clinical practice and scientific research. Electronic health information collected during health care delivery can help address the need for evidence about effectiveness, safety, and quality of medical care. In order to manage the great amount of data from health facilities and to build clinical pathways research systems and public health management policies software systems play a key role. Often distributed networks that combine information from multiple sources are needed in this respect [4].

A. The Liguria Infectious Disease Network (LIDN)

Clinical data collection - both manual and automatic - from diverse data sets by software systems can support patient care, clinical trials, and secondary use of health records [5]. Web based systems have been set up in order to support data exchange in a great number of fields. Data storing and management systems in many medical domains have been set up by multicentric research networks and management systems [6]. In the last few years many health-related networks have been established [7]–[10].

An integrated system of ad hoc interfaces and tools has been set up for clinical data collection, both manually and automatically, to support patient care, research and clinical trials in the Liguria region in Italy. The initial objective was to develop a web-based tool to allow clinicians to collect and manage data of HIV infected patients for patient care and for research. Subsequently, an automatic data transfer system from the hospitals electronic health records (HER)s towards the LIDN and then from the LIDN towards the national health system.

B. A natural language processing pipeline for microorganisms' data

The COVID-19 pandemic has highlighted to a great extent the widespread increasing circulation of pathogenic microorganisms in hospitals and assisted residences. Hospital acquired infections (HAI) are most frequent and serious problems in healthcare. The identification of a pathogenic microorganism causing HAI allows antibiotic treatment and the adoption of infection-control measures. This information is obtained from culture of specimens from infected body sites, and the outcomes are normally reported in laboratory exams. Multidrug resistant (MDR) organisms are a great problem worldwide [11]. Laboratory information systems (LIS)s have managed laboratory analyses for many years, and individual centres set up their own vocabularies. The need to make results from different laboratories comparable brought about the development of coding systems and standards for terminology management. An international vocabulary which can be applied to clinical and laboratory observations is the Logical Observations Identifiers Names and Codes (LOINC), which is the most widely used terminology standard for health observations, measurements, and documents [12]. The common Terminology Service Release 2 (CTS2) standard [13] is focused on terminology management and originates from the Object Management Group (OMG) and Health Level 7 (HL7).

Microbiology is a highly variable discipline and habits of laboratories are quite different. This originated a contrast between the need for great variability of this field and the mandatory use of LISs, which is imposed by national laws, whose structure may be regarded as too stiff. Therefore, to represent and manage microbiology-related information it is often preferred to use clinical notes written as natural text. Such clinical notes have become an important source of information for patient care and research. On the other hand, the need for manual inspection makes their use expensive in terms of personnel effort and time. The limitations of

information collection in LIS and the advantages of concept representation by domain-specific languages can be addressed by artificial intelligence (AI) tools for natural language processing [14].

An NLP pipeline for automatic information extraction from microbiological notes has been set up.

C. An interoperable EHR system for cardiology

Healthcare is currently changing, and its many features require the availability of a wide range of tools to improve aspects of the professional activity of clinicians by contributing to the achievement of optimal diagnose and therapeutic decisions. The EHR is an essential technology for healthcare [4]. Information and communication technology for health e-Health is being increasingly adopted worldwide. In 2013 a resolution on e-Health standardization and interoperability was adopted, and member states of the World Health Assembly were invited to set up strategic plans for the development of e-health services and infrastructures [5]. Traditional patient records were mostly illness focused, but healthcare is increasingly focused on health from wellness to illness and recovery. EHRs are going to increasingly carry health related information, including images and genomic data [15]. Advantages of EHRs are availability of information, entry controls and increase in data quality by validity checks and conditional data entry [16]. Relevant benefits for care quality have been found. Moreover, HER systems affect costs and efficiency of healthcare systems [17]. Their adoption automates data management and supports care related activities, integrating data for different aspects, including treatment effectiveness, adverse condition reporting and research. Adoption of EHRs can improve quality, safety, and efficiency, even though several challenges still need to be overcome. EHRs represent a great data resource for biomedical research and clinical care [18], [19]. Secondary use of EHRs has been carried out in many areas.

The standardization of medical information is receiving increasing attention. To support the development of interoperable and reliable medical systems several medical standards are used, mainly developed by HL7, such as Clinical Document Architecture (CDA) and others. In 2011 HL7 introduced Fast Healthcare Interoperability Resources (FHIR), which extended the previous HL7 specifications to web technologies. FHIR is being increasingly adopted and is regarded as an emerging standard for health data exchange in many domains, including EHRs.

An interoperable EHR system has been developed for the cardiology wards of two hospitals and has been integrated into the hospital information systems (HIS)s to exchange data with the regional health information infrastructure (RHII). The system has been set up according to HL7 specifications.

II. Methods

A. The LIDN

The architectural development of the LIDN is described in [20]. From a technical point of view the approach is similar to the ones described in [21], [22].

According to the General Data Protection Regulation Requirements only minimal sensitive information was collected (such as for example year of birth, gender and nationality). Moreover, the patient hospital code has been collected, in order to track the patient through different hospitals. If this is the case explicit coordination among clinicians is needed, since the LIDN does not contain any personal information that identifies the patient. The platform has been designed to allow the storage of different types of clinical data by specific entities called events. Each event consists of different categories and each category consists of several parameters. The platform's database has been developed on a Microsoft SQL server, which allows for easy addition of new parameters, categories, and event types. The web – user interface has been developed by the Microsoft.NET framework and page visualization uses Microsoft.ascx templates, which allows dynamical loading of the web pages, achieving a fast personalization of the interfaces. The Clinical Data management system is essential to handle the great amount of data in multicentre networks. For the LIDN laboratory data have been considered in the first place because they are the largest dataset which is used for clinical trials. Two possible scenarios have been considered, taking into account the level of the hospitals that were involved:

1 hospital in which data are not stored in digital format or in which data are stored in digital form but external agents cannot obtain access to data.
2 hospital in which data are stored in digital format and external authorized agents can access specific data subsets.

Hospitals belonging to scenario 1 can manually insert data by a web user interface, while hospitals belonging to scenario 2 can exploit a data reuse paradigm. An automatic transfer of clinical data from each hospital has been set up, according to the availability of services for patients' data and according to national regulations. Laboratory data have been organized in standard documents according to the HL7 Clinical Document Architecture (HL7 v3 CDA r2) guidelines.

An additional feature of the LIDN is the univocal interpretation of clinical data. Each code identifying a laboratory result from the local coding system is mapped to the international vocabulary LOINC. A terminology service supports the mapping between coding systems.

B. A NLP pipeline for microorganisms' data

The pipeline consists of 4 main sections: data preparation, pattern recognition, pattern removal and microorganism detection.

The data preparation section prepares the input values, describes the vocabulary database, and loads and pre-processes the clinical notes. The pattern recognition section converts the textual data into numerical representations and builds three models that foresee if a specific pattern is contained in a clinical note. The pattern removal section considers the sentences that have been identified as containing a specific pattern and removes it. The microorganism detection section extracts from the clinical notes meaningful information, such as for example the microorganism name and whether a microorganism belongs to the dangerous microorganism group).

The sample that was considered derived from LIS of the main hospital of Pescara in Abruzzo region in Italy and was

collected from clinical notes extracted from a one-month collection of anonymized laboratory referrals. It contained 499 texts from culture reports.

The pipeline has been developed in Python language using the Pandas library for data analysis and manipulation[1], the Pyodbc open-source model for accessing databases and the Natural Language Toolkit to perform text analysis [23]. The open-source library SpaCy [24], and the Python module Re, which provides operations for work with regular expressions, have been used. Moreover, Scikit-learn, containing several machine learning algorithms have been also included.

C. An interoperable HER system for cardiology

A modular EHRs has been set up to replace the paper-based system in two hospitals in Genova, in Liguria region in Italy.

Specific aspects of the system that have been developed relate to therapy, referrals, and discharge letter.

As relates to therapy, the hospitals' requirements include ensuring the identity of the prescribing doctor the prescribed drug and the identity of the administering nurse. Moreover, the occurred administration has to be confirmed with a high certainty level.

As relates to referrals, the hospitals' requirements included the availability on a platform of results and diagnostics from other platforms.

As relates to the discharge letter the hospitals required that the main data stored during hospitalization are easily transferred to the discharge letter. The letter must comply with the standards by the Italian government.

The architecture of the EHRS is based is based on central federated databases (one per hospital) and on an interactive web-based platform. The databases have been developed using Microsoft SQL server as Management system, implemented with Visual Studio through NET framework, and deployed on the internet information system. A corporate regional/national health information infrastructure (HII) provides timely health information and facilitates communication mostly among healthcare professionals and public health professionals. To warrant interoperability the HII uses standards and integrates systems, applications and technologies for personalised health. Italian regions have developed their own HIIs, but they adopted architectures based on an institutional centred approach. Since the health records are not centrally stored, at least one central index is needed, by which the information on a particular patient can be extracted. When a patient data is requested, the index is used to query the repository where the stored information is located, and the complete patient record data is produced.

An architecture has been developed to integrate a routinely used cardiology EHRS into the RHII system of Liguria region. All documents of the RHII are given as HL7 CDA and messages are sent as HL7 v2 and / or HL7 FHIR. All external interfaces of the CEHRS have been designed according to a service-oriented approach on the Healthcare Services Specification project that uses CDA, v2 and FHIR [25]. In order to obtain a fully interoperable system as defined by the Clinical Data Interchange Standards Consortium the CEHRS can be interfaced with a terminology service [20].

[1] https://pandas.pydata.org/

III. Results

A. The LIDN

At present the LIDN involves the infectious diseases departments of six hospitals and is open to extra regional collaborations on specific projects. Currently data coming from two hospitals in Piemonte region are also present. In the LIDN three hospitals belong to scenario 2, the others belong to scenario 1. These three hospitals have different types of information systems, so three solutions have been developed to enable the sharing of clinical data. Currently, more than 8000 patients have been or are under treatment for at least one infectious disease among human immunodeficiency virus (HIV), hepatitis C virus, severe acute respiratory syndrome coronavirus 2 and tuberculosis. Automatic data transfer has had a great impact on the presence of laboratory tests in the three hospitals belonging to scenario 2. The differences between automatic and manual scoring have been quantitatively evaluated considering the cumulative number of laboratory tests per year and the mean number of parameters collected per single laboratory.

B. A NLP pipeline for microorganisms' data.

The main results relate to the identification and removal of a specific pattern, to the Genus extraction and to the microorganism detection. As relates to the identification and removal of a specific pattern. The best results that have been obtained are in terms of mean accuracy across classifiers (99.06 %). The SVM classifier with a Gaussian kernel obtained a mean accuracy of 98,99 %, the LR classifier obtained a mean accuracy of 98,99 %, and the RF classifier obtained a mean accuracy of 99,19 %. Therefore, the pattern was completely identified using all classifiers, and can be securely removed from the clinical notes.

As relates to genus extension the sample of clinical notes contained a total number of 107 abbreviated genera followed by their species. Processing of the notes has shown that all 107 genera were extended. This completely matched with the expert indications.

As relates to microorganism detection, the sample of clinical notes was composed of 499 texts and 276 of them presented the name of a microorganism. Two tests were carried out. First the entire sample was introduced into the module for microorganism extraction, then only the notes that contained the names of the microorganisms have been introduced. The system correctly identified all microorganism names in both cases.

C. An interoperable EHR system for cardiology

The CEHRS has been adopted in two hospitals in Genova: Villa Scassi (VS) since 2018 and Padre Antero Micone (PAM)since May 2021.

The specific needs of the cardiology staff as relates to storage stability and responsibility attribution have been taken into account, while retaining the confidence of the staff in the paper system, which has been used for many years. The system that has been set up satisfies these needs using the database systems and the authentication systems of both hospitals. The

design features of the EHR guarantee both storage stability and v responsibility attribution. For any stored information the staff member who stored or modified or cancelled it can be known. These features have been obtained by an architecture that is commonly adopted in many hospitals. An additional need has been interoperability with other hospitals and local medical informatics applications – a feature which is present only to a small extent in commercial EHRSs.

The development of the CEHRS has started at the beginning of 2018 with a very close. interaction between software developers and physicians. In December 2018 the CEHRS has been adopted on an experimental basis but has immediately become the only software support of the cardiology ward. In October 2020 the experimental phase has been completed, the CEHRS has been adopted has become the only official health record of the cardiology ward. In May 2021 the CEHRS has also been adopted in the cardiology ward of PAM.

IV. Conclusion

A. The LIDN

This work has involved professionals form various fields for more than 10 years, with the main aim to support patient care, clinical trials and research on infectious diseases. A modular system has been developed to respond to specific needs for infectious diseases, such as for example the COVID-19 pandemics.

B. A NLP pipeline for microorganisms' data

The main result of this work is the development of an NLP pipeline to support the automatic extraction of microorganisms' names and relevant information which is contained in microbiological notes of culture reports. A future step will be the automatic extraction of the antibiogram data from the clinical notes. In this respect, key information is the sensitivity of each microorganism to each antibiotic.

C. An interoperable EHR system for cardiology

In the future the high analytical capacity of the CEHRS will enable the secondary use of EHRs for clinical trials, for clinical studies and for the development of clinical decision support systems. The ability to use all EHR parts based on natural language (anamnesis, clinical diary and hospital discharge letter) for research is an important aspect. In this respect, the interoperability features of the EHR can interface effectively with terminology management systems and with natural language processing systems.

***Abstract*— Low medication adherence is identified as one of the main issues for increased morbidity and mortality in chronic patients. Smart Virtual Assistants (SVA) devices are becoming increasingly common in households, enabling the possibility of using vocal commands to interact with active solutions to non-adherence. Thus, the aim of this study was to evaluate the usability of commercially available SVA devices to support medication adherence in chronic patients. A skill was developed for the most common commercially available SVA environment (Amazon Alexa), together with a cloud database and a connected online dashboard. Each enrolled participant answered the eHealth Literacy Scale (IT-eHEALS) questionnaire and to a question on perceived adherence, then the prescribed medications were inserted into the online dashboard and linked to their SVA device account at home, thus automatically setting reminders at the proper time and 25 minutes later. A 30-minute interval after each reminder was allowed to vocally confirm to the SVA the medicine intake. After seven days, participants participated in a semi-structured interview including the System Usability Scale (SUS) questionnaire. Eleven subjects (7M, 4F, median age 52 (IQR = 13.5) years old) participated in the study. IT-eHEALS scores ranged from 20 to 40. Overall, low adherence to therapy was identified before the experiment. Post-experiment SUS questionnaire resulted in median score of 77.5 (IQR = 11.25).**

Participants were very satisfied with the usability of the developed skill. The high SUS score demonstrates how SVA devices could be perceived as effective, interactive and easy-to-use tools to support medication adherence. Further studies are required to improve the developed skill and quantify its ability to effectively increase adherence in chronic patients.

***Keywords*—Medication adherence, Smart Virtual Assistants, eHealth, mHealth, Telemedicine.**

I. Introduction

The World Health Organization (WHO) has identified low medication adherence as a global concern that poses a significant challenge to the healthcare system. This issue results in increased morbidity and mortality among patients suffering from chronic illnesses [1]. Studies have demonstrated that medication adherence in chronic patients in developed countries averages around 50% after one year of treatment. Furthermore, low medication adherence is a leading factor to hospital admissions and elevated healthcare costs [2], and requires techniques and solutions tailored towards patients to be overcome [3]. Forgetfulness and polypharmacy, defined as the administration of multiple drugs at the same time, are associated with lower quality of life and are some of the main factors in low adherence in chronic patients [4].

Smart Voice Assistants (SVA) are artificial intelligence (AI) systems that allow users to interact with them using voice commands. Examples of such devices include Amazon Alexa and Google Assistant, which can perform a variety of tasks, including setting reminders, playing music, answering questions, and controlling smart home devices. Their popularity has been increasing in recent years, with 30 million units sold in the United States alone by the end of 2020 and a market that continues to grow rapidly [5]. In the healthcare context, SVA devices have the potential to support medication adherence by providing reminders, tracking medication intake, and offering personalized feedback and support. Recent studies have also demonstrated that these devices can effectively streamline data collection across various contexts and could be used to diagnose and monitor chronic conditions, greatly reducing time and cost requirements [6].

Thus, the aim of this preliminary work was to evaluate the usability of the most common SVA device commercially available on the market (Amazon Alexa) to support medication adherence in chronic patients.

II. Materials and Methods

A. Platform structure

The developed platform was based on a three-tier architecture (data – application – presentation) [7], used to identify and separate the various components, as well as to follow the single responsibility principle [8]. Figure 1 presents the elements and frameworks used to create the platform.

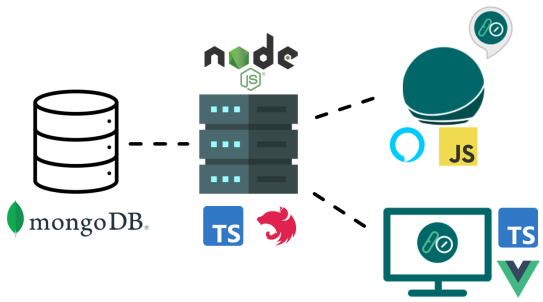

Fig. 1: Three tier architecture of the developed platform. On the left the data tier, in the center the application tier and on the right the two modules concerning the presentation tier. Logos around each element represent languages and frameworks used for their development.

In the data tier, a cloud server was established using a NoSQL database management system. This approach was chosen due to the inherent capabilities of non-relational databases., that do not necessitate strict constraints and schemas, thus enabling greater flexibility in data structure, augmented scalability of the developed system, and improved efficiency in executing queries. [9]

The application tier was developed using the NodeJS and NEST frameworks. It was composed of a series of modular, independent components, including providers and controllers, that receive input from the presentation tier applications, perform logical operations, and facilitate communications with the underlying data tier.

Regarding the presentation tier (i.e., all applications that allow users to interact with the system), two modules were developed: an online dashboard and a skill for the Amazon Alexa environment.

The online dashboard was developed using the VUE framework, defining a single-page interactive application for patients. It allowed users to log in using private credentials and enter their own prescriptions. Prescriptions were formulated by the medication's name, the corresponding dosage, the designated time of intake, and any relevant instructions (i.e,, before, during, after meals). The system allowed programming for all types of therapies: daily, weekly, only on specific days or for a set number of intakes. Users could also access their own data and adherence statistics, both global or associated with only one medication. Through the online dashboard, data was sent to the cloud database via secure HTTPS communication.

The skill was developed for the Amazon Alexa environment, with the aim of providing an interface for patients to assist them in managing their treatment plan. The online dashboard generated a temporary One Time Password (OTP) to securely connect a user's Alexa device with their cloud-stored data. Reminders on the device were configured according to the prescriptions entered into the online dashboard.

The skill included a vocal reminder feature which prompted the user to confirm medication intake when activated. The reminder was designed to verbally state the medication name, dosage, and any associated instructions regarding meals. It also provided a 30-minute window around the scheduled medication intake time: if the medication was taken before the designated time, but not earlier than 30 minutes prior, the corresponding reminder was not sent to the user. Additionally, a second reminder was issued 25 minutes after the first one, in case of no confirmation. These timeframes were decided with the aid of domain experts. Once the medication intake was vocally confirmed, the information was transmitted to the cloud database, along with the time of intake. If no confirmation was received within 30 minutes of the initial reminder, the intake was recorded as missed and could not be modified.

Users could communicate with the skill through set phrases, and their response, or lack thereof, was stored in the database and used to update adherence statistics, accessible either through the online dashboard or the Alexa device.

B. *Study protocol*

The initial usability of the developed skill was tested through a protocol approved by the ethical committee of Politecnico di Milano (45/2021). Participants were enrolled on a voluntary basis, with the requirements of having a stable WiFi connection at home, being previously diagnosed with a chronic disease and taking at least one medication per day. They were asked to install the skill on their own devices, or were provided with a device if they did not have one. Additionally, before the experiment, they were then asked to input their therapies in the online dashboard, complete the Italian version of the eHealth Literacy Scale (IT-eHEALS) [10, 11] questionnaire, which measures health and digital literacy, and answer a question related to their perceived adherence (low, medium or high). Personal data of participants was pseudonymised and kept in a separate server from the cloud database. Volunteers were guided step-by-step through the configuration of the skill and were given instructions on how to operate with it.

During the 7-days test, participants were able to explore all the functionalities of the skill and monitor their own adherence. At the end of the 7-days, they were asked to complete the Italian version of the System Usability Scale (SUS) [12, 13] questionnaire and participate to a semi-structured interview developed ad-hoc for this study to assess the perceived usability, performance, strong and weak points of the skill. The study population consisted of 11 volunteers, 7 (64%) men and 4 (36%) women, with a median age of 52 (IQR = 13.5) years old, that met all predetermined inclusion criteria and gave informed consent for the use of their data.

III. RESULTS

A. *IT-eHEALS and adherence*

Table 1 presents the results concerning all the participants involved in the study of the IT-eHEALS questionnaire, perceived adherence and the percentage of adherence registered by the system computed over all therapies, for the 7-days experiment. As regards the IT-eHEALTS, five participants reached the maximum level or one point below, two scored in the 30-32 range, and four scored in the 20-23 range. Perceived adherence was low for eight subjects (73%), medium in two, and high in one.

TABLE I: AGE, IT-EHEALS, PERCEIVED ADHERENCE BEFORE THE EXPERIMENT AND PERCENTAGE OF ADHERENCE DURING THE EXPERIMENT REGARDING THE 11 PARTICIPANTS IN THE STUDY.

Participant	*Age*	*IT-eHEALS (min: 8; max: 40)*	*Perceived adherence (low, medium, high)*	*Adherence during the experiment (%)*
A	47	40	Low	85.71 %
B	66	20	Medium	100%
C	61	22	Low	100%
D	43	21	Low	85.71%
E	75	40	Low	75%
F	31	40	Low	57.14%
G	46	39	Low	90.65%
H	52	39	High	100%
I	56	31	Medium	75%
J	56	32	Low	71.42%
K	44	23	Low	70.83%

During the experiment, adherence was calculated separately for each therapy and defined as the % of confirmed intakes over the total number of prescribed doses over the 7-day period. If the participant had more than one therapy, the final score was obtained by averaging the adherence % of all

TABLE 2: SYSTEM USABILITY SCALE SCORES REGARDING THE 11 PARTICIPANTS IN THE STUDY. EACH ROW REPRESENTS A QUESTION IN THE QUESTIONNAIRE, WHILE EACH COLUMN REPRESENTS A PARTICIPANT AND THE FINAL ROW IS THE SUS TOTAL SCORE FOR EACH PARTICIPANT. ALL QUESTIONS RANGE FROM 1 (STRONGLY DISAGREE) TO 5 (STRONGLY AGREE), WHILE THE TOTAL SCORE RANGES FROM 0 TO 100.

Participant	*A*	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*I*	*J*	*K*	*Question median value*
1. I think that I would like to use this system frequently	5	4	4	5	2	5	5	4	4	4	4	4
2. I found the system unnecessarily complex	2	1	1	1	1	1	4	4	2	1	1	1
3. I thought the system was easy to use	4	4	5	5	3	4	2	3	4	4	5	4
4. I think that I would need the support of a technical person to be able to use the system	1	3	2	1	1	1	1	2	1	4	1	1
5. I found the various functions in the system were well integrated	4	3	5	5	3	4	4	3	3	3	3	3
6. I thought there was too much inconsistency in the system.	2	1	1	1	2	1	2	1	4	1	1	1
7. I would imagine that most people would learn to use this system very quickly	5	4	5	4	4	4	3	3	5	5	4	4
8. I found the system very cumbersome to use	3	1	2	1	2	1	1	2	2	1	1	1
9. I felt very confident using the system	4	3	5	5	5	5	5	4	4	4	3	4
10. I needed to learn a lot of things before I could get going with this system	2	1	1	1	1	1	1	2	2	3	3	1
SUS Total Score	80	77.5	92.5	97.5	75	92.5	75	65	72.5	75	80	

therapies. The resulting median adherence among the eleven participants was 80.35% (IQR = 21.72%), which indicates an improvement compared to the perceived adherence initially reported in the questionnaire.

B. System Usability Scale

The results of the SUS questionnaire are presented in Table 2. The median score was 77.5 (IQR = 11.25). Only 1/11 participants reported a value below 68, defined in literature as the threshold defining the positive usability of a system [14]. Scores for SUS questions range from 1 (strongly disagree) to 5 (strongly agree), with questions formulated alternatively with a positive and negative connotation to reduce bias in responses [12]. For questions 1, 3, 7, and 9 (i.e., positively formulated), the median value of the answers was 4, one point below the maximum value attainable. Only for the positively formulated question 5, to assess whether the user found the various functions in the system well-integrated, the median value across all participants was 3. For questions 2, 4, 6, 8, and 10 (i.e, negatively formulated), the median value aligned with the minimum score, representing the ideal answer for such questions. The final score was calculated using the formulae defined in current literature [12].

The results of the semi-structured interview can be divided into four macro-groups, according to the questions' theme: setup configuration, skill usage, Alexa device and perceived adherence.

Concerning setup configuration, 9/11 participants reported that the initial configuration was easy to perform. The setup included verbally inputting the OTP and completing the step-by-step vocal confirmations required by the Alexa device to configure the therapies.

Regarding skill usage, only 2/11 participants reported partial dissatisfaction with the skill, while all other participants reported partial or complete satisfaction. Seven participants felt the proposed system as not intrusive into their personal lives. One participant suggested that there was no need to repeat the dosage with every notification, while two found the notifications to be too repetitive. Positive aspects of the system included the automated reminder setting, the ability to communicate via voice, and the ability to use the skill from the Alexa application on smartphones, when out of home. The repetition of the notification 25 minutes after the first one was positively received by 8/11 participants, while two found it not required and one found it intrusive. Four participants felt that the 30-minute range around the set time for the intake was too short. Finally, 8/11 participants reported some initial difficulties in communicating with the skill due to the complexity of the sentences that needed to be used.

Regarding the usage of the Alexa device in general, both participants who were already using the device and those who did not use it previously reported interest in using it as a support for adherence, with10/11 participants stating that they would also be interested in using it for other purposes. With respect to perceived adherence, 7/11 participants reported perceiving increased medication adherence thanks to the skill, while 4/11 reported no perceived improvement.

IV. DISCUSSION

In this study an initial usability test was performed to assess the feasibility of using SVA devices, such as Amazon Alexa, to support medication adherence in chronic patients.

The developed skill is designed to align with and to incorporate certain strategies from the persuasive system design model [15]: specifically, the emphasis was placed on ensuring unobtrusiveness in daily activities and transparency of intent. Additionally, other strategies such as complexity reduction, implemented through fast and secure configuration, tunnelling, customization and self-monitoring, were incorporated into the development of the skill [16].

The population studied, ranging from 32 to 75 years old with a prevalence in the 40-60 years old range, is a good representation of what would be the target users of the skill, where the prevalence of chronic illnesses increases with age [17].

The results of the IT-eHEALS questionnaire indicate that most participants considered themselves capable of using

digital technology for their healthcare needs, while others reported some difficulties in usage of such technology for health or lack of trust in the information received through such means. No correlation (Spearman's correlation) was found between the initial results of IT-eHEALS and the results of the SUS questionnaire (s = -0.232, p = 0.4913) [18].

The obtained scores in the SUS questionnaire indicate that the skill was considered usable, unobtrusive, and not interfering with everyday life. Based on the median responses to each question, participants expressed interest in frequently using the skill, found it easy to use and not complex, and did not feel that technical assistance was necessary for its use. They also considered the skill consistent and easy to learn. However, the worst score (3 out of 5) was obtained for question 5, suggesting that improvements are needed in the implementation of certain features of the skill. Similar concerns were also raised in the semi-structured interview, where participants expressed doubts about specific features and functionalities that should be modified or improved: in particular, participants reported that the adherence information obtained through the skill was not particularly useful or engaging. However, it is worth noting that the limited duration of the 7-day usability test may have contributed to this perception.

Nevertheless, medication adherence estimated through the system showed improvements over the initial perceived adherence by the participants. In fact, the median adherence over the eleven participants (80.35%) is larger when compared to the average adherence in chronic patients in developed countries reported by WHO (50%) [2], confirming the constant participation throughout the test period for most participants and a potential positive effect in increasing adherence throughout the use of such SVA technology. The concordance between the estimated adherence and the SUS scores confirmed further the usability of the skill to support medication adherence.

The trial period of 7 days was too short to draw definitive conclusions about the skill's ability to increase medication adherence, even though preliminary results suggest a positive trend. The main concerns raised by participants in the semi-structured interview were related to the activation phrases required by Amazon Alexa, which were perceived as being too complex in Italian. This limitation can only be partially addressed as it conflicts with Amazon Alexa's guidelines for skill design, suggesting that other voice assistant devices should also be explored. Furthermore, the 30-minute window around the set time to confirm medication intake was considered too narrow by the participants. In future developments, it is suggested that this window could be tailored for each medication in consultation with the healthcare practitioner. However, it is important to note that in this test no doctor was involved and the configuration was standardized for all subjects, while in the final version the central role of the physicians in the configuration phase is expected.

V. CONCLUSIONS

The aim of this study is to assess the usability of a skill developed for the Amazon Alexa SVA to support medication adherence in chronic patients. Very high SUS results and patient satisfaction showed that the developed skill can be used to such objective, without requiring particularly high eHealth literacy or technical knowledge. Further studies are required to assess the effects of the skill in increasing medication adherence, to improve features deemed not interesting and to further simplify its usage.

***Abstract*—Atrial fibrillation (AF) is one of the most prevalent arrhythmias encountered in cardiological practice; it is a leading cause of stroke and heart failure and has a growing financial impact on the healthcare system. The aim of this study is to test the efficacy of deep learning in predicting AF. Early diagnosis can improve patients quality of life, reduce hospitalizations and minimize the financial impact on the health care system. Two methods for automatically predicting AF based on Convolutional Neural Networks (CNN) are proposed. The first model is characterized by a one-dimensional (1D) CNN network that takes, directly, electrocardiogram (ECG) signals as input, while the second model consists of a two dimensional (2D) CNN network that inputs image data corresponding to the numerical values of the most important events associated with each ECG waveform. The 1D-CNN model achieved an accuracy of 71.69%, while the 2D-CNN model reached 76.19%. The second method, in addition of being a novel approach to classification problem, reached a good score in predicting the outcome of atrial fibrillation.**

I. INTRODUCTION

An arrhythmia is an alteration of the regularity of heartbeat. one of the most common types of arrhythmia is AF, it is characterized by the lack of atrial synchronization that make atrial contraction ineffective[1]. The incidence increases exponentially with age and the effects increase the risk of developing other cardiac problems[1], [2], [3]. This condition is caused by an abnormal sinus rhythm which results in an irregular heartbeat. The presence of AF can produce, often, several important adverse health outcomes including stroke and heart failure[4], [5]. The economic and clinical burden of AF is mainly due to repeated hospitalizations and healthcare service utilization. Therefore, the prediction of AF is significant clinically and economically[6], [7]. As reported by *'Velleca et al.'* [8], in Italy, France, Germany and England alone, more than 11 million patients are affected by this disease, with an average annual cost between 660 and 3,286 million euros.

The visual representation of the heart activity is fundamental to highlight eventual abnormalities in the cardiac rhythm and stimulus propagation. The diagnosis is usually carried out by mean of a long-term ECG that is collected using cardiac monitoring devices, such as the Holter monitor[1]. An ECG waveform characterized by the absence of a clear P wave and an abnormal pattern of the R-R interval shows the presence of AF (Fig.1). Traditionally, abnormalities in an ECG waveform are identified through visual inspection by expert cardiologists. This process is effective only if executed by trained personnel[1] and can be time consuming. The aim of this study is to realize an automated method that provide a prediction of AF, in order to reduce the time required for the diagnosis and the dependence from expert personnel. To achieve this objective, deep learning models based on CNNs were developed. CNNs are widely used both in the analysis of ECG signals[9], [10], for the detection[11], [12], [13] and prediction[14], [15] of AF. In this work, two CNN models were developed. The first model is a 1D-CNN that takes ECG signals as input. In the second model, the numerical values of the most relevant features of the ECG signal were transformed and used as input to a 2D-CNN[16]. In both cases the output is a binary output, where one value represent the risk of developing AF, while the other suggest the absence of such a risk.

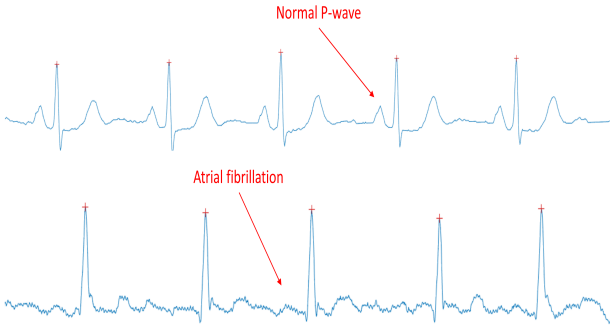

Fig. 1: Normal ECG vs AF ECG

II. METHODS

For the realization of the models, we developed, starting from a database of holter recordings, two pipelines for the pre-processing of data, the realization of CNNs structure and, finally, for the test phase. The overall process was carried out using Python as programming language.

A. Creation of database

The creation of the dataset was made possible thanks to an established collaboration with "USL Toscana centro", in particular with the department of cardiology at the Santa Maria Nuova Hospital (Florence). The clinicians of the structure provided us with the requested, anonymized, database. Summarily, 608 patients who underwent a Holter examination were analyzed. Of these initial number, eligible patients were selected based on:

- Development of at least one episode of AF within three years of the Holter examination.
- Absence of AF within three years of the Holter examination.

Ineligible subjects were those who:

- Had AF during the Holter examination.
- Did not have enough follow-up.
- Had developed AF following surgery.

After the application of the selection criteria, a new database of 134 subjects was created, consisting of 52 patients who developed AF in the three years following the Holter examination, and 82 subjects who did not develop AF in the three years following the analysis. Ethical review and approval were waived for this study due to the fact that there was no deviation from the patient's "normal care" who had provided consent for the management of personal data.

B. 1D-CNN model

The first model proposed for the prediction of AF consists of a 1D-CNN that takes directly the ECG signals as input. The labels associated with each subject were binary, where a 1 represent the future development of AF and 0 the opposite. This model architecture is shown in Table I. Next, The model was trained using K-fold cross validation, with the training parameters shown in Table II.

TABLE I: Structure of the 1D-CNN model.

Layers	Parameters	Activation
Conv1D	Filters 32 / Kernel 5	ReLu
MaxPooling	2

Conv1D	Filters 128 / Kernel 5	ReLu
MaxPooling	2	
Dropout	0.5	
Flatten		
Dense	128	ReLu
Dropout	0.5	
Dense	32	ReLu
Dense	2	SoftMax

The flowchart followed for the data processing and the testing phase of the 1D-CNN model is reported in Fig.2.
For each patient, three-lead Holter ECG signals with a sampling rate of 200Hz and a duration of three minutes were selected. The selection was done manually paying attention to select good quality signal that belongs to the same time span.

TABLE II: Training parameters of the 1D-CNN.

Training parameters	Values
Number of K-fold	10
Epochs	200
Early stopping	30
Optimizer	Adam
Learning rate	0.001
Loss function	Categorical crossentropy

The selected ECG signals were divided into five seconds windows, allowing to increase the dimension of the dataset which, after this process, was composed of 4,068 records.

Of the whole dataset, 85% was used as the training set while the remaining 15% was used for the test set. During the splitting process care has been taken in keeping data from the same patient in the same division to avoid a bias in the model. Among the iterations of k-fold validation we selected the best model that has been, then, evaluated on the test set.

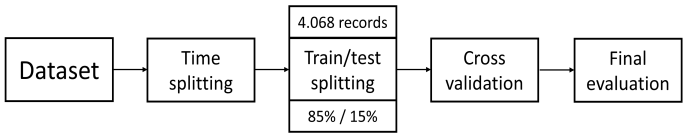

Fig. 2: Flow chart of data processing and testing of the 1D-CNN model.

C. 2D-CNN model

For the creation of the second model, we took inspiration from the work done in[16] in which the authors describe a method that allows numerical features to be transformed into images, for the purpose of serving as inputs for 2D-CNN networks. In this particular implementation, the model architecture is reported in Table III. The training phase was carried out with the parameters shown in Table IV.

TABLE III: Structure of the 2D-CNN model.

Respect to the one applied in the first phase, the flowchart for the second phase, reported in Fig.3, has more preprocessing operations and data manipulation, moreover the starting data was composed by vectors of features instead of ECG signals.

1) The dataset:

TABLE IV: Training parameters of the 2D-CNN.

Training parameters	Values
Epochs	200
Early stopping	30
Optimizer	Adam
Learning rate	0.001
Loss function	Categorical crossentropy

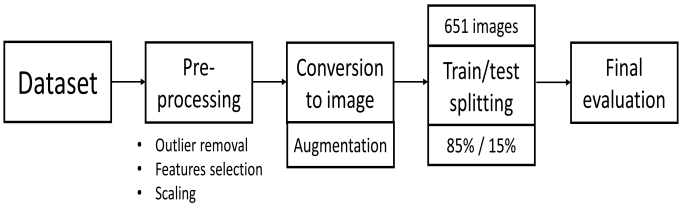

Fig. 3: Flow chart of data processing and testing of the 2D-CNN model

The second dataset was composed by numeric features, representative of the most important characteristic of the considered ECG track. Heart rate-related values and RR interval features were selected to represent each subject.

2) Data pre-processing:
Subject removal based on the absence of one or more of the following parameters:
   - Maximum, average and minimum heart rate during the whole recording.
   - Average heart rate.
   - Minimum and maximum value of the RR interval.

   Secondly, the most relevant features, i.e. those most frequently reported for each patient, were selected. These include all aforementioned parameters as well as the Ventricular (BEV) and supraventricular extrasystoles (BESV). Finally, the values of selected fundamental parameters were scaled between zero and one in order to prepare for the next stage of greyscale image creation.
3) Feature transformation:
The selected, and scaled, feature was transformed into an image. A grid composed of nine sections was created and filled with the selected features. Consequently, a black and white image was created from the grid, with the intensity of each portion depending on the value of each specific feature, as reported in Fig.4
4) Data augmentation:
The data augmentation phase was characterized by rotation operations and various small translations, in order to increase the number of images present in the dataset.
5) Training and test sets:
A final dataset of 651 images was obtained. As previously stated, the whole dataset were splitted in train and test set, whilst also ensuring that the subjects present in the training set were different from those in the test set.
6) Evaluation:
The 2D-CNN model was trained and then evaluated on the test set to check its performance.

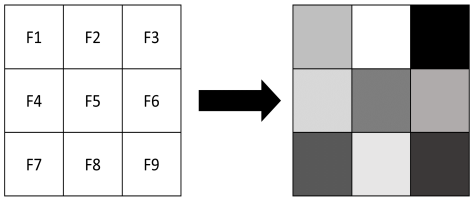

Fig. 4: Schematic representation of the process of transforming features into images

III. Results

The results obtained from the two proposed models have been evaluated using confusion matrices. For the 1D-CNN model, a good convergent behaviour is observed throughout the training, showing an increase in accuracy and a decrease in loss over time. The results on the test set are shown in the confusion matrix in Fig.5. The system showed 71.693% accuracy, 61.077% precision, 70.833% sensitivity, and 72.222% specificity.

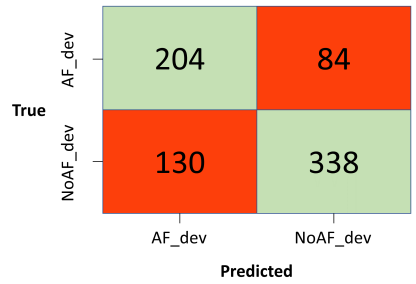

Fig. 5: Confusion Matrix of 1D-CNN model classification on test set

Similarly for the 2D-CNN model, a good behavior characterized by an increase in accuracy and a decrease in loss was observed throughout the training. The results of the test set are displayed in the corresponding confusion matrix in Fig.6. Here, the system achieved an accuracy of 76.190%, 68.627% precision, 71.428% sensitivity, and 79.221% specificity. Comparison of obtained results for the two models is shown in Table V.

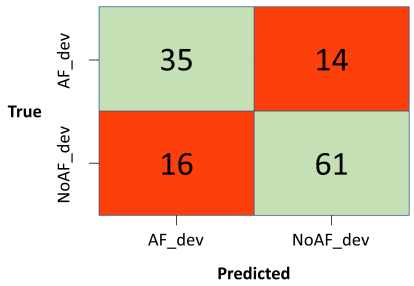

Fig. 6: Confusion Matrix of 2D-CNN model classification on test set

IV. Discussion

In this work, two methods are proposed to provide an early prediction of AF, in order to improve the quality of life of

TABLE V: Comparison between the two proposed models.

Model	Accuracy	Precision	Sensitivity	Specificity
1D-CNN	71.693	61,077	70.833	72.222
2D-CNN	76.190	68.627	71.428	79.221

subjects, reduce hospitalizations and decrease the economic impact on the health system. In particular, for this task, two new datasets were created: the first one was composed of ECG signals obtained from individual patients, while the second one was characterized by a numerical dataset containing the values of the most relevant events occurring during a Holter analysis. These datasets were tested with various models in varying configurations. Specifically, a 1D-CNN network for the dataset composed of ECG signals and a 2D-CNN network for the other composed of numerical features. Respect to similar works, the presented results are comparable to many recent papers and have the potential to grow even more. In [14] the authors obtained a less smaller sensitivity, but using a way bigger dataset and limiting the event time at one year. Using a 1D-CNN the authors of [15] reached more than 98% of accuracy, but with a smaller number of instances. The topic of AF prediction is a growing field of interest given the importance of anticipating such events. A recent review reports that machine learning is a good tool to be exploited[17]; however, the high variability between the size, type and processing of data, makes hard to compare different models directly. It is certain that the direction of the literature push toward the realization of more studies dealing with this problem.

The main contribution of our proposed models is that they showed good accuracy, comparable with other approaches from the literature, with the following pros:

1) Using a small fraction of an ECG Holter.
2) Exploiting an unconventional model by means of a novel technique.

The limitations of the study are represented by the size of data, which needs to be improved to confirm the quality of the models, and the limited amount of computing power that reduced the potential pool of testable models. The selection criteria restricted the pool of available data, but was mandatory due to the defined objectives. Given these reasons, one of the future goals is to increase the number of patients present in the current datasets. In this way, more robust and generalizable results could be achieved. Moreover, different type of networks and a higher number of parameters could be tested and optimized, exploiting also techniques like transfer learning.

The exploration of novel techniques in growing, important, fields like the prediction of AF development, is fundamental to improve the quality and quantity of available tools that have the potential of reducing the burden of disabling disease, both in terms of life quality, for the patients, and in terms of expenses charged on the healthcare system.

Health Information Technology Adverse Events Identification and Classification with Natural Language Processing and Deep Learning

A. Luschi[1], P. Nesi[1], and E. Iadanza[2]
[1] *Department of Information Engineering, University of Florence, Italy*
[2] *Department of Medical Biotechnologies, University of Siena, Italy*

***Abstract*—The main topic of this work is to develop a framework to extract Real-World Evidence through Natural Language Processing (NLP) and Neural Networks. An initial literature analysis has been performed, from which it clearly emerges that adverse events concerning Health Information Technology (HIT) are gradually growing over time. The goal of the proposed framework is to automatically identify adverse event reports related to HIT, aiming to support Health Technology Assessment and Post Market Surveillance as outlined in European Regulation 2017/745 on Medical Devices. The designed model uses a pre-trained version of ClinicalBERT, additionally fine-tuned on 3,705 adverse events reports extracted from the FDA MAUDE database, which had been previously manually labelled by experts. Results show better metrics than other existing HIT adverse events reports text classifiers based on non-BERT models, performing with an accuracy of 0.9906, precision of 0.9840, recall of 0.9973, and F1 score of 0.9906.**

***Keywords*—natural language processing, deep learning, HTA, medical devices.**

I. INTRODUCTION

Lexicon-based approaches are not well suited for capturing the meanings in medical texts and ML methods have been shown to be more effective [1], [2]. The majority of the studies reviewed used ML methods such as Support Vector Machines (SVM), Naive-Bayes, and regression trees, and features such as POS tagging, TD-IDF, BTO, and Word2Vec [3], [4]. Recent works have demonstrated the effectiveness of deep learning models such as Transformers, specifically BERT (Bidirectional Encoder Representations from Transformers) [5] and GPT (Generative Pre-trained Transformer) [6], in solving NLP and biomedical causal relation extraction tasks. Additionally, these models have been fine-tuned to improve performance on specific language tasks and biomedical and clinical text information. BERT-based models, such as SciBERT [7], BioBERT [8], and ClinicalBERT [9], that have been proposed by biomedical and clinical NLP community researchers, process biomedical and clinical text information more effectively and efficiently. This work aims to develop a framework to support Health Technology Assessment (HTA) through the use of Natural Language Processing (NLP) and Neural Networks. HTA is used to provide reliable and timely information on developed devices, medicines, vaccines, procedures and systems to solve health problems and improve quality of life. Real-World Data (RWD) can be used to generate Real-World Evidence (RWE) to assess the effectiveness and safety of a given health technology in a real-world setting. Medical RWD can come from various sources, such as Electronic Health Records (EHR), Computerized Maintenance Management Systems (CMMS) [10], Spontaneous Reporting Systems (SRS), and other clinical sources [11]. Studies have found that computer-related recalls, particularly software faults, have been a significant contributor to medical device recalls and have resulted in serious injury or death [12]. Studies on Health Information Technologies (HIT) failure [13] show that from January 2008 to July 2010, there were 678 reports of 436 different adverse medical device events associated with HIT. Most of the 46 events associated with patient harm were related to the computerized physician order entry and picture archiving and communication systems. Studies have also reported a constant increase in software failure in HIT over the years (Figure 1) [14].

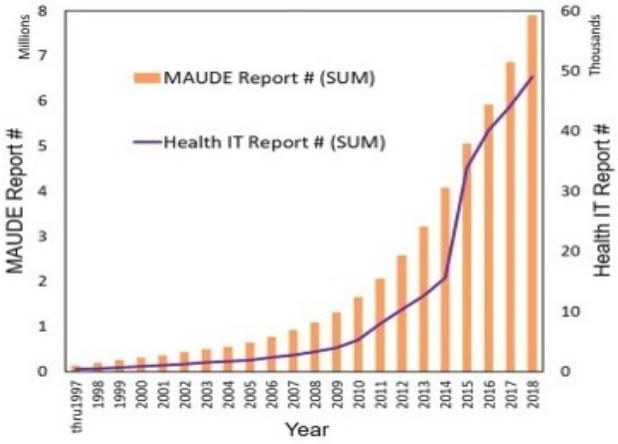

Fig. 1: HIT-related adverse events extracted from MAUDE database up to 2018 [14].

NLP and Machine Learning/Deep Learning techniques are used to extract structured data from SRS databases, which is significant for fulfilling legal obligations regarding Post Market Surveillance (PMS) as outlined in European Regulation 2017/745 on Medical Devices. This includes the continuous analysis of safety signals that emerge from the adverse events of medical devices available on the market. RWE is also useful for market evaluations, analysing faults, planning updates and

interventions, and avoiding recalls by authorities. Decision support techniques such as Multi-Criteria Decision Analysis (MCDA) or Analytic Hierarchy Process (AHP) can also be applied to obtain RWE on different aspects of different health technologies, in order to provide innovation in assessment for public international institutions and authorities, such as the World Health Organization or public health. To achieve this goal, data from the FDA MAUDE database was used and labelled by experts in HIT/non-HIT adverse events. The data was used to fine-tune a pre-trained ClinicalBERT model for binary text classification, which was then validated through a 10-fold validation process and tested against a subset of records to assess its performance.

II. MATERIALS AND METHODS

A. Proposed framework

The proposed framework is illustrated in Figure 2. Input data can originate from different sources (CMMS, SRS, EHR), even though at the moment the only analysed domain is the FDA MAUDE database of adverse event reports. HitBERT module is a ClinicalBERT model fine-tuned with adverse events reports originating from the MAUDE database, which had been manual-labelled by experts [15]. Text classification performs binary classification between HIT and non-HIT reports.

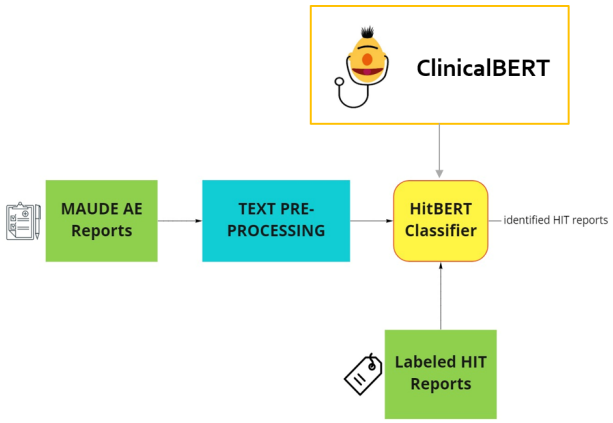

Fig. 2: Proposed framework.

B. Dataset

1,857 reports extracted from the FDA MAUDE were labelled as HIT-related between January, 1st 2008 and June, 30th 2010. The remaining 513,183 reports were identified as non-HIT in the same period. 1,848 reports have been randomly sampled from the non-HIT dataset in order to build a balanced training dataset for the BERT classifier. The combined 3,705 reports have been used for training, evaluation and testing. 20% of the whole dataset has been used for testing, while the remains rows have been split respectively into 80% for training and 20% for validation. Dropout hyper-parameters have been set to 0.5 for the attention layer and 0.1 for the hidden layer [16]. Texts longer than 512 words (0.86% of the whole dataset) have been truncated as the majority of records are between 0 and 200 words in length so no meaningful information was lost (Fig. 3).

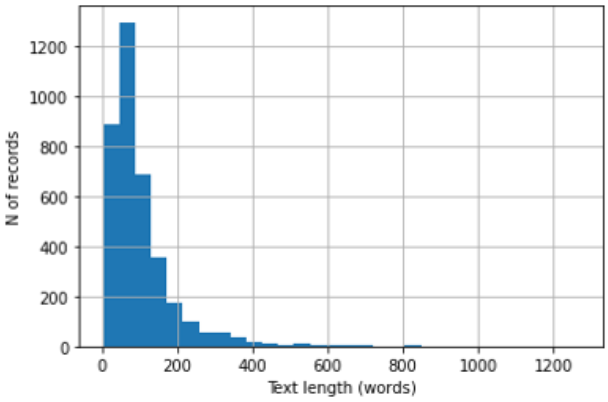

Fig. 3: Number of words for analysed records. The majority of records present a text length which is shorter than 512 words.

Padded texts have been tokenized with a generic class instantiated with a BERT tokenizer. BERT uses special tokens [CLS] and [SEP] to understand input properly. [SEP] token has to be inserted at the end of a single input, while [CLS] is a special classification token and the last hidden state of BERT corresponding to this token is used for classification tasks. Classification performance has been evaluated by comparing training and validation losses, accuracy, precision, recall, and F1-score. Validation of the final model has been performed with 10-fold cross-validation. The best-performing fold has finally been tested and evaluated with the same metrics.

III. RESULTS

Various experiments have been conducted in order to tweak model parameters such as activation function (Sigmoid linear unit – SiLU, Rectifier linear unit – ReLU, and Gaussian Error Linear Unit – GELU), learning rate (5e-5, 3e-5 and 2e-5) [17] for the optimization algorithm, batch size and the number of epochs (2, 3 or 4) [17]. The best performance was achieved with the GELU activation function, a batch size of 16, AdamW optimizer with a learning rate of 5e-5 and 4 epochs (0.9764 accuracy, 0.9609 precision, 0.9933 recall and 0.9768 F1 score). Tuned parameters have been then used for training a new model with k-fold cross-validation (10 folds). Results are shown in Table I.

TABLE I: Results of 10-fold validation on 2,964 records.

Fold	*Train loss*	*Validation loss*	*Accuracy*	*Precision*	*Recall*	*F1 score*
1	0.0216	0.0773	0.9764	0.9797	0.9732	0.9764
2	0.0140	0.0348	0.9966	1.0000	0.9933	0.9966
3	0.0027	0.0001	1.0000	1.0000	1.0000	1.0000
4	0.0115	0.0923	0.9865	0.9932	0.9799	0.9865
5	0.250	0.0547	0.9865	0.9866	0.9866	0.9866
6	0.0028	0.0502	1.0000	1.0000	1.0000	1.0000
7	0.0196	0.0885	0.9730	0.9795	0.9662	0.9728
8	0.0020	0.0059	0.9966	0.9933	1.0000	0.9966
9	0.0204	0.0913	0.9730	0.9667	0.9797	0.9732
10	0.0021	0.0001	1.0000	1.0000	1.0000	1.0000

The best-performing model (fold number 10) has finally been tested on the testing dataset, performing with an accuracy

of 0.9906, precision of 0.9840, recall of 0.9973, F1 score of 0.9906, and a Matthews Correlation Coefficient (MCC) of 98.12%. Receiver Operating Characteristic (ROC) curve and confusion matrix for testing results are shown in Fig. 4.

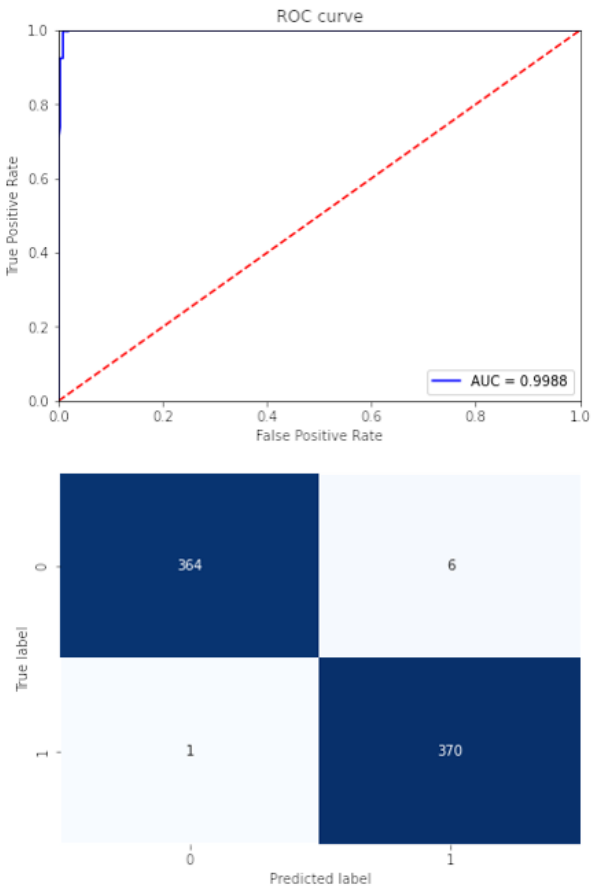

Fig. 4: ROC curve and confusion matrix for Fold #10 tested on 741 records (20% of the whole dataset).

IV. CONCLUSION

The proposed framework employs Natural Language Process techniques and models, such as BERT, to automatically identify adverse event reports related to Health Information Technologies. The framework aims to support Health Technology Assessment, as well as Post Market Surveillance and Post Market Clinical Follow-up as outlined in European Regulation 2017/745 on Medical Devices. The designed model uses a pre-trained version of ClinicalBERT, additionally fine-tuned on 3,705 adverse events reports extracted from the FDA MAUDE database, which had been previously manually labelled by experts. Further connections could be soon available to access data of local hospitals' CMMS and Computer-Aided Facility Management systems (CAFM) [18], [19]. Results show better metrics than other existing NLP HIT adverse events reports text classifiers based on non-BERT models [14], [15], [20], [21] (Table II).

TABLE II: Comparison of performances of the proposed NLP model (fine-tuned ClinicalBERT) and other non-BERT models.

Model	*Accuracy*	*Precision*	*Recall*	*F1 score*
ClinicalBERT	**0.9906**	**0.9840**	**0.9973**	**0.9906**
LR [15]	-	0.9670	0.9420	0.9540
LR [20]	-	0.6940	0.8040	0.7450
SVM+LR+CNN [21]	0.9012	0.8796	0.8606	0.8700

***Abstract*—In home-based motor rehabilitation, bio-feedback and remote monitoring are essential to maintain patient motivation and ensure appropriate monitoring of training effects. Wearable sensors can be exploited to provide this feedback both to the patient and to the therapist. This paper presents an algorithm for the real-time extraction of shoulder and elbow joint angles from three inertial measurement units (IMUs). The five angles extracted are defined according to the International Society of Biomechanics (ISB) convention. The algorithm includes a two-step calibration procedure (N-pose and T-pose), which allows placing the IMUs on the limbs freely, without the need to use the magnetometer, and the real-time computation of the joint angles. The algorithm was validated on the arm of the TIAGo robot by comparing the joint angles measured by the robot encoders against the joint angles derived from the IMU sensors. Results show that the presented method is accurate (the maximum RMSE is 4.96° for the pronation-supination angle) and robust to different IMUs positioning.**

***Keywords*—upper limb joint angles, ISB convention, IMU, home-based training**

I. INTRODUCTION

Disabilities of the upper limb, resulting both from neurological or neuromuscular pathologies and traumatic injuries, can greatly impact the ability to conduct activities of daily living. Rehabilitation is, therefore, fundamental to promote motor recovery and improve the quality of life of those affected by upper limb motor impairment.

Some key ingredients leading to the success of a rehabilitation program are motivation, dose, intensity, and personalization of the treatment [1]. These factors should be guaranteed not only in the clinic, but also at home to maintain and enhance the obtained progresses.

Wearable robots, such as exosuits, have been developed to support at-home therapy both for the lower and the upper limbs. However, the adoption of these devices is still limited and not fully exploited [2]. This is due to the immature state of the technology that has limitations, but also to a lack of motivation [3].

When it comes to home-based rehabilitation, it is necessary to encourage the patients and inspire their enthusiasm whether they are using a wearable robot or not. This could be addressed by providing daily feedback on their motor performance by exploiting wearable sensors, such as IMUs (Inertial Measurement Units). At the same time, the metrics extracted could be sent to the therapist to remotely monitor the patient's progress and tailor the treatment to their needs [4].

II. STATE OF THE ART

To extract performance metrics from the IMUs, the first step is to compute the upper limb joint angles. Several studies addressed the challenge of computing the upper limb angles [5]–[7], but they did not follow the ISB (International Society of Biomechanics) convention, recognized as the standard for reporting joint motions in a clinically relevant way [8].

A recent study aimed at providing bio-feedback during aquatic exercises proposed a method to extract upper limb joint angles according to the ISB convention. The proposed algorithm does not employ the magnetometer and does not constrain the position of the IMUs thanks to a two-step calibration procedure [9]. However, the group only validated shoulder abduction/adduction and elbow flexion/extension angles.

The aim of this work is to provide a complete mathematical explanation of the magnetometer-free algorithm to extract upper limb joint angles according to the ISB convention, and to validate it for all the angles on a robotic arm.

III. MATERIALS AND METHODS

A. Reference frames definition

The reference frames that will be used in the following sections are defined as shown in Fig. 1 and are:

- Global reference frame (G);
- IMU reference frame (I);
- Body segment reference frame (B);
- ISB convention reference frame (ISB).

When left joints are concerned, we used the same reference frame and we applied, when needed, a term that is defined as:

$$\kappa = \begin{cases} +1, & \text{if right arm} \\ -1, & \text{if left arm} \end{cases} \tag{1}$$

B. ISB upper limb angles definition

According to the ISB convention, the rotation matrix describing the orientation of the upper arm body segment (ISB,UA) with respect to the ground reference frame (G) can be defined as:

$$R^G_{ISB,UA} = R^G_{ISB,TH} R_y(\kappa POE) R_x(-\kappa AOE) R_y(\kappa HR) \tag{2}$$

where $R^G_{ISB,TH}$ is the rotation matrix of the thorax body segment with respect to G, POE is the Plane of Elevation angle

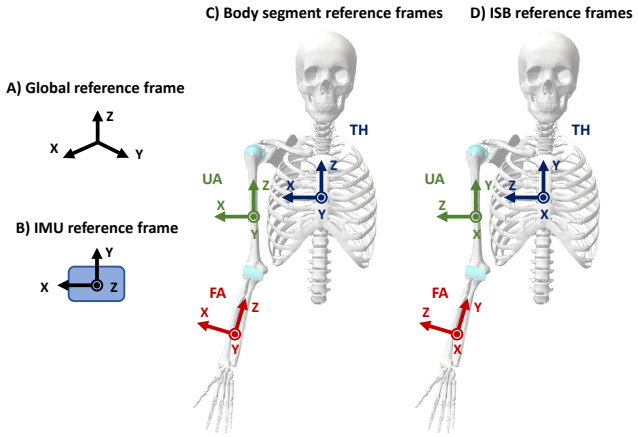

Fig. 1: A) Global, B) IMU, C) Body segment, D) ISB reference frames. TH indicates the thorax, UA indicates the upper arm, FA indicates the forearm.

(positive when moving the arm frontally), AOE is the Angle of Elevation (positive when elevating), HR is the Humeral Rotation angle (positive when the rotation is internal), and R_x, R_y represent the rotation matrices deriving from the rotation respectively around the x and y-axis of the angles indicated between parenthesis.

The rotation matrix describing the orientation of the forearm body segment with respect to G can be defined as:

$$R^G_{ISB,FA} = R^G_{ISB,UA} R_z(FE) R_y(\kappa PS) \tag{3}$$

where FE is the elbow Flexion-Extension angle (positive when flexing), and PS is the forearm Pronation-Supination angle (positive when pronating).

The ISB angles are null when the user is standing with the arms resting and the palms of the hands pointing forward (N-pose).

C. IMUs calibration

Since the magnetometer is not used, in order to make the IMUs share the same G, they are aligned on a rigid surface and the yaw is reset: the G z-axis points up in the direction of gravity, while x-axis and y-axis match the IMU x and y axis at time of reset. The IMUs are then placed on the thorax, upper arm, and forearm.

When placing the IMUs on the limbs, the IMUs axes and the body segments axes are usually not coincident. The calibration procedure is needed to align the IMUs reference frames (I) and the body segments reference frames (B). Calibration is performed by acquiring data from two different poses: i) the N-pose and ii) the T-pose. During the N-pose the user stands still with the arms resting and the palms of the hands pointing forward. In this configuration, the ISB joint angles are ideally null.

The orientation of each IMU with respect to G is expressed by the rotation matrix estimated by the IMU and can be expressed as:

$$R^G_{I_i} = R^G_{I_{i,0}} R^{I_{i,0}}_{I_i} \tag{4}$$

where $R^G_{I_{i,0}}$ is the rotation matrix of the i-th IMU during the N-pose, and $R^{I_{i,0}}_{I_i}$ is the rotation matrix of the i-th IMU calibrated with respect to the N-pose. Inverting Eq. (4), we obtain:

$$R^{I_{i,0}}_{I_i} = (R^G_{I_{i,0}})^T R^G_{I_i} \tag{5}$$

The orientation of each IMU with respect to G is also expressed as:

$$R^G_{I_i} = R^G_{B_i} R^{B_i}_{I_i} \tag{6}$$

where $R^G_{B_i}$ is the rotation matrix describing the orientation of the i-th body segment with respect to G, and $R^{B_i}_{I_i}$ is the rotation matrix describing the orientation of the i-th IMU with respect to the i-th body segment. This rotation matrix is assumed to be constant during the subsequent use of the sensors, such that $R^{B_i}_{I_i} = R^{B_{i,0}}_{I_{i,0}}$, where 0 indicates the N-pose configuration. If the sensors are moved relative to the body segments, the calibration procedure should be performed again.

The rotation matrix describing the orientation of the body segment with respect to G can be expressed as:

$$R^G_{B_i} = R^G_{B_{i,0}} R^{B_{i,0}}_{B_i} \tag{7}$$

where $R^G_{B_{i,0}}$ is the rotation matrix of the i-th body segment with respect to G in the N-pose and is unknown, and $R^{B_{i,0}}_{B_i}$ is the rotation matrix describing the orientation of i-th body segment at the current time instant with respect to the N-pose.

Using Eq. (7), Eq. (6) can be rewritten as:

$$R^G_{I_i} = R^G_{B_{i,0}} R^{B_{i,0}}_{B_i} R^{B_i}_{I_i} \tag{8}$$

During the T-pose the arms are rotated by 90° in the coronal plane. In this configuration, the ISB joint angles are ideally null except for AOE which is equal to 90°.

Assuming that in the N-pose the z-axes of the body segments are aligned with the z-axes of the IMUs calibrated as in Eq. (5) and the z-axis of G, the rotation matrices expressing the orientation of the body segments with respect to G in the N-pose can be expressed as a rotation around the z-axis of an angle θ:

$$R^G_{B_{i,0}} = R_z(\theta) \tag{9}$$

$$\theta = \angle(X_G, -\kappa Z_{I,calib_{UA}}) \tag{10}$$

where X_G is the x-axis of G (namely $[1,0,0]$), and $Z_{I,calib_{UA}}$ is the z-axis of the IMU placed on the upper arm and calibrated with respect to the N-pose. Eq. (6) can be rewritten for the N-pose as:

$$R^G_{I_{i,0}} = R_z(\theta) R^{B_i}_{I_i} \tag{11}$$

The expression of $R^{B_i}_{I_i}$ is then obtained reversing Eq. (11):

$$R^{B_i}_{I_i} = R_z(\theta)^T R^G_{I_{i,0}} \tag{12}$$

Substituting Eq. (9) and Eq. (12) in Eq. (8) we obtain:

$$R^G_{I_i} = R_z(\theta) R^{B_{i,0}}_{B_i} (R_z(\theta)^T R^G_{I_{i,0}}) \tag{13}$$

Finally, inverting Eq. (13) we obtain the following expression:

$$R_{B_i}^{B_i,0} = R_z(\theta)^T R_{I_i}^G (R_z(\theta)^T R_{I_i,0}^G)^T \quad (14)$$

Once this matrix is obtained for each body segment, it must be rotated to be expressed in the ISB reference frame:

$$R_{ISB_i}^{ISB_i,0} = R_{B_i}^{B_i,0} R_x\left(\frac{\pi}{2}\right) R_y\left(\frac{\pi}{2}\right) \quad (15)$$

D. Upper limb joint angles computation

For the sake of clarity, we will refer to $R_{ISB_i}^{ISB_i,0}$ for each body segment as TH for the thorax, UA for the upper arm, and FA for the forearm.

The POE can be computed as:

$$POE = \angle(proj_{XZ_{TH}}(Y_{UA}), -\kappa Z_{TH}) \quad (16)$$

that is the relative angle between the projection of the y-axis of UA (Y_{UA}) onto the plane defined by the x-axis and the z-axis of TH (XZ_{TH}), and the z-axis of TH. It is worth remarking that, in the particular case of a null AOE, Y_{UA} is orthogonal to XZ_{TH}, thus the projection $proj_{XZ_{TH}}(Y_{UA}$ degenerates to a point, and Eq. (16) loses its significance. This means that the POE is ill-defined when AOE is null. Indeed, if AOE is null, POE and HR coincide.

The AOE can be computed as:

$$AOE = \angle(Y_{UA}, Y_{TH}) \quad (17)$$

that is the relative angle between the y-axis of TH and the y-axis of UA.

Inverting Eq. (2), we can compute HR as:

$$R_y(HR) = (R_x(-\kappa AOE))^T (R_y(POE))^T (TH)^T UA \quad (18)$$

$$HR = tan^{-1}([R_y(HR)]_{1,3}, [R_y(HR)]_{1,1}) \quad (19)$$

where $[A]_{i,j}$ indicates the element of the matrix at the i-th row and j-th column.

FE can be computed as:

$$FE = \angle(Y_{FA}, Y_{UA}) \quad (20)$$

that is the relative angle between the y-axis of UA and the y-axis of FA.

Inverting Eq. (3), we can compute PS as:

$$R_y(PS) = (R_z(FE))^T (UA)^T FA \quad (21)$$

$$PS = tan^{-1}([R_y(PS)]_{1,3}, [Ry(PS)]_{1,1}) \quad (22)$$

E. Experimental Validation

Three IMUs (NGIMU, x-io Technologies Limited Bristol, UK) were placed on the TIAGo robot (PAL Robotics Barcelona, Spain) on its thorax, upper arm, and forearm as shown in Fig. 2. The TIAGo robot is a mobile manipulator with a 7-DOFs (degrees of freedom) actuated arm that allows reading the angle values by means of the encoders [10]. Each DOF of the TIAGo robot arm corresponds to one of the angles defined by the ISB convention for the upper limb.

The TIAGo robot was controlled to move its arm in the N-pose, in the T-pose, and then in multiple configurations. During the experiments, both the encoders signals and the IMUs rotation matrices were acquired and saved. The experiment was repeated twice changing the IMUs orientation to better support the validity of the results.

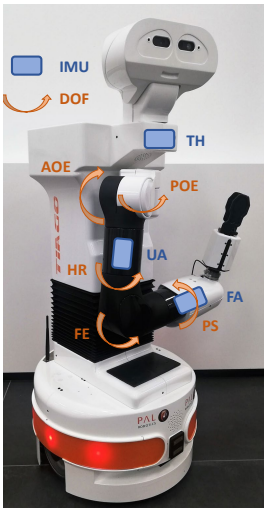

Fig. 2: IMUs (in blue) position on TIAGo robot and DOFs (in orange).

A comparison between the angles computed by the algorithm and those measured by the TIAGo robot, considered as the ground truth, was conducted.

IV. Results and Discussion

The experimental results in terms of root-mean-square error (RMSE) and correlation coefficient are summarized in Table I. The mean RMSE values between the two trials for the POE, AOE, HR, FE, and PS are respectively 4.87°, 2.75°, 2.76°, 4.93°, and 4.96° whereas the mean correlation coefficients r are 0.998, 0.998, 0.999, 0.996, and 0.995. The RMSE values differ slightly between the two experimental sessions showing that the positioning of the IMUs on the arm does not significantly influence the accuracy of the results.

The temporal history of one of the two repetitions is shown in Fig. 3. The error spike that can be observed in the POE, can be traced back to the ill-posed definition of POE when AOE is equal or close to 0°. We hypothesize that the other errors are mainly due to imprecisions during the three-phase calibration procedure (i.e., IMU alignment, N-pose, T-pose).

TABLE I: Correlation coefficient r and RMSE between the upper limb joint angles measured by the encoders and estimated with the proposed method during the two runs.

	Run 1		Run 2		Mean	
	r	RMSE [°]	r	RMSE [°]	r	RMSE [°]
POE	0.998	3.99	0.998	5.75	0.998	4.87
AOE	0.998	3.16	0.999	2.33	0.998	2.75
HR	0.999	3.23	0.999	2.27	0.999	2.76
FE	0.997	4.57	0.995	5.28	0.996	4.93
PS	0.997	2.54	0.993	7.37	0.995	4.96

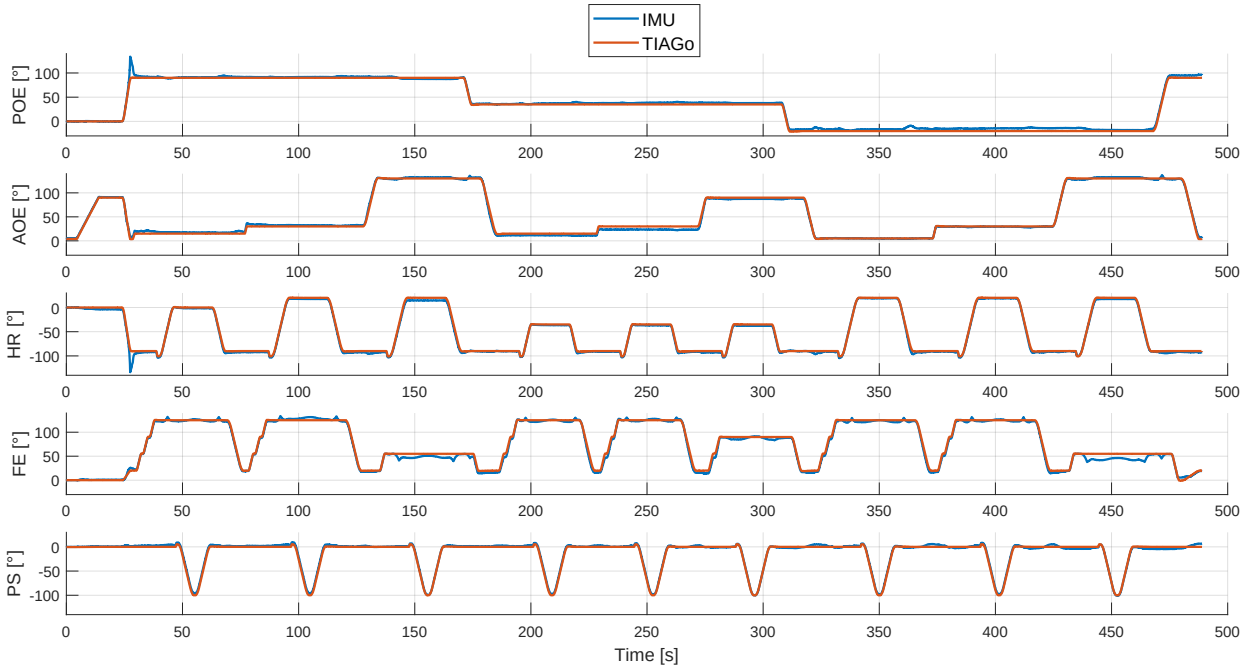

Fig. 3: Comparison between joint angles measured by TIAGo encoders (in orange) and computed by the IMUs (in blue) during run 1.

We acknowledge that the errors derived from the calibration might grow more significant when the calibration is performed on humans since the N-pose and T-pose configurations will be less precise. Moreover, since the muscles and the skin do not move rigidly with the bones, we expect higher errors in humans, especially in HR estimation.

V. Conclusion

The presented algorithm effectively estimated the upper limb joint angles according to the ISB convention on a robot arm. The algorithm does not need the magnetometer, and it allows for free positioning in terms of the orientation of the IMUs on the segments. Nevertheless, since the human body is not rigid, future works must include the validation of the whole algorithm on human participants. Moreover, the angle accuracy should be evaluated over a long period of time (i.e., a day). The extraction of meaningful metrics on motor performance could be finally carried out to compile a report.

***Abstract*—Next-generation sequencing technologies have been producing a growing volume of genomic data, increasing the challenge of clinical sequence variant interpretation. Identifying disease-causing mutations within millions of variants relies on the research of evidence in support of or against variant pathogenicity, a process regulated by specific American College of Medical Genetics and Genomics (ACMG) guidelines, which leverages data from biological databases and scientific literature. Despite recent improvements towards automation, searching shreds of evidence for pathogenicity in the literature still requires manual curation, a time-consuming process, due to the ever-growing number of published papers.**

As a first step towards automatic annotation, with this work we provided a reliable manually curated dataset of articles which activate two types of ACMG evidence code, namely PS3 and BS3, (positive articles) and articles which do not activate any of the above evidence code (negative articles). Moreover, we demonstrated that such dataset can be used to train a predictive model that automatically identifies positive articles.

We started from analysing PS3/BS3 evidence codes collected by ClinGen expert curators and then we performed our own manual curation on 132 articles retrieved from EuropePMC: 71 positives and 61 negatives. We used a combination of bag-of-words encoding and logistic regression to efficiently identify positive articles, with an F1-score of 0.85.

The model' performance constitutes a clear proof of concept for automatic PS3/BS3 evidence identification. Our dataset represents a useful resource to train further models.

***Keywords*—Variant Annotation, Clinical Genetics, Pathogenicity Assessment, ACMG guidelines**

I. Introduction

RECENTLY, Next Generation Sequencing (NGS) of whole exomes or genomes has become a widely accessible and relatively inexpensive practice, resulting in its increased use in clinical diagnostics for precision medicine. Indeed, NGS approaches can identify most of a person's genetic variants, thus allowing clinicians to provide suitable therapies to patients or assess disease risk [1].

Variant identification is followed by variant interpretation and prioritisation, which are crucial steps in the clinic, as they deeply impact healthcare decisions. To correctly assign a variant to its pathogenicity class, a biocurator firstly needs to perform a complete variant annotation, a process which consists in gathering all relevant information about the nature and the effect of the specific variant from databases and literature [2].

In 2015 the American College of Medical Genetics and Genomics (ACMG) published recommended standards and guidelines for variant interpretation [3]. The guidelines defined 28 criteria, each identified by an evidence code representing evidence in support of variant benignity or pathogenicity [4]. Criteria are applied on the basis of evidence contained in biological databases (variant frequencies, pathogenicity prediction scores, etc.) while others require information contained in scientific literature (variant functional studies, analysis of the pattern of inheritance of a particular trait throughout a family, etc.).

Specifically, the task of mining evidences of a variant malignity/benignity from the literature, a process known as manual curation, is extremely complex and time-consuming as it requires highly qualified curators that analyse all relevant papers and combine information coming from different resources. Typically, the curator queries literature search engines with "*Variant_Name* AND *Gene_Name*" and proceeds by reading all retrieved articles, searching for relevant information in figures, tables, sentences which contain the name of the variant and those nearby (e.g. the previous or next sentence) [5].

As a result of such a lengthy annotation process, currently there is the lack of a complete and constantly updated database containing papers curated following the ACMG guidelines for each variant and for each criterion. Several automatic tools have been proposed to speed up variant annotation, such as the Ensembl Variant Effect Predictor [6], that associates each variant to its transcripts and regulatory regions, or ANNOVAR [7], that predicts variant functional consequences. However, none of them can perform a comprehensive screening of the extensive and ever-growing literature, nor automatically extract from papers the information needed for the assignment of ACMG criteria.

With this work, we want to provide a reliable, manually curated dataset of articles, which activate, for a specific variant, one of two opposing ACMG criteria, named PS3 and BS3, (positive articles) or which activate neither (negative articles). PS3 and BS3 are alternatively assigned to a specific pair (variant, article) when the article describes a well-established functional test (in vitro or in vivo), carried out on the variant, that is supportive of a damaging or null effect on protein function, respectively. Moreover, we demonstrated the utility of our dataset as training set by performing a preliminary exploratory analysis concerning the development of an automatic, machine learning based predictive model to perform automatic positive (variant, article) evidence identification. This can be thought as a first step before a second classification step in PS3 vs. BS3.

II. METHODS

A. Retrieval of articles to be included in the curated dataset

To build our dataset, we started from the ClinGen Evidence Repository [8], an expert-curated registry that provides the evidence codes of each variant in the database, accordingly to the ACMG standards. In particular, ClinGen contains information about 4581 curated genetic variants, which can be distributed across 78 genes of interest. Each curated variant is reported with its standard nomenclature and the associated ACMG evidence codes. Also, ClinGen provides a summary of the variant interpretation where each ACMG evidence code is briefly explained, specifying the source of evidence, which can be a database or one or more scientific papers, identified by PubMed [9] identification codes (PMIDs). PubMed is a free search engine for retrieval of biomedical literature abstracts, indexed through their PMIDs. Also, PubMed provides links to articles' full-texts, when these are available from other sources, such as PubMed Central [10] (PMC), in which full-texts are indexed through PMCIDs.

As mentioned before, we decided to focus only on variant curations where either PS3 or BS3 evidence codes are assigned, given that the evidence needed for these assignments is often contained in papers plain texts. ClinGen contains 385 genetic variants (*ClinGen variants*) with PS3 or BS3 criteria for which we extracted the corresponding PMIDs (*ClinGen articles*). As we want to analyse papers full-texts, we converted PMIDs to PMCIDs. *ClinGen articles* with no PMCID were ignored. We choose to use EuropePMC as literature search engine, for it has a very convenient R interface, provided by the package *europepmc* [11]. Specifically, the user can define a query through the function *epmc_search* and obtain PMCIDs of retrieved articles.

Given that *ClinGen articles* are curated by expert biocurators, we expect querying of EuropePMC by *ClinGen variant* specific nomenclatures to produce a pool of retrieved articles which contains at least one already curated positive article, the so called *ClinGen article*, and, eventually, some other positive articles (not identified by ClinGen curators) and some negative articles, which have to be manually curated in order to build the dataset.

As we want to mimic the same procedure followed by manual curators, our queries contain "*Variant_Name* AND *Gene_Name* AND *Keywords*". Given the great variety of nomenclatures commonly used for genetic variants such as: i) nucleotide change (e.g. c.1A>G); ii) one-letter amino acid change (e.g. p.M1V); iii) three-letters amino acid change (e.g. p.Met1Val); iv) rsID (e.g. rs786204467), etc., we choose to consider as *Variant_Name* for each *ClinGen variant* only the specific one used in all of its *ClinGen articles*.

Keywords is a set of 113 words we added to the query syntax in order to retrieve articles containing at least one of these terms, thus slightly narrowing the research. We extracted *Keywords* from two resources: Mastermind [12], which is a commercial search engine that allows paid users to rank retrieved articles according to ACMG relevance through criteria-specific keywords, and *ClinGen articles*. In particular, Mastermind contains 68 keywords for PS3/BS3, while the other 45 keywords were words recurrently found in *ClinGen articles*, which are known to be positive for PS3/BS3. For example, *Keywords* contains names of functional tests (ELISA, FISH, etc.), experimental materials (in vivo, in vitro, human cells, animal model, etc.), and species (drosophila, mouse, zebrafish, etc.). Considering that the aim of functional tests is typically the functional comparison between one or more mutants with the wild-type, i.e., the non-mutated genomic sequence (often referred to as wild type, control, mock, water, etc.), or with other mutants known to cause functional alterations (e.g., activating/inactivating mutations) these latter words were included as well in *Keywords*.

Furthermore, we refined the query syntax by adding the following flags:

- BODY: query terms are searched within the body of full-text articles. Sections such as "References" and "Acknowledgements" are not considered.
- OPEN_ACCESS: it limits search results to articles that are Open Access in EuropePMC. This is needed as we need access to the full-text.
- PUB_TYPE: filter by publication type. Only journal articles were considered.

These customised queries produced lists of retrieved articles, identified by their PMCIDs, for each *ClinGen variant*. As some *ClinGen articles* are not Open Access, some queries do not contain any *ClinGen articles* and thus they were discarded in the current analysis.

Finally, 1466 distinct articles were retrieved using queries related to 47 *ClinGen variants*: 31 *ClinGen articles* and 1435 articles not included in *ClinGen articles*.

B. Manual curation of retrieved articles

Manual curation is needed to distinguish between positive articles (assigned to the label 1), i.e., articles that contain sentences that activate either PS3 or BS3 evidence codes and, negative articles (assigned to the label 0), which do not contain any of these sentences. The presence of at least one positive sentence inside an article confers positivity to the whole article itself. It is worth noting that the positive or negative label also depends on the specific variant considered, thus, more specifically, it is assigned to each (variant, article) pair.

We selected for manual curation only *target sentences*, i.e., sentences containing *ClinGen variants* specific name concatenated to the ones immediately adjacent (the previous and next sentences). In this way, we considered only textual information, easily interpretable for an automatic algorithm (tables and figures are excluded, as they would require additional, specialised modules). We performed sentences extraction through the R package *tidypmc* [13].

For each *ClinGen variant*, we read all *target sentences* extracted from its *ClinGen articles* and, for sake of time parsimony, given the burden of human curation in terms of time, from a random subset of articles not included in *ClinGen articles* but retrieved by our queries.

We performed manual curation considering the following rules and ensuring consistencies with the Genomic Variant Analysis & Clinical Interpretation [5] procedure. We assigned to each article the label negative (0) if:

- None of *target sentences* contains sufficient information for assigning PS3 or BS3 as defined by ACMG guidelines (i.e., all *target sentences* are negative), regardless of the content of tables or figures (which could contain information for assigning PS3 or BS3).

Instead, the positive (1) label was assigned to papers for which:

- At least one *target sentence* contains information for assigning PS3 or BS3 (i.e., at least one *target sentence* is positive). Positive *target sentences* include sentences that refer to other papers or sentences where the comparison to wild-type is implicit.

We excluded articles for which there were no *target sentences* (the name of the variant only appears in tables).

C. Preprocessing and Train, Test and Validation set

We trained the automatic classification model on this dataset according to a by-sentence perspective, where we considered each sentence as an independent entry. For performance evaluation only, we considered also a by-paper perspective by only distinguishing between positive and negative papers according to the classification of each of their target sentences (the paper is positive if it contains at least one positive sentence). We pre-processed the sentences included in the dataset according to the following typical steps [14]:

- Deletion of English stop words;
- Word stemming;
- Deletion of the 10% least frequent words;
- Exclusion of sentences consisting of less than 3 words.

Finally, the pre-processed dataset was split into training-set, test-set and validation-set (70%, 15%, 15%), making sure that proportions of positive and negative articles and sentences are similar in the 3 subsets.

D. Model and hyperparameter optimisation

We performed a preliminary exploratory analysis on automatic PS3/BS3 evidence identification using a simple logistic regression (LR) trained after applying the bag-of-words (BOW) [15] approach to transform the original dataset into a version where each sentence was represented by the number of occurrences of each word within it. For this model, we considered a L2 regularisation loss-function with a single hyperparameter that needed optimisation, the inverse of the regularisation strength C.

We performed hyperparameter optimisation considering only the training set using a 5-fold cross validation [16] and a random search approach [17] accounting for 10,000 values of C, randomly sampled from a log uniform distribution ranging from 10^{-4} to 10^{2}. We selected the best hyperparameter as the one that led to the minimum average binary cross-entropy across the 5 folds.

To transform the model from a ranker into a classifier useable in practice for automatic PS3/BS3 evidence identification, we implemented a thresholding approach by identifying one probability threshold (th) to discriminate between sentences that would activate PS3 or BS3 (1, if predicted probability $p \geq th$) and negative (0, if $p < th$) predictions. We selected the optimal threshold by using each probability value predicted for sentences in the validation set as a threshold and choosing the one associated to the maximum geometric mean between true positive and true negative rate.

E. Performance evaluation

In the by-sentence perspective, we evaluated the discrimination performance of the model via five metrics: area under the receiver operating characteristic (AUROC) and area under the precision-recall curve (AUPRC) [18] for the continuous probability output; as well as precision, recall, and F1-score after applying the aforementioned thresholding approach. In the by-paper perspective, we did not consider AUROC and AUPRC as predicted labels were assigned by conglomerating by-sentence outputs after thresholding.

III. Results

A. Manually curated dataset

Manual curation was actually carried out on 755 sentences belonging to 196 articles. However, as 64 articles were discarded (see Section II.B), the manually curated dataset finally comprises 649 sentences belonging to 132 articles. Table I and Table II provide a comparison of assigned labels in *ClinGen articles* and non-*ClinGen articles* and among train, test and validation sets, respectively.

TABLE I: ClinGen Articles VS Non-ClinGen Articles

		Total	Positive	Negative
ClinGen articles	**Sentences**	281	162	119
	Articles	23	22	1
Non-*Clingen articles*	**Sentences**	368	167	201
	Articles	109	49	60

TABLE II: Train Set VS Test Set VS Validation Set

		Total	Positive	Negative
Training	**Sentences**	477	241	236
	Articles	92	50	42
Testing	**Sentences**	109	56	53
	Articles	20	11	9
Validation	**Sentences**	63	32	31
	Articles	20	10	10

The dataset contains almost the same amount of positive and negative sentences, respectively 329 and 320. The same goes for positive and negative articles, which are respectively 71 and 61.

B. Classification results

The performance metrics obtained in both considered perspectives (by-sentence where we considered each sentence independently from the others, and by paper where we conglomerated sentences according to the paper they belonged to) are shown in Table III. As explained above (Section II.D), AUROC and AUPRC are not reported in by-paper perspective.

TABLE III: Classification results

Perspective	AUROC	AUPRC	F1-score	Precision	Recall
By-sentence	0.822	0.821	0.741	0.769	0.714
By-paper			0.857	0.900	0.818

BOW+LR model performance evaluation metrics computed on the test set for the by-sentence and by-paper perspectives. N_sentences = 109, N_papers = 20.

The BOW+LR model performed well in both perspectives according to all considered metrics with AUROC and AUPRC well above 0.8. As the number of false negatives was higher than the one of false positives, precision was higher than recall. This result suggests that correctly identifying negative

sentences and papers was slightly more challenging than correctly identifying positive cases. While not directly comparable, performance was overall better in the by-paper setting than in the by-sentence one, which was expected as it is easier to obtain a correct classification looking at multiple sentences for each paper rather than classifying each sentence independently.

IV. Discussion And Conclusions

The main aim of this work was to define a reliable manually-curated dataset that associates each variant to its PS3/BS3 evidence code associated articles (positive set) and not associated articles (negative set), and to demonstrate its utility by developing a predictive model to perform automatic positive article identification.

The manually curated dataset comprises 649 sentences of 132 articles. In order to be sure enough to have a sufficient number of positive examples, we included in the dataset 23 *ClinGen articles* and, to consider a more representative sample of the entire corpus of articles retrieved when querying for a specific variant, 109 non-*ClinGen articles*. As expected, most of *ClinGen articles* were positives (only 1 was reclassified as negative, as we analysed only textual information). Overall, about half extracted sentences contained sufficient evidence for PS3 or BS3 evidence code, and same for the articles. A positivity offset is given by the elevated number of positive sentences extracted from few *ClinGen articles*, but generally positive sentences and articles are respectively less than negative ones (167 vs. 201 sentences extracted from 49 vs. 60 non-*ClinGen articles*). However, we found a significant number of positive articles in non-*ClinGen articles* (49 out of 109), suggesting that manually curated information contained in ClinGen is incomplete and/or not updated frequently enough.

Despite the limited size of the dataset and the relatively simple methodological approach that we decided to consider for a preliminary exploratory analysis, discrimination performance concerning automatic identification of PS3 or BS3 evidence code vs. negative articles was good both in the by-sentence and by-paper perspective, with F1-scores above 0.7 and 0.8 respectively. This result suggests that reliable tools could be developed in support of manual curation, providing to clinicians all information needed for a complete and correct variant interpretation.

Future developments include increasing the dataset sample size, i.e., the number of curated articles, considering all possible variant synonyms, and optimising the workflow for automatic sentences extraction. Moreover, we will focus on a more specific classification for the (variant, article) pair. The solid manual curation procedure described in this work may be applied to variants which are not included in ClinGen and expanded to the evaluation of other evidence codes among the 28 covered by ACMG guidelines.

***Abstract*—Multiple Sclerosis (MS) is an autoimmune degenerative disease of the central nervous system, in which chronic inflammation leads to demyelination with transient or permanent axon damage. Symptoms of MS include problems with vision, movement, sensation and balance, which can be intermittent or progressively increasing over time until bringing to permanent disability. Predictive models of MS disability progression can be very useful to support the clinician in choosing the best care for each patient.**

The aim of this work is to develop predictive models of short-term MS disability progression. Data are part of the Multiple Sclerosis Outcome Assessments Consortium (MSOAC) Placebo database, which includes longitudinal demographic and clinical data of 2465 MS patients who were enrolled in the control arm of different MS clinical trials. Variables collected in the first visit were used to predict a binary outcome of disability progression at 6 months and 18 months from the baseline, using a logistic regression model. Disability progression was defined as a 1.5 increase in the Expanded Disability Status Scale (EDSS) value compared to the baseline time. 20 input variables were considered in each model, including demographics, medical history, functional tests, questionnaires, and MS phenotype. Preprocessed data were split into a training and a test set with an 80%-20% proportion. Logistic regression models were trained on the training set, using over-/undersampling techniques for balancing the classes. The identified models were tested on the test set by assessing the area under the receiver operating characteristic curve (AUC).

Prediction performance on the test set was satisfactory, although not optimal, with AUC equal to 0.74 at 6 months and 0.71 at 18 months. These prediction performances are comparable with results obtained by other literature studies on smaller cohorts.

Future developments of this work include the use of other machine learning techniques for model training, the application of feature selection and variable ranking techniques, the incorporation of new variables (e.g., imaging variables), and the external validation of the models on new populations.

I. Introduction

Multiple Sclerosis (MS) is a chronic autoimmune and inflammatory disease involving the central nervous system, characterised by demyelination and transient or permanent damage to axons [1]. MS is a multifactorial disease whose causes are still not fully determined. Probable underlying causes include genetics, environmental factors, as well as viral infections [2]. MS causes a variety of physical and cognitive symptoms. The course of the disease can consist of isolated recurring attacks, named relapses, that characterise the relapsing-remitting MS (RRMS) phenotype, or of a progressive decline of the subject's functionalities, that can either occur since the first phases of the disease (Primary Progressive Multiple Sclerosis, PPMS) or in a second phase only (Secondary Progressive Multiple Sclerosis, SPMS). The care for MS mainly consists of pharmacological treatments administered to delay disease progression or mitigate the symptoms.

In this context, the employment of prognostic predictive models would lead to many advantages, including promoting the understanding of the mechanisms of MS, anticipating treatments for patients in need of preventive therapies, thereby improving the risk/benefit ratio and the quality of life of these individuals, as well as informing patients and caregivers about the future evolution of the disease. Several literature studies have investigated the prediction of progression in terms of different outcomes, such as the values of functional tests performed by the patients or a related score [3], [4], the increase of fatigue [5], the shift from one MS phenotype to another [6], [7], or the time/chance of occurrence of a relapse [8], [9]. To this end, various classical machine learning methodologies have been used, adopting regression, classification, or survival analysis approaches.

In this work, we focused on modelling the progression of MS in terms of the worsening of the patient's disabilities. We considered as the outcome the Expanded Disability Status Scale (EDSS) [10], a score that is used in clinical practice for monitoring the status and capacities of MS patients and whose variation over time is typically used to define an exacerbation of the disease. The EDSS ranges from 0 (normal status) to 10 (death due to MS), with increasing values as the disability progresses. This score incorporates the status of eight functional systems (pyramidal, cerebellar, brain stem, sensory, bowel and bladder, visual, mental, and other functions), which together express all possible neurological alterations induced by the disease. After defining a threshold on EDSS variations and a prediction horizon, i.e., a temporal time-window in

[†]Data used in the preparation of this article were obtained from the Multiple Sclerosis Outcome Assessments Consortium (MSOAC). As such, the investigators within MSOAC contributed to the design and implementation of the MSOAC Placebo database and/or provided placebo data, but did not participate in the analysis of the data or the writing of this report.

which the subject is observed, each subject can be associated with a binary outcome (progression of disability occurred or not), and the prediction can be approached as a classification task.

This approach mimics the ones proposed in the literature by Zhao et al. [11], [12], by Law et al. [3], by Tommasin et al. [13], and by Yperman et al. [14]. In that literature studies, however, we observed that the cardinality of the cohorts used for model development was often limited to only a few hundred patients, which clashes with the requirements of machine learning to have a sufficiently large number of instances to learn models appropriately. To overcome this issue, in this work we employed the Multiple Sclerosis Outcome Assessments Consortium (MSOAC) Placebo database [15], [16], which includes demographic and clinical data of 2465 MS patients who were involved in clinical trials of MS treatments as the control groups. Starting from the first recorded visit (baseline), we identified two prediction horizons, namely 6 and 18 months after the baseline, computed the outcomes, and developed a logistic regression model for each setting using as input the variables collected during the first trial visit. We then assessed the prediction performance of the model on an independent test set.

II. Materials and Methods

A. Dataset and preprocessing

The MSOAC Placebo Database includes fully anonymized longitudinal data of 2465 MS patients from 9 clinical trials [15], [16]. The database contains data on demographics, medical history, performance outcome measures (e.g., Timed 25 Foot Walk (T25FW), 9-Hole Peg Test (NHPT), Paced Auditory Serial Addition Test (PASAT)), clinician-reported outcome measures (e.g., EDSS, Kurtzke Functional Systems Scores (KFSS)), patient-reported outcome measures (e.g., 36-Item Short Form Health Survey (SF-36)), relapse information, and MS phenotype (e.g., relapsing-remitting), for a total of 104 longitudinally-collected variables. The MSOAC database does not include imaging data. Due to the nature of the dataset, enrollment time and follow-up duration may vary for subjects participating in different clinical trials.

We extracted the information collected at the first visit of each patient to be used as input for the predictive models and preprocessed it as follows. After removing the data that referred to an under-represented MS phenotype (Progressive-Relapsing MS, 2 patients only), we filtered the variables to remove the ones with too much missing information. By excluding the variables with more than 30% of missing values, the total number of features was reduced to 23. We then filtered out three more boolean features – namely the one indicating the need for more than 2 attempts to perform the T25FW test, the NHPT with the dominant hand, or with the non-dominant hand – that were excluded since the occurrence of positive cases was extremely limited. This brought the final number of features to 20. Table I reports a description of the included variables, with the percentage of their missing values (fourth column), the mean and interquartile range (IQR) of numerical variables or the levels of categorical variables (fifth column).

B. Model development pipeline

Data collected at the first visit of each subject, referred to as baseline, were used to predict subject's disease progression at two prediction horizons (PH), i.e., at 6 and 18 months after the time of the baseline visit (t_B). For each subject, the EDSS value at baseline, $EDSS_{t_B}$, was defined as the first available EDSS value. The EDSS at PH, $EDSS_{t_B+PH}$, was defined as the EDSS value recorded at $t_B + PH$. Subjects with no EDSS value recorded at $t_B + PH$ were excluded from the analysis. For each PH value, a binary outcome of disability progression was defined as follows. A subject was provided label "1", i.e., progression of disability, if $EDSS_{t_B+PH} - EDSS_{t_B} \geq 1.5$ in accordance with the work by Zhao et al. [12]. Conversely, a subject was assigned label "0", i.e., no progression of disability, if $EDSS_{t_B+PH} - EDSS_{t_B} < 1.5$.

A different predictive model was developed for each PH using logistic regression as a binary classification model. Labelled data were randomly split into a training set, with 80% of the subjects, and a test set, with the remaining 20% of the subjects. The training-test split was stratified by model outcome in order to maintain the same proportion of classes in the two sets. Missing values in the input variables were imputed using the Multiple Imputation by Chained Equations (MICE) method [17]. The parameters of the imputation algorithm were learned from the training set, and used to impute both the training and the test set. Then, categorical variables were encoded using dummy variables. Finally, numerical variables were scaled in the range 0-1, by subtracting to each variable its minimum value in the training set, and then dividing the result by the range of the variable values in the training set. In order to manage the strong class unbalance, two strategies were adopted for balancing the classes on the training set. The first one consisted in oversampling the less frequent class, until the two classes are balanced ("Oversampling"). The second one consisted in oversampling the less frequent class, and undersampling the more frequent class, until the two classes are balanced ("Both Over-/Under-sampling").

A logistic regression model was trained on the balanced training set. The logistic regression equation is:

$$ln(\frac{P}{1-P}) = \beta_0 + \beta_1 \cdot X_1 + ... + \beta_n \cdot X_n) \qquad (1)$$

where P is the probability of the class "1", X_i, i = 1,..., n are the input variables, β_i, i = 1,...,n are the model parameters associated with the input variables, and β_0 is the intercept parameter. Model parameters were estimated on the training set by maximum likelihood. Variables significantly associated with the outcome were identified by the Wald test (significance level 5%).

In total 4 models were developed (2 PH values x 2 strategies for balancing the training set).

TABLE I: BASELINE VARIABLES SELECTED AS INPUT FOR THE PREDICTIVE MODEL AFTER DATA PREPROCESSING.

Domain	Name	Description	NA (%)	Mean [IQR] / Levels
Demographics	AGE	Age at first visit (in years)	3.37	41.77 [18, 72]
	SEX	Sex	0	Male / Female
Findings about Medical History	P1Y_RELAPSES	Number of relapses experienced in the year previous to the first visit	27.75	1.376 [0, 7]
	T25_FW_first	First T25FW test performed: time taken to cover a straight stretch of 25 feet (in seconds)	0.81	9.217 [0.7, 218.2]
	T25_FW_second	Second T25FW test performed: time taken to cover a straight stretch of 25 feet (in seconds)	0.85	9.095 [0.7, 232.1]
	PASAT_tc_3s	PASAT: number of correct answers (out of 60) presented every 3 seconds each	3.41	47.24 [0, 60]
Functional Tests	NHPT01_DH1	First NHPT performed with the dominant hand: time taken to complete the test (in seconds)	3.41	25.1 [1, 300]
	NHPT01_DH2	Second NHPT performed with the dominant hand: time taken to complete the test (in seconds)	3.45	23.88 [8.5, 300]
	NHPT01_NDH1	First NHPT performed with the non-dominant hand: time taken to complete the test (in seconds)	3.77	26.87 [1.4, 312.7]
	NHPT01_NDH2	Second NHPT performed with the non-dominant hand: time taken to complete the test (in seconds)	3.85	26.16 [1.2, 356.7]
	EDSS	EDSS score value (in the 1-10 range)	3.29	3.406 [0, 6.5]
	KFSS101	KFSS score value on pyramidal functions (in the 0-9 range)	15.62	1.853 [0, 5]
	KFSS102	KFSS score value on cerebellar functions (in the 0-9 range)	13.35	1.29 [0, 9]
	KFSS103	KFSS score value on brain stem functions (in the 0-9 range)	15.62	0.6351 [0, 4]
Questionnaires	KFSS104	KFSS score value on sensory functions (in the 0-9 range)	15.62	1.178 [0, 5]
	KFSS105	KFSS score value on bowel and bladder functions (in the 0-9 range)	15.62	0.8322 [0, 6]
	KFSS106	KFSS score value on visual functions (in the 0-9 range)	15.62	0.7543 [0, 6]
	KFSS107	KFSS score value on cerebral (or mental) functions (in the 0-9 range)	15.62	0.5827 [0, 3]
	DH	Dominant hand	3.25	Left / Right
Medical History	PHENOTYPE	MS phenotype at first visit	0	RRMS / SPMS / PPMS

C. Performance metrics

Each model was applied to the test set to assess its performance. As performance metrics, we considered the receiver-operating-characteristic (ROC) curve, i.e., the plot of sensitivity vs. 1-specificity for different classification thresholds on the predicted probability of class "progression of disability" (P in eq. 1), and the area under the ROC curve (AUC). The AUC varies between 0 and 1, with 0.5 corresponding to the model that randomly assigns the classes, 1 corresponding to the model that perfectly classifies the data, and 0 to the model that perfectly divides the two classes but switches them.

III. Results

There were a total of 2232 subjects with a definite outcome at 6 months after baseline, of whom 103 had a progression of disability (i.e., EDSS worsening $\geq$ 1.5) and the other 2129 have no progression of disability (i.e., EDSS worsening $<$ 1.5). At the 18-month PH, 1605 subjects have a definite outcome, of whom 164 are in the "progression of disability" class and 1441 in the "no progression of disability" class. After splitting the data, the training and the test sets for the prediction of disability progression at 6 months include 1786 and 446 subjects, respectively. For the 18-month PH, the number of subjects in the training and the test sets is 1284 and 321, respectively.

The AUC values obtained on the test set are reported in Table II. At 6 months, the models achieve satisfactory, though not optimal, prediction performance, with the best results obtained by the model trained with oversampling of the training set. The ROC curve for this model is shown in Fig. 1. At 18 months, the model prediction performance is slightly lower than those at 6 months. At 18 months, the technique that performs both over- and undersampling of the training set achieves a slightly higher prediction performance. The ROC curve for this model is shown in Fig. 2.

In Table III we report for each final model the list of variables that resulted significantly associated with the outcome according to the Wald test (significance level 5%) and the corresponding p-values.

TABLE II: AUC VALUES ON THE TEST SET

Prediction horizon	*Sampling strategy*	*AUC value*
6 months	Oversampling	0.7404
6 months	Both over-/undersampling	0.7284
18 months	Oversampling	0.6969
18 months	Both over-/undersampling	0.7101

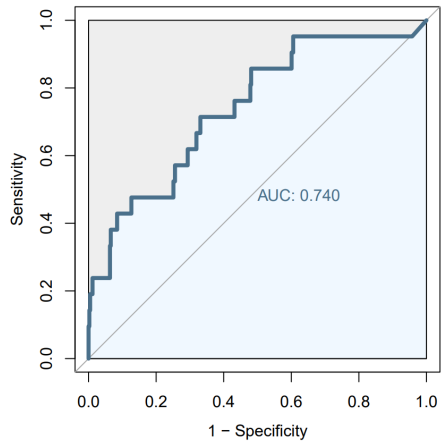

Fig. 1: ROC curve on the test set of the logistic regression model that predicts disease progression at 6 months, using the oversampling technique for balancing classes on the training set.

IV. Conclusion

In this work, we used the data of the MSOAC Placebo Database to develop logistic regression models of short-term disability progression, defined as an increase of the EDSS score larger than 1.5, with a PH of 6 months and 18 months. The developed models achieved satisfactory prediction performance on an independent test set, with AUC values of 0.74 at 6 months and 0.71 at 18 months. The slight deterioration of prediction performance at 18 months is somehow expected because, given the large variability among disease progression profiles observed in MS, the larger the PH the more difficult is to predict with confidence the progression of disability. These prediction performances are comparable with results obtained by other literature studies on smaller cohorts (AUC=0.62 at 6 months in Law et al. [3] using a cohort of 485 patients; AUC=0.79 at 24 months in Tommasin et al. [13] using a cohort of 163 patients; AUC=0.75 at 24 months in Yperman et al. [14] using a cohort of 642 patients), confirming the feasibility of MS progression prediction.

By comparing the variables most significant for outcome prediction at different PH (Table III), we can observe that some variables are significantly associated to progression of disability at both 6 and 18 months (i.e., number of relapses in the last year, EDSS, NHPT01_DH1, and MS phenotype). Interestingly, the role of other variables varies with the PH, with demographic variables (i.e., age and sex) being not significantly associated to progression of disability at 18 month.

The prediction performance is still not optimal, but several margins for improvement exist. Although the dataset used in this study is larger than those used by studies in the literature, indeed, this dataset poses some major challenges, such as significant class imbalance, absence of imaging data, short follow-up period, and possibly different enrollment times. Class imbalance can significantly affect model training, although in this study we mitigated its effect by using over/undersampling techniques. Magnetic resonance imaging (MRI) of the central nervous system is the main diagnostic test to quantify the effects of demyelination, and it is routinely performed to monitor MS progression. Therefore, the inclusion of MRI-derived variables in the models could bring some important information to improve the prediction of disease progression. Finally, datasets with longer follow-up periods could allow the development of predictive models of long-term disease progression.

Future developments of this work include the use of other machine learning techniques for model development (e.g., support vector machines or random forest), application of feature selection and variable ranking techniques, incorporation of new variables (e.g., MRI variables if available), and external validation of the models on new patient populations.

***Abstract*—The development of prognostic models for rare diseases is often limited by the latter's extremely low prevalence, which, in turn, affects the breadth of modelling techniques that may be applied. Notably, a severe lack of training data may hinder or prevent the implementation of high-capacity models, such as deep neural networks, despite their known effectiveness in predicting adverse outcomes and efficiency in making use of longitudinal data. To address this issue, in the present work, we propose a novel methodological pipeline where we first train a dynamic Bayesian network (DBN) on the few available data to simulate an adequate number of virtual patients whose variables are linked by the same probabilistic relationship over time as in the original data; then, we train a deep learning model based on recurrent neural networks on the simulated data; and, finally, we apply finetuning, a transfer learning (TL) technique, to adapt the model to the real data. To demonstrate the potential usefulness of our approach, we apply it to the prediction of 3-year mortality in amyotrophic lateral sclerosis (ALS), a rare (<0.01% prevalence), fatal neurodegenerative disease, starting from a population of 985 patients from the Piemonte and Valle d'Aosta ALS (PARALS) register. We show that our pipeline of DBN and TL effectively combines the simulated data it is able to generate and the few available real data, leading to an 8.2% AUROC improvement over a reference deep learning model trained only on the real data.**

I. Introduction

Prognostic model development for rare diseases presents an additional set of challenges compared to more frequent conditions. Notably, whereas, for many clinical applications, data scarcity can partially be remedied by extending the study to different types and sources of data (e.g., by making a secondary use of administrative or routinely acquired data), the inherently small number of people affected by rare diseases sets a hard limit to data availability. In turn, this reflects on the breadth of modelling approaches that can be applied with the reasonable expectation of obtaining robust results. Particularly, the usage of high-capacity models such as deep neural networks, which have been successful in tackling complex modelling tasks, especially using longitudinal data [7], seems difficult to justify in light of the disproportionately limited sample size of many rare-disease databases.

To address this issue, one possibility might be resorting to standard data augmentation techniques to artificially increase the number of available training examples via transformations of the data [8]. However, while some domains, such as image analysis, naturally lend themselves to the application of data augmentation techniques, the best way to augment typical clinical data, including patient characteristics, vital parameters, and, possibly, longitudinally-acquired timeseries, is still unclear. An alternative approach would be to leverage data generation techniques [16] to produce a sufficient number of virtual patients, and, then, train a model using the simulated data. Dynamic Bayesian networks (DBNs) are an effective tool to perform purely data-driven simulation of clinical data by, first, learning the joint probability distribution of patient covariates over time, and, then, resampling from the trained DBN to simulate the static and longitudinal data of an arbitrary number of virtual patients. While these simulated data can be (and have successfully been [14]) used for model training as if they were real patient data, there is no guarantee that the resulting model would then translate directly to real-life individuals. Challenges such as this are the focus of transfer learning (TL), a range of techniques aiming at transferring knowledge across tasks. A typical transfer learning workflow starts from a model that is known to solve a task on a given domain, the *source* domain, which is then adapted to solve a similar task on an adjacent domain, the *target* domain. This approach has shown great promise in different fields, especially in image recognition where, e.g., a deep neural network developed on generic image data (source domain) can be successfully adapted to radiology applications (target domain) without full retraining [5].

In the present work, we propose a novel approach combining DBNs and TL to develop deep, sequence-based models despite low data availability. Briefly, we first train a DBN on the training data and use it to simulate a large number of virtual patients, complete with their longitudinal data; then, we train a deep learning model based on recurrent neural networks on the simulated data (source domain); finally, we apply finetuning, a TL technique, to adapt the network trained on the simulated data to the target domain, i.e., the original, real data. Specifically, we focus on the case study of predicting 3-year mortality in amyotrophic lateral sclerosis (ALS), a rare (<0.01% prevalence) but fatal neurodegenerative

disease, based on the longitudinal data of 985 patients from the Piemonte and Valle d'Aosta ALS (PARALS) register [3], and show that our approach leads to a 8.2% performance improvement relative to an equivalent model trained from scratch on the real data only.

II. Data description and preparation

A. Database

We studied the data of a real-world cohort of 985 ALS patients extracted from the PARALS register. The data consisted of demographic and clinical information collected during routine screening visits, outlining the patients' status from diagnosis onwards. The information collected at diagnosis included sex, age at onset, site of onset (spinal or bulbar), diagnostic delay, body-mass index (BMI) both premorbid and at diagnosis, forced vital capacity (FVC) at diagnosis, the result of a genetic test on the main ALS-related genes (namely C9orf72, FUS, SOD1, and TARDBP), ALS familiality, and presence of frontotemporal dementia (FTD). Additionally, longitudinal information was also available both at the time of diagnosis and at each follow-up visit: namely, the use/administration of non-invasive ventilation (NIV) and percutaneous endoscopic gastrostomy (PEG), and the values of the Milano-Torino staging (MiToS) system [2], a scale comprising four binary variables reflecting impairment (or lack thereof) in the following four functional domains: breathing, walking/self-care, swallowing, and communicating. Finally, the date of death or tracheostomy (henceforth referred to simply as death, as tracheostomy-free survival is a conventional endpoint in ALS clinical trials) is also reported, if applicable.

B. Outcome definition and exclusion criteria

The prediction outcome for this study was 3-year mortality, i.e., the occurrence of death within 3 years after the 9-month longitudinal baseline that served as the input to the predictive model (see Section III-B).

Starting from the initial cohort of 985 patients, we applied the following exclusion criteria.

a) Subjects whose date of death preceded their first recorded visit.
b) Subjects with fewer than 2 visits before and 1 after the 9-month mark (the baseline length for prediction), to help the convergence of the DBN and ensure that all subjects had at least some longitudinal data.
c) Subjects for whom it was impossible to determine the prediction outcome, i.e., survivors censored before the 3-year mark.

This process resulted in the selection of 626 subjects, for a total of 7241 visits.

C. Data split and imputation

We split the data into a training, a validation, and a test sets, comprising 64%, 16%, and 20% of the subjects, respectively. The data characteristics are shown in Table I, with the continuous and categorical variables reported as means $\pm$ SD, and frequencies and proportions, respectively.

We then imputed the missing data by chained equations using the *mice* R package [15] with default parameters. To fit our modelling pipeline (see Section III) and avoid information leakage, we trained two imputers, one on the training data to impute missing values on the training and validation sets, and another on the union of the training and validation data to impute missing values on the entire database, including the test set. These steps resulted in a training set of 399 subjects and 4640 visits, a validation set of 98 subjects and 1128 visits, and a test set of 129 subjects and 1473 visits with no missing values.

TABLE I: DEMOGRAPHIC AND CLINICAL FEATURES OF THE STUDY POPULATION AFTER PREPROCESSING.

	Levels	**Training (n=399)**	**Validation (n=98)**	**Test (n=129)**
Sex	Female	197 (49.4%)	39 (39.8%)	60 (46.5%)
Familiality	Yes	44 (11.0%)	4 (4.1%)	10 (7.8%)
	<NA>	1 (0.3%)	0 (0%)	2 (1.6%)
Genetics	Mutated	44 (11.0%)	9 (9.2%)	8 (6.2%)
	<NA>	17 (4.3%)	6 (6.1%)	17 (13.2%)
FTD	Yes	42 (10.5%)	7 (7.1%)	19 (14.7%)
	<NA>	141 (35.3%)	31 (31.6%)	44 (34.1%)
Onset site	Bulbar	122 (30.6%)	26 (26.5%)	48 (37.2%)
Age at onset (years)		62.67 ± 11.17	62.78 ± 10.79	62.56 ± 10.34
Diagnostic delay (months)		12.00 ± 10.06	11.04 ± 10.28	12.00 ± 13.56
BMI premorbid (kg/m^2)		26.14 ± 4.39	26.17 ± 4.22	25.80 ± 3.73
BMI at diagnosis (kg/m^2)		25.19 ± 4.40	25.09 ± 4.71	24.32 ± 3.73
FVC at diagnosis (%)		93.41 ± 22.00	93.66 ± 23.13	90.69 ± 24.21
NIV	Administered	164 (41.1%)	42 (42.9%)	51 (39.5%)
PEG	Administered	134 (33.6%)	31 (31.6%)	49 (38.0%)
MiToS walking/self-care	Impaired	319 (79.9%)	77 (78.6%)	94 (72.9%)
MiToS swallowing	Impaired	142 (35.6%)	33 (33.7%)	50 (38.8%)
MiToS communication	Impaired	109 (27.3%)	31 (31.6%)	35 (27.1%)
MiToS breathing	Impaired	184 (46.1%)	44 (44.9%)	55 (42.6%)
Cumulative incidence of 36-month mortality		70.90%	68.40%	76.60%

III. Methodology

The proposed methodological pipeline is based on the cascade of a DBN and a TL approach known as finetuning [12]. Briefly, we performed the following sequence of actions.

i) Train a DBN on the training set and use it to simulate data from the training and validation sets.
ii) Develop a deep learning model based on recurrent neural networks on the simulated training data and use the simulated validation data for early stopping and hyperparameter optimisation. We call this model the encoder.
iii) Remove the output neuron from the encoder and attach a fully-connected subnetwork in its place to obtain the TL model.
iv) Train the TL model as per Section III-B on the real training data and use the real validation data for hyperparameter optimisation.

Finally, we compared the predictive performance of the TL model to that of a model with the same architecture as the encoder, but trained and optimised on the real data, on the real test set. The target metric was the cumulative/dynamic area under the receiver-operating characteristic curve (AUROC) [1] at 3 years.

A. DBN

DBNs are probabilistic graphical models capable of encoding the joint conditional probability distributions (CPDs) over time of a set of longitudinally-collected variables [10]. DBNs are well suited to modelling the evolution of diseases for descriptive and prognostic purposes (e.g., [13]). After a DBN has been trained, the probability relationships over time that it has encoded in the learning phase can be used to simulate,

starting from an initial (clinical) condition, the evolution over time of a population of subjects, thus obtaining an in silico population that preserves the trends seen in the real training population.

Here, we learnt a DBN starting from the training set using the *bnstruct* R package [4]. First, in order to better model the temporal evolution of ALS, we computed two derived variables for each visit: the distances of each visit from the onset (time since onset, TSO) and from the following visit (time between visits, TBV). Then, to allow the DBN to observe a more balanced occurrence of the death outcome, we coded survival at each visit as a binary variable answering the question "Will the subject die within the next 9 months?" We set the layering for the DBN, i.e., the rules that govern forbidden relationships, in accordance with literature knowledge (e.g., MiToS score values must depend on TSO, as they are expected to change as the disease progresses) and common sense (e.g., sex cannot depend on clinical values). The DBN structure was inferred using the Max-Min Hill-Climbing algorithm, using the Bayesian information criterion as the score function, while the CPDs' parameters were computed via maximum a posteriori estimation.

After learning the DBN on the training set, we simulated 100 synthetic repetitions of each real patient of both the training and validation sets starting from their first recorded visit, and ending after 40 virtual visits or on (simulated) death.

B. Transfer learning

1) Input data coding: The TL part of the proposed pipeline was based on recurrent neural networks. We considered a baseline window of 9 months to predict subsequent 3-year mortality. To leverage longitudinal information on the MiToS scores during the first 9 months, we used an input coding scheme that had previously proved successful for other applications [6]. Specifically, we built a (17×10) matrix where each row represented a variable and each column a visit within the 9-month baseline (up a maximum to 10). The first 6 rows were dedicated to dynamic data (the four MiToS scores, NIV, and PEG), while the remaining 11 to static variables (sex, age, familiality, genetics, onset site, FTD, diagnostic delay, time since onset, premorbid BMI, BMI at diagnosis, FVC at diagnosis). The data were right-aligned such that the latest visit within the baseline was in the tenth column. Static data were only reported on the tenth column as well. We used a masking value of "-1" to signal that either a visit was missing (which resulted in the 6 dynamic columns being masked at the missing row) or that the column referred to a static variable (which resulted in all rows except the tenth one being masked). Masked values were ignored during training.

2) Encoder and reference model: Developing an encoder is the first step to applying finetuning-based TL. In this context, an encoder is simply a model trained on the source domain (simulated data), which we will then extend to the target domain (real data) by attaching a fully-connected subnetwork to it and performing a second round of training on the real data. Particularly, for the encoder, we implemented a deep learning architecture based on recurrent layers as follows: the masked input matrix described in Section III-B1 enters a recurrent layer, possibly with dropout; then, the transformed sequence passes through a series of fully-connected layers with ReLU activation, of progressively halving size, finishing on a single output neuron with a sigmoid activation function, representing the predicted outcome, i.e., 3-year mortality. The hyperparameters of the architecture were: the type of recurrent layer (GRU or LSTM), its size (16, 32, or 64), its dropout (0 or 0.1) and recurrent dropout (0 or 0.1) levels, its activation function (ReLU or tanh), the number of fully-connected layers (2 or 3), and the number of nodes in the first fully-connected layer (16, 32, or 64). We used the simulated training data to tune the weights of the encoder via the ADAM algorithm (0.0001 learning rate) and the binary cross-entropy loss function. We used the simulated validation data to perform early stopping when the loss function on the simulated validation set stopped improving, and also to select the best hyperparameters as the ones maximising the (simulated) validation AUROC.

We followed the same procedure to train a reference model on the real data, i.e., a deep neural network with the same architecture, but trained and optimised on the real training and validation data, respectively. This model served as a comparison for the TL model.

3) Finetuned transfer learning model: To turn the encoder, i.e., the model able to solve the 3-year mortality prediction task on the source domain of simulated data, into the full TL model, we proceeded as follows. First, we removed the output neuron and retained the model, with its pre-trained weights, up until the last fully-connected layer, and we attached an untrained fully-connected subnetwork (hyperparameters: 2 or 3 progressively half-sized layers; 16, 32, or 64 nodes in the first layer) ending with a sigmoid-activated output neuron; then, keeping the encoder weights fixed for a number of pretraining epochs (0, 10, or 20), we trained only the newly-added fully-connected layers with the ADAM algorithm (learning rate 0.00005) on the real training set; finally, we finetuned the entire network, including the encoder weights, with a 100 times smaller learning rate. We used the real validation set to perform early stopping and hyperparameter optimisation. This procedure yielded the final TL model.

IV. Results and discussion

Figure 1 shows the DBN obtained on the training set, with nodes representing the variables and directed edges entering a node corresponding to the conditional dependency effect of the child node on its parents. Self-loops on the dynamic variables (blue nodes in the figure) represent the dependence of the variable at a time point from itself at the previous time point. Analysing the resulting relationships, we can see that the DBN effectively integrates the imposed literature relationships with others directly learned from the data. Numerous known relationships emerge, such as the relationship between ALS familiarity and age of onset [9], or the dependence of diagnostic delay on gender and site of onset [11]. The fact that the credibility of the relationships learnt by the DBN can

be checked via inspection of the graphical model allows for greater control over the expected quality of the simulated data compared to generic data augmentation techniques.

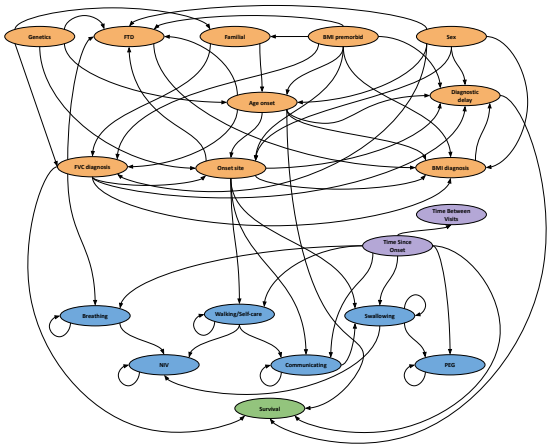

Fig. 1: DBN obtained on the training set. Dynamic variables are reported in blue (MiToS scores, NIV, and PEG), purple (TBV and TSO), and green (survival), while static variables are in orange.

Hyperparameter optimisation yielded the following results. The optimal reference model was made up of a size-32 ReLU-activated GRU with 0.1 dropout and 0.1 recurrent dropout, and two fully-connected layers of 32 and 16 neurons. The optimal TL model was the cascade of the optimal encoder (similar hyperparameters to the reference model, but different weights: size-32 GRU, ReLU activation, no dropout; two fully-connected layers of 32 and 16 neurons) and an optimal subnetwork of two fully-connected layers of sizes 16 and 8; the optimal number of pretraining epochs during which the encoder weights were fixed was 20.

TABLE II: PERFORMANCE EVALUATION ON THE REAL TEST SET (n=129).

Model	Training data	AUROC
Reference model	Real	0.649
Finetuned TL model	Real and simulated	0.702

Table II compares the reference model and the TL model on the task of predicting 3-year mortality after a 9-month baseline on the real data. The difference between the two was that the former only used the real data, whereas the latter was finetuned starting from an encoder learnt only on the data simulated by the DBN. We observed a substantial relative performance improvement of 8.2% between the reference model's AUROC of 0.649 and the TL model's AUROC of 0.702.

These results support the hypothesis that, while small-sample datasets might be insufficient, on their own, to develop deep sequence-based models, the opportune application of a cascade of DBNs (to simulate an adequate number of virtual subjects retaining the same conditional probability relationships over time as the original, real subjects) and TL (to adapt the model from the source domain of simulated data to the target domain of real data) may allow deep recurrent neural networks to learn a robust temporal representation of the data regardless of the original sample size. Having learnt such representation, a very limited number of real data are sufficient to finetune the model's parameters and improve on the reference model's performance. Future developments will pertain to the optimisation of the trade-off between the number of simulated data (computationally expensive) and model performance. This preliminary result is especially encouraging in the field of rare diseases, as it presents a novel, but effective way to implement high-capacity, sequence-based models despite the inevitably low cardinality of the available data.

***Abstract*—Interaction between the clinical and engineering worlds is essential for the development of new medical technologies, as well as the maintenance of medical advancements. In this context, software applications represent the potent, user-friendly, and highly analytical bridge between the two disciplines. In this research, we have developed a distributed web application whose computational core consists of a compartimental model of cardiac troponin release following acute myocardial infarction. This system allows reconstruction of the cardiac troponin release curve in patients with ST-Elevation Myocardial Infarction. The developed software represents an innovative platform geared toward personalized medicine, aming to simplify and expedite patient triage, as well as to support physicians during the diagnostic and prognostic phases. The application is also a valuable research tool since it enables for the structured and reliable collection and retrieval of clinical data to support further studies.**

I. INTRODUCTION

Cooperation between the information technologies (IT) world and the clinical sector is becoming increasingly cohesive and enables a significant reduction in the time and cost of diagnosis, the production of large volumes of data for research, and their classification and analysis in order to generate knowledge. In the literature, there are many examples of IT that can be used in the medical field. These range from simple toolboxes to computer programs with online or desktop interfaces. These software programs are typically used to analyze and/or extract information from experimental evidence transferred to computer data [1], [2], [3]. This type of applications are only a few instances of how small stand-alone programs may streamline healthcare operations and help research. However, designs that expand the reachability of such tools and systems that enable the gathering and handling of massive volumes of data (e.g. client-server, peer-to-peer) are frequently required. In this paper, we present a distributed web application for the reconstruction of the cardiac biomarkers release curves in patients with ST-Elevation acute Myocardial Infarction (STEMI), and that retains the core concept of the previously developed Cardiac Biomarker Release Analyzer (CBRA) [4]. The software consists of several interfaces, realized in MATLAB App Designer. These allow the definition of a customized flow of operations for each type of intended user, in an effort to simplify data entry and analysis. The development of a user-friendly interface for the implementation of the model-based algorithm for the reconstruction of the troponin curve was given special consideration. In fact, this allows for both the dynamic visualization of the curve and the modification of model resolution parameters. Finally, a system for anonymizing and recognizing shared data was developed, allowing the export of sensitive data to be omitted while still retrieving the patient's identity in response to a formal request containing the unique code. A distributed infrastructure was implemented to manage the workload and large quantities of data generated by multiple centres. The proposed distributed system is comprised of one datapoint per centre, with each datapoint consisting of a single machine with client-server architecture to make the software easily reachable. This serves to have a common data scheme for the various centres, and makes the workload and quantity of data easier to handle. As a result, the program adds a system for obtaining and analysing patients data, comparing the release curves of various patients, and providing large datasets, a hint for future research, to its fundamental role.

This article is structured as follows: Section II is dedicated to providing basic knowledge on the clinical aspect treated. All the information about the methodologies, development and deployment of the software platform are presented in the Section III, while Section IV is dedicated to the conclusions and future developments.

II. BACKGROUND

Acute myocardial infarction (AMI) represents the most frequent acute coronary syndromes as well as the primary cause of mortality in the world. An AMI occurs as a consequence of a coronary obstruction inducing necrosis of tissue due to insufficient perfusion of oxygen and nutrients [5]. The diagnosis is based on the analysis of the ECG trace, to monitor the electrical activity of the heart, and on the investigation of the presence of specific biomarkers for cardiac damage in the blood of patients. About the last point, the

gold standard biomarker for AMI detection is represented by cardiac troponin (cTn), a protein involved in the contraction of myocardial muscle cells, and composed of three constituent parts, C, I, and T. While the cTnC is similar to its skeletal isoforms, cTnT and cTnI are extremely specific for the necrosis of the heart tissue, [6], and they are commonly exploited in clinical practice.

Two types of AMI patients are distinguished: STEMI and NSTEMI. Due to complete coronary obstruction, STEMI patients exhibit the characteristic ST-tract elevation on the electrocardiogram. For NSTEMI patients, often with a non-complete obstruction, biomarker release curve analysis is essential at this point to assess their clinical situation [7]. Procopio et al., in [8], presented an ad-hoc mathematical model describing the variation of the concentration of cTnT among the cellular compartments of the sarcomere, cytosol, and plasma. Under physiologic conditions, cTnT is undetectable in the plasma: following an AMI, as a result of cell dismantling, the concentration of cTnT in this compartment rapidly increases. The mathematical model was derived from these physiological observations; specifically, it consisted of three differential equations that exploit Fick's first law of diffusion. The purpose of this model, [8], [9], integrated into CBRA, is therefore to reconstruct the missing data, beginning with those obtained from highly specific assays during the patient's hospitalization. Therefore, analyze the specific patient response and extract diagnostically useful information, such as the values and times of maximum concentration points or the time of AMI onset.

III. MATERIALS AND METHODS

A. Data management system

To prepare the application for workload management and maximise data acquisition from multiple centres, a distributed system was chosen. Each data centre consists of a database and application server running on a client-server architecture. Although the use of a single centralized server implementation allows for greater control, particularly in terms of version control over the entirety of the data, it is currently regarded as posing critical issues. The distributed implementation seeks to eliminate the need for a big data centre capable of storing a potentially large quantity of data over time. It also significantly improves client-server response times by having clients report to various independent server, due to the fact that each server can manage fewer simultaneous connections and, consequently, fewer tasks. Therefore, the entire amount of work performed by a single client-server architecture can be divided into as many tiny, independent same architectures. Because of the distributed and multi-center character, information acquired by several centres may be combined and conveyed into the same database structure. The data sharing system, on the other hand, enables for the download and import of a dataset built over time in one centre into another, as well as analysis between patient curves. Furthermore, once a substantial dataset has been produced, its export provides an ideal foundation not just for developing the model itself, but also for performing additional research on the data, using techniques such as machine learning.

In order to provide the capability of collecting and organizing data in a consistent way, a new database was designed. In the database composition, all the data have been organized in order to correctly identify their source (origin center and physician's data) as well as the related patient. The sensitive data have been differentiated from the clinical ones to establish a degree of separation between two different entities, which allows a convenient extraction of shareable data. The information required to reconstruct the release curve has been separated into two distinct classes: hospitalizations and acquisitions. Hospitalization serves to store data relating

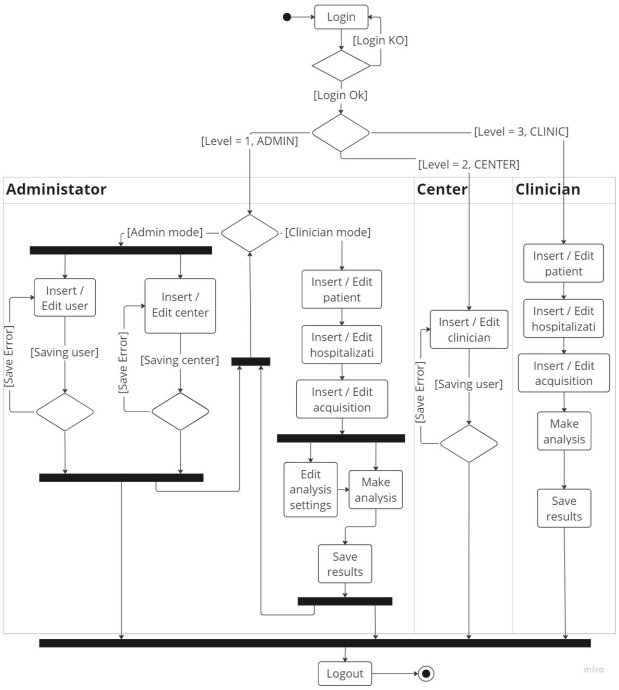

Fig. 1: Activity diagram outlining the available pathways of functionalities based on user types that logs in.

to the AMI, including the date and time of the event and admission, along with other patient clinical information. Acquisitions, on the other hand, are used to record data regarding experimental measurements, taking execution date-time and instant biomarker concentration. Due to these factors, it have been considered the following constraint rules:

1) Each user must be associated with a type that defines its functions and views within the system;
2) Users and patients must be limited to one center membership;
3) Access to all the system functions and the data must be available to admin users;
4) Clinicians users can only access to data of their patients;
5) A patient may be hospitalized more than once and each new admission may be associated with new acquisitions and simulations;
6) Each hospitalization must be associated with the patient, as well as the clinician user who inserts it;

7) Any acquisition must be associated with the current hospitalization.

B. User types and security system

The architecture of the security system starts with the login. To avoid unauthorized access, each user has a unique username and a password encrypted through a SHA-256 algorithm. The system validates these credentials and then determines level of access privileges granted to the user who is attempting to log in. To conduct the preceding check, the system refers to the external key in the user table, which contains the user type identifier. Three different types of users (ADMIN, CENTER, and CLINICIAN) are defined hierarchically, as a consequence, as shown in Figure 1, each has access to distinct functions. The ADMIN user has complete control over the system, including managing the centers on the same server and their user accounts as well as the personal and medical information of patients. In summary, an ADMIN can insert and modify centers, users, and patients, and he/she is able to manage clinical data related to experimental acquisitions or admissions and perform analysis for each patient. CENTER user is constrained to the simple management of the accounts associated with the reference center. Lastly, CLINICIAN user is limited to the management of patients with which he is affiliated, as well as performing standard analyses. Different user interface pathways, which direct the available functions depend on each user's security level, define these boundaries. To prevent cyberattacks, especially SQL injection, each text field is under the supervision of a function that scans the input field to ensure that no MySQL keywords are contained. This prevents the unexpected retrieval of data through the interface by attempting to send commands directly to the DBMS and provides an additional layer of protection between the user and the database. To significantly enhance the network security aspect, it is reasonable to equip the host server with a firewall that restricts access to the software to IP addresses that have been authorised. To preserve anonymity in the sharing system, clinical data is maintained as a distinct entity from personal data. Each patient is associated with a unique code to enable the tracing of any anomalous data about the patient. This code is generated upon insertion and identifies the patient individually. As described in Figure 2, it is composed of 24 alphanumeric characters made up of database source data. In order to reduce user input mistakes, a check system analyzes and reports indications of any empty fields.

C. Interfaces and scenarios

The entire software was written in MATLAB, with heavy reliance on App Designer for the user interface (UI) development. This section describes the different functions provided by the UI, and how the sequence of these produces a specific path of tasks for each type of user. Starting from the activities of the clinician, this user can enter all the information related to the personal and clinical data of his related center patients, as well as conduct analysis on the cardiac troponin release curves. The home page for clinicians users is composed of i) a navigation menu, ii) a summary table of patients, iii) a panel for the modification of personal data, and iv) a pop-up menu to select the collected patients, and access their hospitalizations and acquisitions data. Clinicians can access the page "Hospitalization", dedicated to the patient's clinical data through the navigation menu. The hospitalizations list for chosen patients, the time-series of cTnT based on related acquisitions, and a panel for adding or changing data can all be found on this page. Information about potential thrombolysis and subsequent revascularization in addition to the temporal data related to the hospitalization and the AMI occurrence are also stored. Additionally, there are clinical data for the TIMI Score calculation, used to gauge the risk of death in STEMI patients 30 days after the event: age, systolic blood pressure, heart rate (HR), weight, Killip classification, anterior ST elevation (STE), left bundle branch block (LBBB), diabetes mellitus, hypertension, angina, and time to thrombolytic treatment, [10]. The data relating to the concentrations of cTnT could be added using the same navigation menu to access the page "Acquisitions". The analysis interface presents commonly an output plot in the upper left corner, along with a patient summary. To perform a good analysis, the selected patient must have at least one hospitalization and 5 acquisitions. The Analysis page for clinicians consists of a panel showing a summary of the selected patient, the run button for the simulation start, and the axes where the curve will be plotted. Once the simulation is complete, the graph is plotted, and the results and time was taken are displayed in the relevant panel at the bottom. Regarding the user center, it was designed to have an intermediate level of security that would allow an administrator to manage the utilities of the center. Therefore, it consists of one interface that allows one to insert new users and navigate between those already present. The creation of new users is limited to the inclusion of clinical users. The admin view is designed to act as both a profile to manage the entire system of centers that are placed on the same server, as well as to perform more advanced analysis of the data. To reach this aim, the admin user can switch between the Admin and Clinician Advanced modes. Through the clinician mode, all the clinician interfaces, with some additional features, are available to the admin. The main difference between an Administrator and a Clinician user is present in the analysis interface: whereas the clinical user has the exclusive ability to run a simulation and check the results, an admin can change the initial configuration of the analysis, such as upper and lower bounds, initial values, and optimization algorithms. Once the simulation is complete, the graph is plotted, and the results and time was taken are displayed in the relevant panel at the bottom. Both the admin and the clinician users have also access to the sharing system: on the Home Page of the patient data management system, there are two buttons labeled Import and Export Data, which allow, respectively, the import, and export of clinical data through .csv or .xlsx files. In particular, to flavor the import of data, an ad hoc excel standard has been developed with database table-compatible fields, as well as a system that

automates and checks file loading. In compliance with patient privacy, the resulting CSV/XLSX can be utilized with third-party analytic tools in addition to serving as data exchange material between the centers.

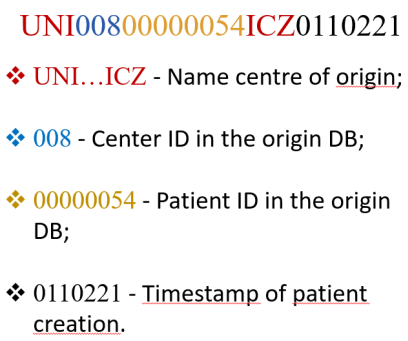

Fig. 2: Composition of the patient's identifying code, which includes i) the name, and id of the center, ii) the id of the patient, and iii) the creation time in the database of the origin center.

D. Deployment

MATLAB Web App Server and MATLAB Runtime v912 are required for software deployment. The minimum hardware requirements for running MATLAB Web App Server with a MATLAB Runtime are an x86-64 based CPU with at least one core, 1 GB of RAM, as well as an SSD of at least 60 GB. More precisely, the number of MATLAB server sessions that could be started at once, determines how many CPU cores and GB of RAM are needed. As a result, each center, that wants to utilize the program on a local server, can customize it to correspond to its requirements, and available resources based on the maximum number of concurrent users it wishes to support. For instance, the MATLAB server has to create 4 workers in order to support 4 concurrent sessions, hence at least 4 CPU cores and 4 GB of RAM must be accessible. All the tests are performed on a server with an Intel i7 octa-core CPU with 16 GB of RAM.

IV. CONCLUSION

The developed software, implementing the model-based core in a web-based application, provides a distributed platform for reconstructing the cTnT release curve, and for managing all collected patients data. The combination of the model-based approach and the capabilities of the web has enabled the development of a software with an intuitive UI that can improve data input and management operations. The remote connection to the server via network facilitates the clinician's ability to enter and retrieve data from any connected device. The new database associated enables data collection in a consistent and robust way and provides the doctor with an instant and comprehensive overview of the clinical status of the patients. The multi-centric architecture paired with the data-sharing system represents a further strength of this new software. This association reduces costs by constructing an ad hoc server with features specific to the requirements of the individual center, while the sharing system works as a bridge between the centers. In this manner, meaningful data for both clinical and scientific reasons may be acquired in large quantities and with minimal effort and enables the use of comprehensive software for collecting and analyzing measurements data of cardiac biomarkers. This application was developed in collaboration with the Interventional Cardiology unit of the University of Magna Graecia of Catanzaro, where it's currently being tested. As demonstrated by previous research, the model has also been extended to another cardiac biomarker, creatine kinase isoenzymes (CK-MB) [11]. The subsequent phases of development will therefore concentrate on supplying a system for analysing this and other biomarkers in future, as well as enhancing the software's performance and safety. Other potential future advances might be based on the integration of machine learning techniques for patient classification, and new clinical knowledge generation. Finally, the future goal will be to take advantage of the developed distributed platform for the implementation of a federated learning framework, to avoid privacy concerns and automate the process of model refinement.

***Abstract*—Work-related musculoskeletal disorders (WMSDs) represent one of the major issues concerning the occupational safety and health of workers. Thus, a reliable evaluation of workers' exposure to the risk factors that may contribute to WMSDs development is mandatory, above all, within an industrial context. At present, standard synthetic indices are widely used in this frame, presenting – however - several limitations due to poor reliability and time efficiency. The aim of this work was to investigate the contribution of the displacement quantified for each single joint during the execution of simple reaching tasks, to the overall discomfort of the worker evaluated by means of standard observational methods.**

Forty-five healthy volunteers were included in the analysis; each subject was asked to reach and rotate 2 spheres placed on a custom-made rack in standardized positions, i.e., above the head and one at floor level at centre side. Whole-body kinematics was acquired via a system based on wearable inertial measurement units. Standard ergonomic scales including RULA (Rapid Upper Limb Assessment), REBA (Rapid Entire Body Assessment), and MMGA (Method for Movement and Gesture Assessment), were assessed for each subject and each sphere position. Moreover, a quantitative index based on actual joint kinematics, i.e., W_1 index, was computed for each joint angle involved in the task. Correlation analysis was performed for W_1 relative to each joint with respect to RULA, REBA, and MMGA scores.

Considering REBA and MMGA scores, the most comfortable reaching areas were the ones in which the sphere was positioned at the top; in contrast, the lowest positions evidenced the most increased discomfort indexes. The RULA did not result sensitive to the different positions, while REBA and MMGA seemed to be more influenced by the range of motion of the lower limb joint angles than the upper limb ones.

This study underlines the necessity to focus on multiple potential contributors to WMSDs and underlines the importance of subject-specific approaches toward risk assessment by exploiting quantitative measurements and wearable technologies, which indeed represent key enabling approaches even in consideration of the novel "Industry 5.0" perspective.

***Keywords*—Ergonomics assessment, wearable technologies, kinematic monitoring, risk assessment, standard scales, RULA, REBA, MMGA.**

I. Introduction

Work-related musculoskeletal disorders (WMSDs) have been widely reported to be a leading cause of sick leave in many occupational contexts [1]. Indeed, within working environments, it is still common to suffer from repetitive arm movements, and awkward postures are widely adopted despite very recent improvements also due to the introduction of several enabling technologies, including exoskeletons and robots [2]. Indeed, within the actual context defined by "Industry 4.0", work intensity has been growing because of the presence of "hybrid" manufacturing lines which can involve workers in increasingly complex activities. For these reasons, very recently, "Industry 5.0" human-centric approach has been proposed also to mitigate these problems and promote the concepts of overall occupational well-being.

From a general perspective, health and welfare costs for workers must be considered when applying policies aimed at minimizing WMSDs risks. At present, to prevent WMSDs, the best practice is to properly evaluate the exposure to risk factors of a class of workers in a defined working environment during the realization of specific tasks characterizing their working shift; following this analysis it is mandatory to plan ergonomic interventions, as – for instance - a workplace redesign [3]. In this picture, a large number of observational methods, which are widely used in industry, have been presented in the last decades, most of which involve direct visual observation of workers during their activities [4,5]; this approach supports the need to assess the risk of developing WMSDs, which led to the definition of ergonomic scales addressing overall discomfort. In particular, RULA (Rapid Upper Limb Assessment) [6], and REBA (Rapid Entire Body Assessment)[7] represent the main applied methods during ergonomic risk assessment. On the other hand, these two scales present several limitations and have the main disadvantage to require a field expert who performs a time-consuming analysis of the postures.

Over the years some progress has been made to overcome the limits of these methods, leading - for example - to the definition of the MMGA (Method for Movement and Gesture Assessment) [8] and the introduction of wearable technologies, as inertial measurement units (IMUs) which allow for quantitative assessment [9].

However, the use of discrete parameters could be a limitation considering the inherent variability that exists in the ways individuals can complete a specific working task; in fact, most of the movements we perform during daily life activities involve different muscles and multiple joint coordination.

Recently, Lorenzini *et al.* designed a multi-index framework based on kinematic and dynamic parameters estimated via wearable technologies [9]. In particular, the authors proposed a kinematic-based displacement index (W_1) for each joint and degrees of freedom. However, the authors did not provide cues concerning possible relations between standard assessment methodologies and joint-specific metrics.

Therefore, this work aimed at investigating the contribution of the displacement quantified for each single joint (W_1)

during the execution of simple reaching tasks, to the overall discomfort of the worker evaluated by means of standard observational methods and scores. In fact, we hypothesized that W_1 represented a paradigmatic kinematic index able to better highlight the multi-factorial aspects that affect the overall discomfort of the worker and – vice versa – we focused on the need to introduce specific quantitative and subject-specific approaches able to better characterize the occupational risks and, thence, guide the mitigating strategies.

II. Materials and Methods

A. Participants

Forty-five healthy volunteers (33 females, 12 males, mean age 25.1 years old) were enrolled in the study. All the subjects reported no previous history of neurological disorders or recent orthopedic injuries. All subjects were right-handed according to the Edinburgh Handedness Inventory [10]. All the subjects were instructed with respect to the assessment procedure and signed informed consent. The study was approved by the local institutional review board (Comitato Etico dell' Area Vasta Emilia Nord, 10084, 12.03.2018).

B. Experimental setup and Testing procedure

Subjects were asked to perform motor tasks which consists of reaching and manipulating 2 soft spheres (6 cm diameter) placed on a 2x1 meters rack, adapting the experimental paradigm proposed by Andreoni et al. [8]. In particular, the 2 spheres were positioned according to the anthropometric measures of the subject and centered on the midline; the one in the lower position was placed 6 cm above the floor, whereas the one in the top position was moved in correspondence to the participant's height plus 10 cm. The subjects stand still in front of the rack with the feet behind a reference cross placed considering the length of the forearm plus 30 cm, to make the task more challenging. Each movement started from a static standing position with the arms by their side and the subject was asked to perform the task without crossing the reference line and without lifting their feet completely off the ground. From the starting position, participants reach and grasp the sphere addressing the manipulation of each sphere, i.e., three times clockwise rotations with the right hand. The task was repeated five times for each position of the spheres (i.e. the upper and lower ones). The experimental setup and task execution are reported in Figure 1.

C. Motion tracking

Whole-body kinematics was acquired by using a full-body motion tracking system based on IMUs (MVN Link and Biomech Awinda, XSens, The Netherlands). The motion trackers were positioned within the suit according to the protocol required by the manufacturer; in particular, 17 sensors were positioned on the subject to capture the movement of the following 23 body segments, which included the head, neck, eighth and tenth thoracic vertebra, third and fifth lumbar vertebra, right and left shoulder, right and left arm, right and left forearm, right and left hand, pelvis, right and left thigh, right and left shank, right and left foot, and right and left forefoot. Before starting the recording session, a calibration procedure was performed to align the motion trackers to the anatomical segments of the subject. The movement were acquired by using a sampling frequency of 240 Hz.

D. Data analysis

Data acquired by IMUs were first exported by using the Xsens MVN-Analyze software (XSens, The Netherlands). From the kinematic variables provided by the software, we selected three-dimensional joint angles which were exported via custom routines developed in a numerical computing environment (Matlab2018a; MathWorks Inc.). Before additional data processing, the start and end frames for each trial were determined. In particular, we focused only on the reaching phase which was segmented according to the tangential velocity of the hand [11]; the temporal boundaries of the reaching phase were identified as the times at which the hand velocity surpasses and returns below 5% of the peak velocity (reaching start and end, respectively).

Once defined the overall repetition, RULA and REBA indices were estimated and MMGA scores were calculated for each subject, each sphere position, and each trial and then averaged among trials. Moreover, the kinematic-based displacement index W_1 was computed for paradigmatic joints, including pelvis-trunk, right shoulder, right elbow, right wrist, right and left hips, right and left knees, and right and left ankle; W_1 was averaged among trials as well. We decided to not consider the joint angles relative to the left upper limb since all subjects were right-handed.

To evaluate the difference between lower and upper conditions, paired t-tests were conducted for RULA, REBA, and MMGA. Pearson's correlation analysis was performed for the values of W_1 relative to each joint with respect to the obtained, REBA, and MMGA scores, and Spearman correlation with RULA scores to assess their sensitivity with respect to the contribution of each individual joint.

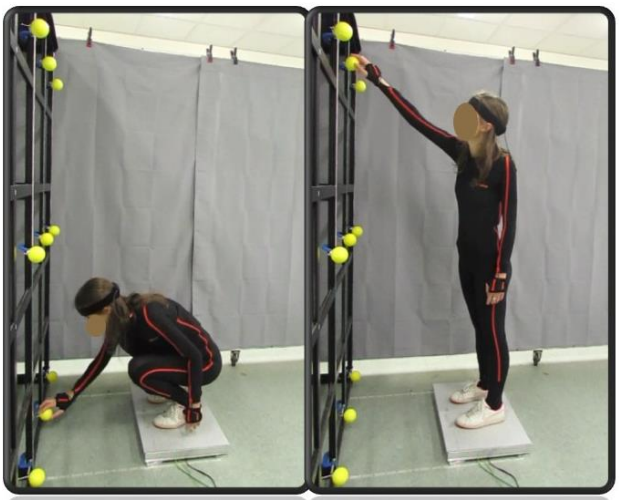

Fig. 1: Experimental setup; spheres on right, left sides and in the middle line were not used for this study.

III. Results and Discussions

Concerning the lowest and highest positions, the average scores of RULA were 6.08 (±0.56) and 5.97 (±0.33) ($t(44) = 1.56$, $p = 0.12$), whereas focusing on REBA we obtained a score of 10.04 (±0.72) and 7.46 (±0.71) ($t(44) = 22.73$, $p < 0.01$), respectively; from the analysis of

MMGA, the score was 424.75 (±44.62) for the lower and 190.42 (±21.72) for the highest position ($t(44) = 39.8$, $p < 0.01$).

Considering both REBA and MMGA scores, the reaching areas presenting less discomfort were the ones in which the sphere was positioned at the highest level; on the other hand, the lowest position evidenced the most increased discomfort indexes. Surprisingly, the RULA index did not highlight any difference between the tasks devoted to reaching the sphere positioned at the highest level with respect to that placed at the lowest one, highlighting a lack of sensitivity towards this kind of task.

Focusing on the correlation analysis, the main results are reported in Table 1.

TABLE 1 – SPEARMAN AND PEARSON'S CORRELATION COEFFICIENT AMONG W1 RELATIVE TO EACH JOINT WITH RESPECT TO RULA, REBA, AND MMGA SCORES. (*) INDICATES P < 0.05.

W_1	RULA	REBA	MMGA
Pelvis_trunk bend	*0,03*	*-0.64**	*-0.64**
Pelvis_trunk rot	*0,16*	*0.37**	*0.51**
Pelvis-trunk tilt	*0,29**	*0.92**	*0.95**
RShoulder Ab	*0,00*	*-0.72**	*-0.75**
RShoulder Rot	*-0,09*	*-0.76**	*-0.86**
RShoulder Flex	*-0,06*	*-0.61**	*-0.76**
RElbow prono	*0,02*	*0.11*	*0.10*
RElbow Flex	*-0,18*	*-0.79**	*-0.87**
RWrist Flex	*0,19*	*0.61**	*0.63**
RHip Ab	*0,18*	*0.72**	*0.85**
RHip Rot	*0,30**	*0.65**	*0.74**
RHip Flex	*0,16*	*0.90**	*0.96**
RKnee Flex	*0,13*	*0.89**	*0.97**
RAnkleFlex	*0,23**	*0.86**	*0.91**
LHip Ab	*0,21**	*0.71**	*0.81**
LHip Rot	*0,20**	*0.70**	*0.77**
LHip Flex	*0,17*	*0.90**	*0.96**
LKnee Flex	*0,06*	*0.88**	*0.96**
LAnkleFlex	*0,17*	*0.87**	*0.91**

In this frame, the RULA index significantly correlate with any W_1 of trunk bending, right and left hip rotation, right ankle flexion and left hip abduction. However, the correlation coefficient does not exceed 0.30 ,further underling the lack of sensitivity of this assessment method with respect to these specific tasks. On the other hand, both REBA and MMGA negatively correlate with trunk bending, all shoulder rotations, and elbow flexion ($r < -0.65$, $p < 0.01$); further, both indices positively correlate with trunk tilt and all rotations of the lower limbs' joint angles ($r > 0.65$, $p < 0.01$).

As we expected, and as it was confirmed by the analysis of W_1, the movements toward the highest vs lowest positions recruited body segments differently. Figure 2 shows, as a paradigmatic example, the difference in terms of joint angles curves. It is possible to notice that participants expressed higher shoulder flexion in movement toward the upside with respect to the ones in the low side. On the contrary, higher grades of knee flexion characterize the movement in the lower part of the rack. Finally, RULA seemed to be not sensitive to the different positions, whereas REBA and MMGA seem to be more influenced by the range of motion of the lower limbs' joint angles than the upper limbs' ones.

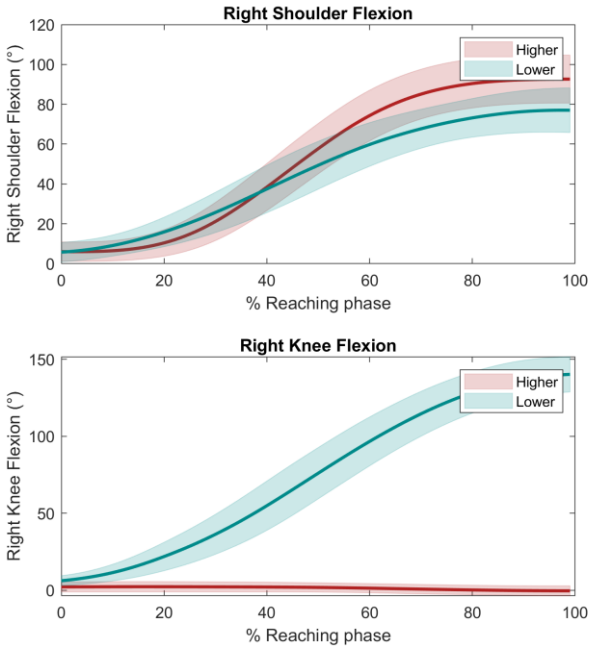

Fig. 2: Mean and standard deviation among subject of the normalized joint angle curves. Right shoulder flexion curves relative to task in the higher and lower position is depicted on the top. Right knee flexion is depicted in the bottom of the figure.

IV. CONCLUSION

The aim of this work was to investigate the contribution of each single joint, in terms of overall joint displacement (W_1) to the overall discomfort of the worker during the execution of manipulative tasks evaluated by means of standard observational methods and scores. In fact, we focused on the need for assessing which standard ergonomic index is more sensitive to the variations of the position of individual body districts.

From the main findings obtained in this study emerged that RULA index was indeed not sensitive to the different tasks required to reach the sphere placed at different positions; on the other hands both REBA and MMGA seemed to be more suitable to underline the ergonomic difference emerging from the two tasks. The reaching areas presenting less discomfort were the ones in which the sphere was positioned at the highest level, while the lowest position evidenced the most increased discomfort indexes.

Moreover, the REBA and MMGA seem to be mainly influenced by the range of motion of the lower limb joint angles than the upper limb ones.

Further studies should be conducted considering different tasks combining different body positions and applying different loads.

These findings suggest the need to focus on multiple potential contributors to WMSDs and underline the importance of subject-specific approaches toward risk assessment by exploiting quantitative measurements and wearable technologies, which indeed represent key enabling approaches within "Industry 5.0" perspective.

EyeLab: a user-friendly Matlab tool for real-time monitoring of eye movements

G. Olla[1], G. Sedda[1], A. Bonfiglio[1], S. Traccis[2], and D. Pani[1]

[2] *Dept. of Neurology, Ospedale Antonio Segni, Ozieri (Italy)*

***Abstract*—Despite the advantages of objective analysis of oculomotor behaviour and the continuous progresses in eye-tracking technologies, eye-movement studies are likely confined to research laboratories and seldom applied in the clinical practice. The neurologist's expertise in reading the traces from eye-trackers, along with the specialized technical knowledge required to manage, program and use such tools, hampered their widespread adoption.**

Recently, many open-source software tools have been developed to expand the usability of eye tracking systems to study oculomotor functioning, but none of these allows the experimenter to simultaneously control the trial and visualize and monitor eye movements in real-time.

In this work, we present EyeLab, a new MATLAB graphical user interface developed for the analysis of both saccadic and smooth pursuit eye movements while using the video-based Eye Link II eye-tracker by SR Research. Developed by exploiting the Psychophysics Toolbox, it extends the functionalities of EyeLink II by introducing and managing an intuitive real-time monitoring user-friendly interface on a third screen, which also allows personalizing the experimental procedure and managing data acquisition, visualization, processing, and storage, without requiring programming skills to the user. The real-time features enable the prompt adaptation of the experimental protocol to the ongoing results and the correction of any setup problem that could affect the correct acquisition of a whole set of tests.

***Keywords*—eye tracking, graphical user interface, real-time monitoring.**

I. Introduction

EYE movements are excellent markers for predicting, documenting and diagnosing multiple neurological abnormalities. For example, reduction in pursuit gain has been reported in patients with schizophrenia [1] and with mild traumatic brain injuries, the latter in conjunction with a decrease in vergence velocity and an increase in the trial-to-trial variability of eye movements [2, 3]. In addition, an increase in the number of errors on anti-saccade tasks and prolongation of the saccadic latency have been documented in patients with dementia or with Parkinson disease [4, 5].

Although these changes in eye movements are large enough to produce disturbances in patients, at the same time they are often too small to be detected by direct qualitative observation by the doctor, typically representing the standard approach during a clinical examination [6, 7]. The quantitative study of eye movements allows the ophthalmologist or the neurologist obtaining oculomotor measurements with very high spatial and temporal resolution, to permanently record the data and access them during the post-processing phase, in order to calculate quantitative indicators of eye movement such as the response gain, which corresponds to the speed of the eye relative to the speed of the objective, the speed of the head, and so on.

Despite the obvious advantages of objective and quantitative analysis of oculomotor functioning and the continuous advances in eye-tracking technologies, they remain relatively rare in current clinical practice compared to subjective evaluation [8]. Specialty clinics often have devices that are dedicated to particular kinds of eye movement testing, such as video-oculography for the evaluation of vestibular function [9], or limbal trackers for recording eye movements during reading [10].

In comparison, video-based eye tracking systems are more confined to research applications [11, 9], because they are more expensive and require high programming skills to the user in order to be integrated in custom experimental protocols [12, 13]. They generally are stand-alone devices with proprietary software and have the advantage of being portable, lightweight and optionally head-mounted, which makes them ideal for tracking the eyes in natural head-free condition and for vestibular testing. For many applications this is enough to make accurate clinical judgments, because of the richness of relevant features of eye movements.

The current rapid rate of technological improvement should ensure that systems with integrated sophisticated eye-tracking capabilities will be deployed more commonly in the clinic, for example by providing appropriate and user-friendly interfaces to allow for eye movement signals to be sampled, stored, and visualized and possibly exploited to the best clinical advantage.

In the present study, we introduce EyeLab, a novel open-source MATLAB graphical user interface that leverages on the features provided by Psychtoolbox-3 f to allow both clinicians and researchers to use the commercial EyeLink II eye-tracking system by SR Research with intuitive and novel intuitive features, without requiring users to have programming skills and with the aim to encourage the introduction of this technology in the clinical practice.

II. Materials and Methods

EyeLab is a new open-source tool provided with a user-friendly graphical user interface (GUI), which substantially extends the conventional capabilities of the EyeLink II eye-tracker by SR Research, providing a real-time control interface on an additional screen to configure and personalize the experimental procedure and manage data acquisition, visualization, processing, and storage.

The EyeLab GUI is intuitive and does not require users to have programming skills; it consists of three main processing

modules:
1. the Real Time Analysis Interface, for real-time monitoring the binocular oculomotor signals during the experiment, while the participant is performing the task. Figure 1 shows the panel of the interface where the signals acquired and processed in real-time (position and velocity of both eyes) are displayed.

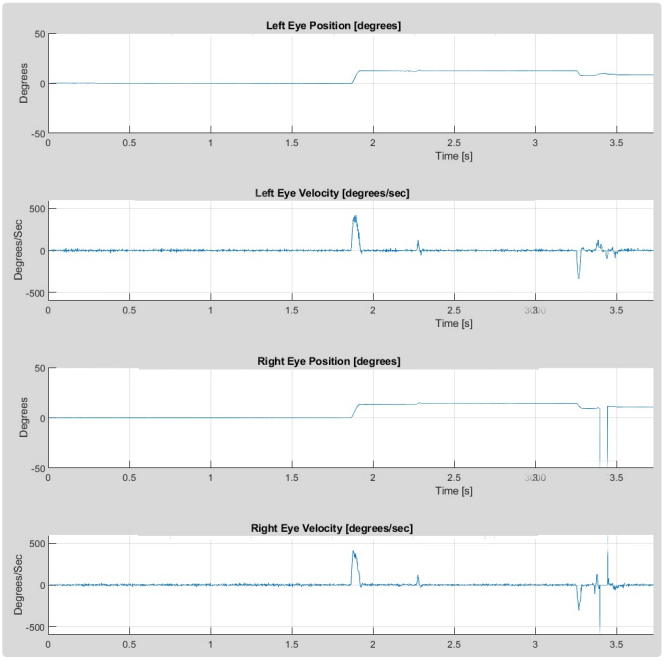

Figure 1. Visualization of eyes' position and velocity in the Real-Time Analysis Interface.

2. the OffLine Analysis Interface, which allows the experimenter to offline post-process the acquired signals (eye position and velocity),and provides several tools for performing the quantification and analysis of saccadic and smooth pursuit eye movements and fixations. For instance, the 'Show Saccades' panel displays one saccade at a time, specifying which eye it refers to, the temporal and spatial position and the duration (see Figure 2). This analysis can be performed using different algorithms [14] and setting constraints to filter the saccade search, such as the minimum temporal interval between two consecutive saccades, the latency interval, the window width, the minimum duration of the saccade or the velocity threshold.

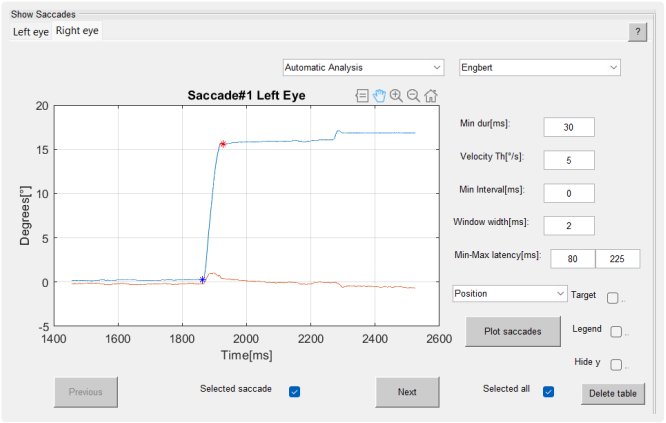

Figure 2. The 'Show Saccades' panel allows both post-processing and visualization of each saccade in the Offline Analysis Interface.

3. the Protocol-based Settings Interface (see Figure 3), which supply many functionalities to create and customize new experimental protocols, for example by generating automatic target movements in specific positions, for the study of saccadic movements.

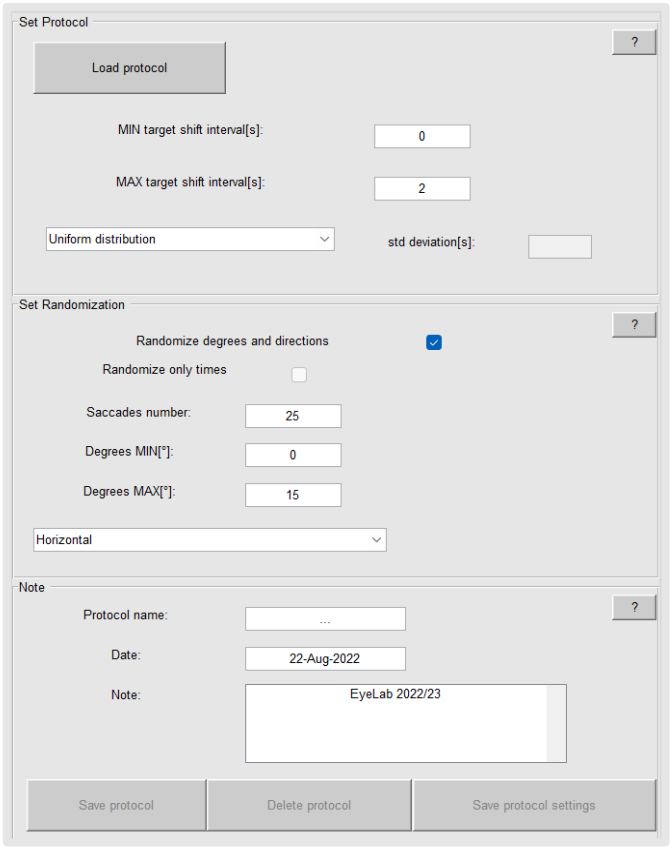

Figure 3. The Protocol-based Settings Interface

The 'Set Protocol' panel allows the experimenter to load a previously designed protocol or to create a new one, defining the visualization interval of the stimuli, which can be fixed or variable, and in this second case they can follow a certain statistical distribution (for example, a uniform distribution). Other panels of the same interface define the randomization protocol, the position of the targets, the pattern (for inducing, for example, saccades), repetitions and more.

Moreover, EyeLab can be installed on different operating systems (Windows, Linux, MacOS) as it is based on the Eyelink Toolbox functions, which provide an interface between the Psychophysics Toolbox Version 3 (PTB-3) for Matlab and the Eyelink II system. These functions work on raw data collected by EyeLink II, in particular the binocular time series of the participant's gaze on the screen on a normalized scale (using the screen size and the distance from the observer as reference). The application is standalone, so it does not require a Matlab license to function properly, but since it was developed under an academic license, it can currently only be released for educational purposes.

In summary, Eyelab is an intuitive and user-friendly GUI, allowing even less experienced users to better exploit the high potential and performance of the Eye Link II system, in order to encourage the introduction and diffusion of this type of

technology in the clinical ophthalmology practice and in research.

Integration with the EyeLink II system

The EyeLink II is the head-mounted video-based eye tracker with high resolution (less than 0.01°) and fast data rate (500 Hz). It is equipped with the Host Computer, which hosts the system application and is connected to the EyeLink II monitor, and the Display Computer, with its monitor surrounded by four active infrared markers in the corners, to track head movements, and adopted for displaying the visual stimuli.

The head-mounted system is composed of three miniature cameras mounted on a padded headband: one head-tracking camera is used to detect the infrared markers, while two eye cameras focus respectively on the left and right eye, providing high-quality computer-based eye tracking.

The Host Computer is used for performing the setup, the calibration and the validation procedures by using its proprietary GUI. The setup interface allows the experimenter to adjust the focus and position of the cameras relative to the pupils, in order to correctly place the headband on the subject's head; moreover, the user can choose many settings, including the number of points for calibration, the sampling frequency (250Hz or 500Hz), the tracking mode (Pupil-Corneal or Pupil Only Reflection mode), and others. The EyeLink GUI provides also two optional tools: the Experiment Builder function to set up a new experiment, and the Data Viewer, which allows the offline displaying, filtering, extraction and manipulation of EyeLink data.

On the Display PC, the experimenter can run the experimental applications by using the EyeLink API. With EyeLab it is possible to use a second monitor connected to the Display Computer, to provide the control interface that allows the experimenter to customize the experimental protocols, visualize the data acquired during the experiments in real-time, monitor, process and store the recorded signals, by disruptively widening the standard functionalities of the EyeLink II eye-tracker (see Figure 4).

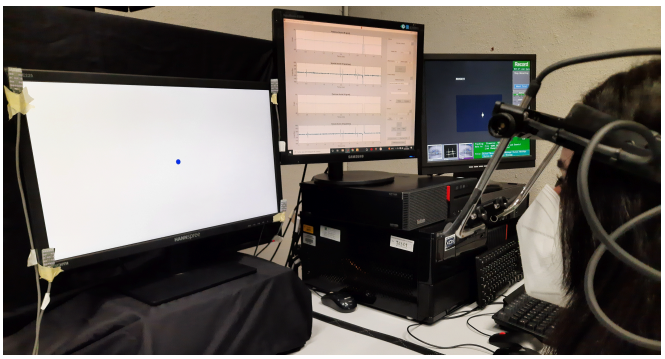

Figure 5. The EyeLab setup, with one monitor connected to the Host Computer (on the right) and two monitors connected to the Display Computer.

III. Preliminary Results

EyeLab allows the user to visualize, record, store and process the oculomotor signals of both eyes, such as saccades, smooth pursuit movements, fixations, and blinks.

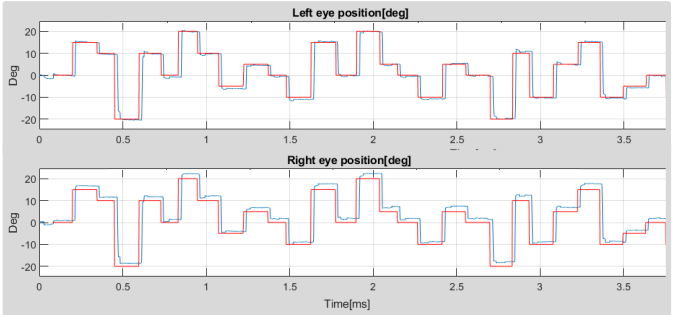

Figure 4. Binocular eye positions (see blue traces) recorded during a test for studying saccades, where the target (red traces) changes position quickly in the horizontal direction only.

For example, Figure 5 shows the binocular traces (in blue) of the right and left eye during a test for the study of saccades, carried out through the protocol-based interface. The exercise involves a single target (in red), initially placed in the center of the screen. Subsequently, the target moves by a pre/selected position, between ±20 deg in the horizontal direction only, with a random time interval between 125-135 ms. The experimenter can decide to pre-assign a test duration or to end the exercise by pressing a key on the keyboard.

Another example is reported in Figure 6, which reports the binocular traces (in blue) of the right and left eye during a sinusoidal smooth-pursuit exercise. In this case the target (in red), initially placed in the center of the screen, moves with harmonic motion only in the horizontal direction, with an excursion of ±20 deg.

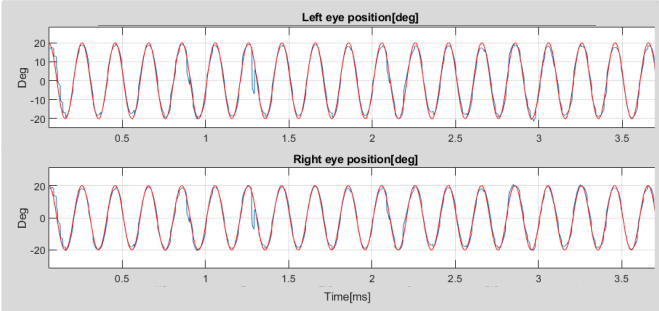

Figure 6. Binocular eye positions (in blue) recorded during harmonic smooth pursuit test (the target is in red).

IV. Conclusions

The benefits of objective analysis of oculomotor functioning and continuous advances in eye-tracking technologies are likely confined to research laboratories. EyeLab is a simple and intuitive interface for the study and assessment of eye movements, whose real-time features enable the adaptation of the experimental protocol to the ongoing results.

EyeLab was developed with neurologists longing for a usable tool that could go beyond neurological research, to enter the clinical practice. Tool validations are currently being performed.

Co-design of a points-based reward system to boost motivation in children and improve adherence to learning serious games

C. Piazzalunga[1], A. Donati[1], S. Ferrante[1]
[1] *Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy*

***Abstract*—Specific Learning Disorders are disabilities that impair the ability to learn, which can be mitigated through timely training. However, administering such training can be challenging due to screening difficulties, including teachers' inadequate training and clinicians' lengthy waiting lists, and to challenges posed by distance modalities and children's low compliance. To improve adherence and motivation, gamification techniques should be used. After a co-design process carried out with clinicians, teachers, and children, we thus added a coin-collection system and an in-game shop to the learning games of the ESSENCE project, and analyzed the trend of the usage and of the performance in the games to verify its impact. 66 children participated in the testing, for a total of 6822 serious games uses. Weekly usage increased after the introduction of both coins and shop (84.0 before, 145.6 after coins, 403.2 after shop), while performance improved significantly after the introduction of the coins, but not of the shop (0.66±0.24 before, 0.86±0.16 after coins, 0.87±0.13 after shop), suggesting that the presence of rewards was enough to improve adherence and lead to better results.**

***Keywords*—serious games, learning, gamification, adherence**

I. INTRODUCTION

Specific Learning Disorders (SLDs) are conditions that cause difficulties comprehending or processing information, and lead to subpar academic performance given proper conditions like age, intelligence, the absence of sensory-motor problems, and an adequate opportunity to learn. As of now, these disorders cannot be cured, but adequate training can alleviate their effects to lessen the impact of the disability on the subject's life. These training activities are especially effective if carried out early in a child's life. Thus, it is important that children are screened from a young age to allow for a timely intervention. To guarantee this, the 170/2010 Italian law [1] mandates that during the first years of primary school teachers are supposed to observe students to check if their evolution in reading, writing, and calculation skills are in line with their peers. If teachers notice that a student's development is subpar, they must try to compensate their difficulties with additional training; if the gap is not filled after the skills enhancement attempt it is likely they have a SLD, and teachers must report the case to the child's family and, eventually, to clinical professionals for further evaluation. This process presents several criticalities, like the teachers' lack of training or the length of waiting lists [2]. In addition to these problems, the lockdowns related to the COVID-19 pandemic impacted not only children's performance and mental health [3], but also SLD management [4]. The screening process, in fact, is much more difficult to carry out remotely, since the observation may not be as effective as in-presence, making it harder for teachers to exploit the benefits of personalized plans without adequate inspection upstream. Moreover, adherence to this kind of training is not guaranteed, as, without enough motivation and the control of a school environment, students may just ignore the proposed exercises, particularly if they find them challenging [5].

The pandemic was, however, a catalyst for technological development to cope with these new challenges, even leading the Italian Ministry of Education to include technological tools in their SLD managament guideline [2]. A recent European project, ESSENCE (Empathic platform to personally monitor, Stimulate, enrich, and aSsist Elders aNd Children in their Environment), is aimed at designing and developing a platform to support vulnerable populations (children and elders) through home-based care. In particular, the portion of the system catered to children includes several modules that strive to enrich every step of the SLD screening. In this work, we focus on ESSENCE's training tools, a set of serious games covering the three areas of learning: writing, reading and mathematics. The games were co-designed with psychologists, child neuropsychiatrists, teachers, and children by gamifying existing exercises.

The gamification process consists in the insertion of game design elements to exploit engagement, human competitiveness and ambition as strategies to make the user accomplish the task [6]. Some examples of gamification techniques are game elements, like points, badges, levels and scoreboards or leaderboards, game dynamics, with interactive elements and decision-making processes, parasocial relationships [7], and rewards [8].

However, gamifying reading, writing, or calculation exercises without distorting the rationale behind them is not an easy task; it means that the gamification features used can barely act on the mechanics and the stimuli, but have to focus on other aspects. To boost motivation in ESSENCE's users, we thus added an element which was external to the games: a system of rewards based on the collection of coins, which can be spent in an in-game shop to customize the main character, Bianchetto.

The central aim of this work is therefore to analyze the impact of the coins system and, later, of the shop, on the usage frequency of the games and on the children's performances in the games.

II. MATERIALS AND METHODS

A. Co-design of the rewards system

The target users of the ESSENCE platform are children attending the first and second year of primary school. One of the main principles adopted in the creation of the platform was that of co-design, which consists in the involvement of the relevant stakeholders in the design process. For the development of the shop, we involved clinicians, teachers, and children that were participating in the pilot testing of ESSENCE and were thus already acquainted with the platform and the games. Firstly, we organized focus groups (FGs) with clinicians and teachers, to identify which gamification factors were, in their experience, the most effective to boost adherence and motivation in primary school children. Then, we organized an in-presence FG with children, during which they were asked questions to investigate their opinions about a system of rewards, their preferences in terms of items to buy in an hypothetical shop, and the way in which they would have liked to customize the serious games experience.

Finally, the shop was developed using Unity 2021.3.8f1 (https://unity.com/).

B. Pilot testing

The ESSENCE project's platform was tested during a pilot testing phase which started in December 2021, and lasted until December 2022, whose protocol was approved by Politecnico di Milano's Ethical Committee n. 04/2021, date of approval March 23, 2021. 66 children participated, 30 females and 36 males; 21 of them were attending first grade, while 45 were in second grade. During the pilot testing, children were given a tablet (Samsung S6 Lite with the Samsung S-Pen) on which we gradually released 21 serious games, which implemented gamified exercises in the domains of reading, writing, and calculation. Even though access to the games was unrestricted, the families of the participants were instructed to monitor the children to avoid excessive usage and to encourage them to use the games once a week under the guidance of a teacher. The coins system was introduced on May 26, 2022, while the shop was introduced on October 24, 2022. For every element of the platform, from the shop to the games themselves, low-fidelity prototypes were used to gather feedback and refine the designs accordingly.

During the pilot testing phase, the serious games logged their results on the ESSENCE servers, recording the children's performances along with the number of coins they earned and the items they bought.

At the end of the pilot testing, the activities in the ESSENCE project were evaluated. Among other questions regarding the project, we asked:

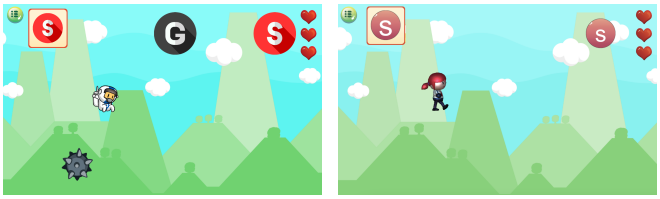
- What did you like the most about the serious games?
- Do you have any suggestions to improve the serious games?
- What did you like the most about the ESSENCE project?
- Do you have any suggestions to improve the ESSENCE project?

C. Data analysis

Data analysis was performed offline in Python 3.8 (https://www.python.org/).

Our hypothesis aimed to test whether the utilization of serious games increased following the implementation of both the coins system and the shop. We thus extracted the number of entries from the database to compare the frequency of usage before the introduction of the coins, between the introduction of the coins and the introduction of the shop, and after the introduction of the shop.

It is not enough to simply increase the usage of a tool, but its increased usage should lead to an improvement of performances. We thus chose the game that was played the most and which had some sort of quantitative measurement of performance, then computed the Moving Average of its results. We used a Friedman test to compare the distributions of the accuracy in each phase, identifying the phases that differ significantly with a Nemenyi post hoc test. Finally, we used the `ruptures` library [9] to locate change points in the time series. We used the Dynamic programming algorithm in the library, which needs to know in advance how many points to find. We firstly set this parameter to 1 to identify the most relevant change point, then we increased it up to 3 to locate other interesting dates.



III. RESULTS

A. Co-design of the rewards system

The FG with clincians highlighted the impossibility to distort the serious games' mechanics in favor of gamification. Because of this, the techniques chosen were rewards and customization, which act on factors that are external to the games themselves.

Regarding the children FG, the vast majority of the suggestions that emerged regard clothing, while the remaining ones concern the appearance of Bianchetto (shape of facial features, color of skin). It was thus decided to allow the customization of the character in these two aspects, while ignoring other popular customization options, such as animations, or voices.

The results from the FG were also used to define how to structure the collection of currency. To encourage children to explore all of the games, we introduced three different currencies, one of each learning domain, instead of having just one type of coins. The type of coin is determined by the domain to which the game belongs and is symbolized by an icon coherent with its setting: leaves for reading, which is set in the forest; suns for writing, set in the savannah; droplets for calculation, set in the pond. The number of coins that games grant ranges from 1 to 10, proportional to the child's performance, but never amounting to zero. This was done in accord with the advice of clinicians and teachers, to

(a) (b)

Fig. 1: A screenshot of the game Quick catch **(a)** without the customized character and **(b)** with the customized character.

encourage children who may struggle with some games and avoid feelings of mortification.

Regarding the way in which children wanted to make use of the items bought in the shop, during the FG the idea of seeing the customized character inside the game themselves emerged. Therefore, after the introduction of the shop, we included a dressed-up version of Bianchetto in some of the games. This can be observed in Figure 1.

B. Description of the shop

The final version of the shop can be observed in Figure 2. The coins' values are retrieved from the user's profile, which is stored in ESSENCE's database. We included a tutorial, which is loaded automatically the first time the shop is open and can be then accessed through a button.

Fig. 2: Final shop implementation

C. Pilot testing

By the end of the pilot testing, 3 first-grade children and 2 second-grade children had dropped out of the study because they had changed schools. Because of this, the final questionnaire was filled by 59 children. Regarding the unstructured questions about preferences, we reported the answers in Figure 3. Regarding the suggestions, most children wished either for more games or for more customization options.

D. Impact of the reward system on the adherence and the performance

1) Game usage: The total number of usages of the serious games was 6822. Table I reports the number of usages and the weekly frequency of usage in the corresponding period.

TABLE I: Usage of serious games.

Period	*N. of usages*	*N. of usages / week*
Before coins	1462	84.0
Between coins and shop	3112	145.6
After shop	2248	403.2

(a) (b)

Fig. 3: Word clouds of the preferences of the children regarding **(a)** the serious games and **(b)** the whole project.

2) Game performance: To check if the introduction of the rewards had any impact on the performance in the game, we chose to analyze the results of "Quick catch", a reading game, which was the one that children appreciated the most. It was the second most played game, at 1258 times. We discarded the most played game, "Tunnels", as it did not have an objective quantitative measure of performance, while "Quick catch" had a numerical outcome, namely the accuracy. The average accuracy values can be found in Table II. The results are shown in Figure 4, while the Moving Average of the accuracy can be observed in Figure 4..

TABLE II: Average performance of Quick catch.

Period	*Accuracy*
Before coins	0.66 ± 0.24
Between coins and shop	0.86 ± 0.16
After shop	0.87 ± 0.13

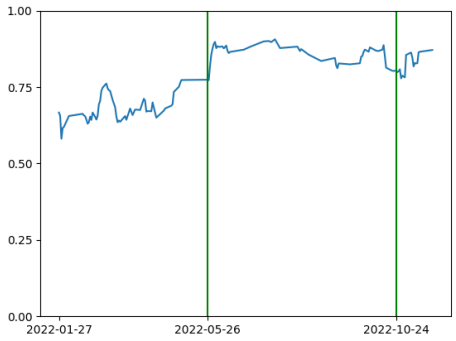


Fig. 4: Plot showing the Moving Average of the Quick catch accuracy, along with the date of introduction of the coins and of the shop.

The Friedman test found the averages of the accuracy were different in the three considered periods (t: 39.18, p-value < 0.001). The post hoc test located differences between the period before the introduction of the coins and the other two (p-value < 0.001), while the introduction of the shop did not generate a significant difference. The `ruptures` library detected the day of the introduction of the coins as a breakpoint in the trend of the accuracy. Conversely, the day of the introduction of the shop was not detected as a change point, not even when increasing the number of breakpoints to look for.

IV. DISCUSSION

Specific Learning Disorders (SLDs) are conditions that impair the ability to process information and cause difficulties during schooling. To strengthen the training, which is necessary to alleviate their effects, we co-designed with teachers, clinicians and children some gamification elements to enrich the serious games of the ESSENCE project. We identified rewards and customization, in the form of coins and of a shop, as adequate techniques. Children tested the serious games during a year-long pilot, at the end of which they filled a satisfaction questionnaire. To verify whether the aforementioned gamification elements contributed to an increment in usage and an improvement in performances, we compared the weekly usages of the games before and after the introduction of the coins and of the shop, along with the average accuracy obtained by users in the most relevant game. We then used the `ruptures` package to identify changes in the trend in this game's accuracy.

The pilot testing included 66 first- and second-grade children, who played the serious games for a total of 6822 times. Looking at the number of uses per week (84.0 before coins, 145.6 between coins and shop, 403.2 after coins) it is apparent that the introduction of the rewards caused an increase in usage frequency, which grew even more after the introduction of the shop.

Accuracy was then taken into consideration, comparing the average results in the three different periods. It emerged that the average accuracy increased over time (0.66 ± 0.24 before coins, 0.86 ± 0.16 after coins, 0.87 ± 0.13 after the shop), although the starkest difference is the one consequent to the introduction of coins. The Friedman test and the Nemenyi post hoc test confirm this, since it emerged that the three periods have different averages of the accuracy (t: 39.18, p-value $<$ 0.001), but only the differences between the first period and the other two were significant ($p < 0.001$). The increasing of performances by itself is surely not enough to impute credit to the gamification elements, since other confounding factors, such as the increasing familiarity with the games and the age of the children, may have influenced this increment. However, when looking for breakpoints in the trend of accuracy, the first point that was detected was exactly the introduction of the coins. This suggests that the impact of the rewards on the performance was strong, and that their introduction was not the sole cause, but a driving force that brought children to engage more with the games, acquiring more familiarity, and achieving better results. Conversely, the introduction of the shop was not relevant. This may be explained by its late introduction, or may mean that children did not necessarily need a way to employ the rewards that they earned during the games, since the satisfaction of collecting the coins was, in itself, a sufficient reason to engage with the games more. However, the shop was particularly appreciated by children, as emerged from the questionnaire, so its importance should not be undermined, particularly because it is plausible that the appeal of the coins' collection came from the knowledge that they would have a way to spend them. It is also important to note that some children stopped caring about the collection of coins after they had acquired the items they were interested in. Consequently, the shop could be a source of further engagement if enriched with more customization options.

ACKNOWLEDGEMENT

This research was funded by European Union's Horizon 2020 research and innovation programme under the call SC1-PHE-CORONAVIRUS-2020-2B grant number 101016112.

The authors wish to thank the schools in which the subjects were recruited and in which the data acquisition was carried out, primary schools "Risorgimento" and "San Benedetto", from Gavirate, province of Varese.

***Abstract*—The theme of usability in the medical field is becoming of vital importance for the development of new software and medical devices that can meet users' needs. The main purpose of this work is to design a usability test of a 3D viewer for biomedical images, by following the guidelines for the development of usable software, and then to define the procedures that should be used for future usability evaluation. In our specific purpose, the fastest access to all basic functionalities of the viewer was identified as the goal. The entire usability evaluation was designed to test the software from this perspective. The test environment was setup with all equipment necessary to conduct the test, specific and exploratory tasks were defined, test administration and collection of results have been planned. Finally, participants have been recruited and a pilot test was successfully conducted, validating the designed usability test.**

***Keywords*—usability, 3d viewer, healthcare, medical device.**

I. INTRODUCTION

Usability, according to the international standard ISO 9241, is "the extent to which a system, product, or service can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [1]. Assessing usability means evaluating the ease of an interface to be used by a group of users to perform a given operation. This assessment can be performed via usability testing, defined as "an evaluation that involves representative users performing specific tasks with the system to enable the measurement of efficiency, effectiveness, and/or user satisfaction" [2]. To fulfil the goals of improving the delivery of health care and increasing patient safety, the technologies must be demonstrated as not being error-prone. Usability evaluation, part of the whole process of risk management for medical devices [3], is one way of ensuring that interactive systems are adapted to the users, to their tasks and that there are no negative outcomes of their usage [4]. In this sense, it is part of a process of health technology design management based on evidence [5], [6] which can be also applied to several other aspects of the healthcare environment [7], [8], [9]. Human Factors Engineering (HFE) is a discipline concerned with the design of tools, machines, and systems that take into account human capabilities, limitations, and characteristics. The goals are to design for safe, comfortable, and effective human use. Ergonomics, usability engineering, and user-centred design are considered synonymous [10]. "User-centered design" is built on an HFE process. The human-machine interface design approach here emphasizes user requirements, user characteristics, and end-user testing. The idea of iterative design and testing is another crucial aspect of this user-centred design methodology. Simply said, the design is iteratively improved throughout the design cycle based on the results of user testing (also known as usability testing), which is repeated at the very beginning of the design cycle [11]. ISO 26800 describes the ergonomics principles for interfaces, in order to improve safety, performance and usability by analysing the population target, the environment, the goals and the expected results [12]. ISO 9241-11 describes users, environment, resources, goals and tasks as different aspects of the context of the use of the analysed system, product or service, whose usability evaluation outcomes its effectiveness, efficiency and user's satisfaction [1] (Fig. 1).

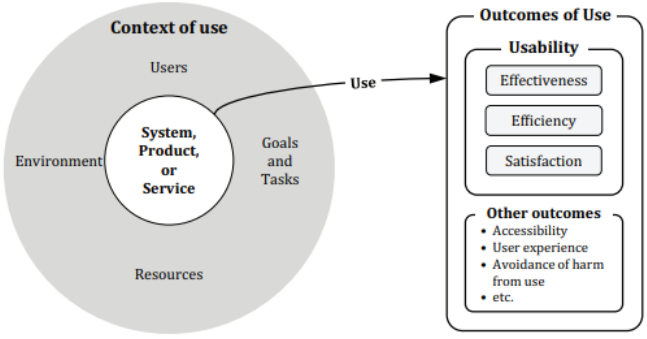

Fig. 1: Schematic representation of the different aspects of the context of the use of the analysed system according to the standard ISO 9241-11.

Finally, ISO 25066 examines different existing usability testing approaches: inspection and heuristics review of the interface, tests and post-market surveys [13]. Usability testing is a highly effective methodology for identifying barriers to use and for finding opportunities for making products, services and systems more effective, efficient and satisfying to use [14]. Usability tests can be conducted in a variety of environments

with varying degrees of formality, collecting various types of qualitative and quantitative data, and with different types of teams working with the end-users. Usability tests can be conducted both in a preliminary developing phase so that possible problems can be immediately identified and solved and after the distribution of the product. In the latter case, tests can reveal criticalities which may lead to updates with the aim of improving the user experience [15]. Tests must be thoroughly designed and planned by defining the number and the type of involved users, the methods of implementation, the measurements and the tasks to be verified. In this paper, the design of a test for the usability evaluation of a multi-modal medical imaging viewer platform, developed by Epica Imaginalis (Sesto Fiorentino, Italy), is presented. The software is a complex image viewer platform conceived to be used in diagnosis and planning, allowing visualization, exploration, measurement, comparison of multiple studies and planning of surgical procedures in compliance with the DICOM (Digital Imaging and COmmunications in Medicine) standard. The paper presents the methods employed to design and administer the tests.

II. METHODS

The designed usability test is structured to be performed as moderated in-lab testing (Fig. 2) with three well-defined phases so that a linear and homogeneous path could be followed. The main phases are:

- Preparation: in this phase, the questionnaires and the task lists have been designed according to the previous heuristic evaluation performed on the interface [16], together with the consultations of experts. Moreover, the typologies of users have also been defined, together with the location where the test will be administrated, and the tools needed.
- Execution: the real administration of the tests to the selected users. Testers have been monitored with specific tools (chosen in the previous phase) while interacting with the interface. In this phase, the two figures of the "observer" and the "moderator" are introduced. The former verifies the correct execution of the tasks, while the latter talks to the user, forcing him to "think aloud" so that every faced complexity can be addressed and noted.
- Analysis and Report: collected data are analysed, errors are pinning-out, and possible restyling of the interface is proposed according to the obtained results.

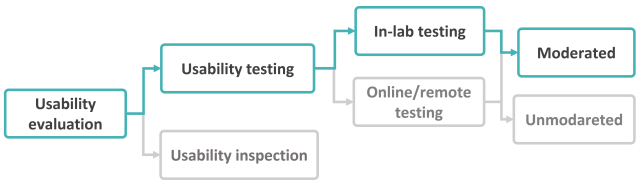

Fig. 2: Chosen structure of test administration.

In this paper, the authors focus on the technical choices made on preparation phase.

First of all, the goal of usability test was identified, as suggested by ISO 9241-11, 5.3.3. As the time the physicians spend for image exploration is critical, the focus of the preparation phase was to design the usability test, specifying as a goal the fastest access to all basic functionalities of the viewer platform. Analysing the heuristic evaluation previously performed on the interface, the total amount of 55 exploratory tasks and 4 specific tasks (Table I) was designed for each test: the former consist of tasks designed to explore the various functionalities of the viewer, while the latter are based upon hypothetical use cases which can include more than one exploratory task.

Next, the environment for the text execution was setup. Tests were thought to be conducted within two adjacent rooms, one for the user, and the other one for the moderator and the observer. Both a front and an external camera should be used to allow the moderator and the observer to look at the user's facial expression and his interaction with the interface (Fig. 3).

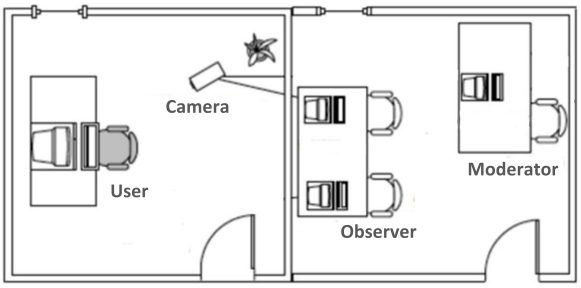

Fig. 3: Implemented environment for test administration.

Finally, the test was validated by the administration of the pilot session, that confirmed the reasonableness of the proposed methods.

III. RESULTS

Nielsen claims that five people are sufficient to identify more than 80% of the usability issues [17]. The intricacy of the study must be taken into account, though, because the harder the activities are, the more complex the study should be and the more volunteers would be needed. The complexity of the study is effectively decreased, enabling you to use fewer participants, if the same training is provided to the entire intended user population. Context and complexity have a major impact on the ideal participant count. According to Virzi, three to twenty people are the appropriate amount of participants for many studies [18]. Faulkner estimated that ten persons would likely identify at least 82% of the flaws [19]. Turner thinks that seven people is the ideal amount, even for challenging studies [20]. According to research, between three and twenty people can yield trustworthy results, with five to 10 being a good place to start. Generally speaking, more volunteers are needed for more difficult, risky initiatives, but fewer volunteers are needed to test more creative ideas. At the moment of writing this paper, 11 participants have been recruited for composing the testing population, which

is a satisfactory participants number according to the above statements. Four of the participants are biomedical engineers, two radiographers, two radiologists, one electronic engineer, one software developer, and one application specialist. They are mostly women (73%), with a working experience between 0 and 10 years (82%).

To assess the results of the usability tests, efficacy, efficiency, and user satisfaction will be evaluated. Efficacy is scored with the degree of completion of each task: 0 is for a failed task, 1 is an indirect success (a success accomplished within an easy task or with little help by the moderator), 2 is for a partly-corrected task, and 3 for a completed task, achieve without any help by the moderator and also without inspecting out-of-context functionalities. Efficiency is scored with the average time employed to complete each task. In case of failure, the maximum time defined for the task will be noted. Finally, user satisfaction will be evaluated with a post-test questionnaire.

In order to validate the designed test a pilot test was conducted on an external volunteer. The pilot test allows to verify all the technical choices made on preparation phase, such as the use of "transparent" screen recording software, camera position, and recording quality. Moreover, pilot test allowed to test the moderator and performer roles during the execution phase and evaluate the overall duration of the test to plan its administration. The results of the pilot test allowed to confirm the goodness of the overall design of the usability test, in term of location, tools and roles. The pilot user took 40 minutes to conduct the pilot test.

IV. CONCLUSIONS

The examination of a product's usability is advised as a crucial step in both its creation and enhancement. Nevertheless, many businesses still struggle to include usability assessment in their design and development processes, despite the practice's widely acknowledged benefits. The lack of research based on actual user contact with any program might result in the creation of a product that is sometimes dangerous or does not meet the needs of the user. This paper presents the design of a usability test following the best-practice guidelines and standards observed from the literature. The test will be administered to a group of recruited users, assessing efficacy, efficiency, and user satisfaction in relation to a multi-modal medical imaging viewer platform. Future works will analyse the whole method, presenting both quantitative and qualitative results emerging from the assessment. Moreover, a possible user-interface redesign to mitigate the observed criticalities will be also taken into account.

TABLE I: List of 55 exploratory tasks and 4 specific tasks.

Task Number	*Type*	*Task*
1	Exploratory	Open CAT CT on the desktop.
2	Exploratory	Open Settings and explore the various layout options and overlays. Chose the preferred one.
3	Exploratory	Test the layout for left-handed people. If you are not left-handed, go back to the default setting.
4	Exploratory	Test zoom, rotation, and panning. Edit window width and intensity level.
5	Exploratory	Switch to 2D modality in axial view and test again zoom, rotation, and panning.
6	Exploratory	Reset the geometry of the axial view.
7	Exploratory	Switch to 3D modality. Reset the volume to the initial state.
8	Exploratory	Make a screenshot and save it as "screenshot1" on the desktop. Do not anonymise the screenshot.
9	Exploratory	Anonymise the current study and hide all objects from the scene but the volume.
10	Exploratory	Open and then close DICOM tags.
11	Exploratory	Make objects visible on the scene again. Open the histogram.
12	Exploratory	Edit the current intensity with the histogram: set the value of width to about 2500 and the intensity to 1000.
13	Exploratory	Save the preset as "Preset1".
14	Exploratory	Open filter settings and change luminosity to 70. Apply the filter.
15	Exploratory	Open filter settings again and bring back luminosity to 50. Apply the filter.
16	Exploratory	Apply filter settings and undo the last setting.
17	Exploratory	Apply colour inversion. Reset the whole volume to its initial state.
18	Exploratory	Open the "Intensity Preset" menu and choose the "CT Cardiac" preset.
19	Exploratory	Move the histogram and set the values between 200 and 2500.
20	Exploratory	Save the preset as "Preset2".
21	Exploratory	Open "Transfer Function" and select "CT Lung Transfer Function".
22	Exploratory	Change the colour of some points to taste.
23	Exploratory	Add a new point.
24	Exploratory	Add a new tissue.
25	Exploratory	Remove a point to taste.
26	Exploratory	Save the preset as "Transfer1".
27	Exploratory	Open the coronal view in widescreen.
28	Exploratory	Measure a length and an angle.
29	Exploratory	Perform a measurement with the ellipse tool.
30	Exploratory	Change the colour of the ellipse measurement, then delete it.
31	Exploratory	Reset the layout to its initial state.
32	Exploratory	Browse through the slices of the coronal view, open the list of performed measurements, and select the angular one.
33	Exploratory	Open the list of performed measurements, hide the one referred to length.
34	Exploratory	Hide all the measurements only in the 3D view.
35	Exploratory	Delete the length measurement, and then delete all the measurements.
36	Exploratory	Open "Slab Thickness" function.
37	Exploratory	Edit the thickness to 46mm. Test the following functions: maximum, averaging, and minimum projection. Unselect the "Slab Thickness" function.
38	Exploratory	Cut the 3D series with the cube tool.
39	Exploratory	Hide the cube tool.
40	Exploratory	Try the "axial cut" modality.
41	Exploratory	Choose the "ISO Surface" visualization algorithm, then reset the volume to its initial state.
42	Exploratory	Try the "Play" modality. Set the frame rate to 20fps and then stop it.
43	Exploratory	Open SIMBA Single Stack CT on the desktop.
44	Exploratory	Open advanced menu and select "compare".
45	Exploratory	Inspect the volumes to taste, then lock them and continue the exploration.
46	Exploratory	Reset the geometry of both volumes to their locked states.
47	Exploratory	Unlock and reset the geometry of both volumes to their initial state.
48	Exploratory	Exit the "compare" modality.
49	Exploratory	Open "planning" modality.
50	Exploratory	Plan an intervention with the cannula: place it to taste.
51	Exploratory	Open the list of performed planning, hide the planning and then delete it.
52	Exploratory	Try the "scalpel" tool, save the planning and exit the modality.
53	Exploratory	Select the axial view and try the "multislices" modality.
54	Exploratory	Change the layout and edit the space between slices.
55	Exploratory	Switch to the sagittal view and then exit the "multislices" modality.
1	Specific	Locate the post-traumatic fracture by performing the appropriate reconstructions.
2	Specific	Locate the screw, and calculate the inclination between it and the vertebrae in relation to the vertical axe. Then check the correct placement.
3	Specific	Locate the dental cavity and perform a comparison between the current and the past state of the tooth acquired with a CT.
4	Specific	Make the 2D views visible and locate the spine calcification.

A computational platform to assess the metabolic-electrophysiological behaviour of neurons cultured in monolayers

R. Fabbri[1, 2], A. Ahluwalia[1,2], and C. Magliaro[1,2]

[2] *Research Center "Enrico Piaggio", University of Pisa*

***Abstract*—Current computational models of biological neural networks do not include oxygen concentration as an input variable influencing neuron electrophysiological activity. However, oxygen concentration constitutes a limiting factor for cell viability and function in vitro. The aim of this work is to develop a platform to model the oxygen dependent electrophysiology of neurons cultured in monolayers. The model accounts for oxygen diffusion and consumption to supply metabolic energy for the electrical firing of a neuron. The platform is built to be modular: each block simulating a neuron can be connected to create neuronal network models with different layouts. Preliminary results show the expected oxygen-dependent behaviour of the model. The platform can be a powerful tool in the field of neuronal models, allowing different types of neurons, synapses and networks to be implemented.**

***Keywords*—neuronal cultures, computational platform, firing, oxygen.**

I. Introduction

In vitro models of neural tissues represent invaluable tools for the study of the human brain in both its physiological and diseased conditions. Different cell sources, substrate materials and architectures can be adopted to obtain in vitro models with controlled and tailored features [1].

Traditional cellular models of the brain are represented by two-dimensional (2D) monolayers, where neurons are seeded on Petri dishes or culture flasks either directly or after coating them with a substrate for promoting cell adhesion. Then, the well is filled with a medium, containing substances allowing cells to survive and maintain their viability. The presence of medium also enables the diffusion of ambient oxygen to the neuron monolayer. Thus, the availability of oxygen is a crucial factor affecting cell viability and functioning, as well as their electrophysiological behaviour. Indeed, since neuron firing is an ATP-dependent process, and local oxygen concentration plays a key role in determining how the neuronal networks behaves [2], [3].

However, generating and maintaining neural constructs is expensive due to low-throughput technology and costly reagents, especially if stem cell-derived neurons or primary neurons are involved [4]. Moreover, their lack of reproducibility limits their applicability in research (e.g., neurotoxicity) and regulatory testing [5]. Finally, the technologies currently available for characterizing the electrophysiological activity *in vitro* (e.g., patch clamp, micro-electrode array technology) do not enable a faithful characterization of the 3D electrophysiological activity at the single-cell level [6], [7]. In this scenario, computational model-based solutions can support the understanding of *in vitro* neural network behaviour. However, current computational models of biological neuronal networks do not include the local oxygen concentration as a variable.

To this end, we developed a novel computational platform for assessing the electrophysiological and metabolic behaviour of neurons in monolayer cultures. The platform embeds a model of neuron firing activity over time, considering its dependency on the local oxygen concentration. In Section II the mathematical model of the single neuron metabolism and electrophysiology is described, together with the neuronal network layouts and the development of the computational platform. Section III reports the results where the dependency of the simulation outputs on the local oxygen concentration is shown. Finally, Section IV summarises the main findings of the work and describes future developments.

II. Materials and Methods

A. Computational model of the single neuron

The model comprises neurons arranged on a culture plate filled with medium. Since oxygen is consumed by the cells for fuelling both their metabolic and electrophysiological functions, three phenomena occur: i) diffusion of oxygen from the outer environment through the medium, ii) neuron oxygen consumption and iii) their electrophysiological activity.

Since diffusion happens along the vertical direction (i.e., from the outside to the bottom of the culture plate), the system can be simplified and 1D geometry can be adopted. Thus, each neuron of the monolayer is modelled as a cube of edge 50 μm and a column of medium of height 1mm (h) which allows oxygen to diffuse along the z axis and reach the cell for fuelling its metabolic and electrophysiological activities (Fig. 1).

The governing equation of the single neuron behaviour is a modified version of the reaction diffusion equation where a term for oxygen dependent firing is introduced:

$$\frac{\partial C}{\partial t} = D\nabla^2 C + R(C) + F(C) \quad (1)$$

Eq. (1) states that the local oxygen concentration (C) over time depends on the diffusion of oxygen governed by the diffusion coefficient D, but also on its metabolic rate $R(C)$ and electrophysiological $F(C)$ consumption.

The consumption of oxygen is modelled using Michaelis-Menten kinetics:

$$R(C) = -\frac{OCR\ \rho\ C}{k_m + C} \quad (2)$$

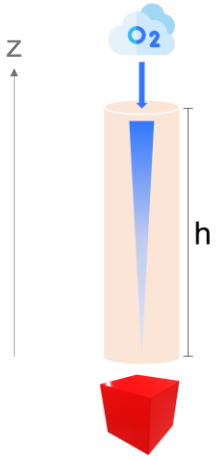

Fig. 1: Model of the single neuron within the monolayer

Where OCR is the maximum Oxygen Consumption Rate of a single neuron and k_m is the Michaelis-Menten constant.

The electrophysiological activity of the neurons is described by a modified version of the Hodgkin-Huxley model [8], where the dependency on oxygen is introduced:

$$F(C) = -\alpha\lambda\left(I_{pump}(C) + I_{gliapump}(C)\right) \quad (3)$$

I_{pump} and $I_{gliapump}$ are respectively the ionic current of the Na-K-ATP and Na-K glial pumps, both of which depend on the local O_2 concentration [8]. All the parameters of the model are listed in Table I.

TABLE I: PARAMETERS OF THE COMPUTATIONAL MODEL

Symbol	*Model parameter*	*Value*
D	Oxygen diffusion coefficient	1.75 e-12 m^2/ms
OCR	Oxygen Consumption Rate	8.6 e-16 g/s
ρ	Cell density	8 e12 cell/m^3
k_m	Michaelis-Menten constant	0.03 mM
α	Conversion factor	5.3 g/mol
λ	Relative cell density	1

B. *Neuronal network models*

Neurons arranged in monolayers can form synaptic connections [9], [10]. Thus, the single neuron model is exploited for implementing networks of neurons, to analyse the influence of oxygen on their collective electrophysiological output. The connections were modelled as electrical synapses, i.e., gap junctions, with conductance gain following a log-normal distribution with values from 0.1 to 1 mS/cm^2 [11].

For studying the electrophysiological behaviour of neurons when connected in a network, three different layouts were defined. Two topologies reproduce the arrangement of the electrodes of microelectrode arrays (MEA), the technology usually used to measure the electrophysiological activity in vitro [12]. The grid arrangement of the 60 electrodes in the MEA layout and the corresponding neuronal network models are depicted in the first line of Fig. 2. The first network model comprises 60 neurons and the other one 256. Although the MEA-like grid arrangements do not reproduce the actual distribution of neurons, these layouts facilitate the comparison of the model outputs with experimental data from neurons cultured on MEA chips. In the network with 256 neurons the outputs of four cells were mediated to simulate the real setting acquisition of electrophysiological signals where each MEA electrode records the activity of about four adjacent neurons. In both the MEA-like layouts, connections between neuron blocks were randomly generated [13], [14].

The third network layout reproduces the so-called Small World (SW) networks [15]. SW networks have been reported to mimic the functional graphs of neural networks both in the brain and in vitro [16]–[18]. They are characterised by highly connected clusters of neighbour nodes. The SW network implemented in this work is made up of 60 neurons and 120 connections (Fig. 2, second line).

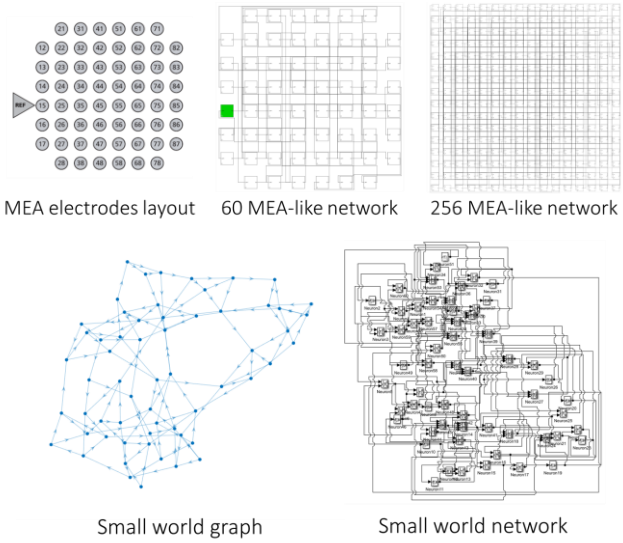

Fig. 2: Representations of the MEA-like and small world networks

C. *Computational platform*

The computational platform was developed in Matlab (The Mathworks Inc.) exploiting the Simulink toolbox. Specifically, the platform is constituted by a Simulink library where the functions describing the single neuron behaviour of Eq. 1 are embedded. Matlab scripts are used for the creation of the neuronal network layouts.

The output of each simulation is the membrane potential over time of each neuron of the network and the oxygen concentration in the medium above the cell, discretized into six intervals. The membrane potential signals are collected and processed to detect spikes and calculate the mean firing rate (i.e., number of spikes per second). The workflow is depicted in Fig. 3.

Statistical analysis of the firing rate of the models was performed in GraphPad Prism 8.0. The Mann-Whitney test with a significance level equal to 0.05 was adopted.

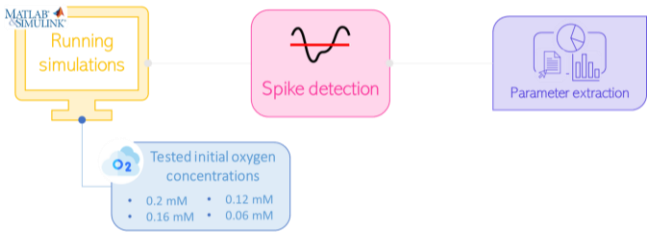

Fig. 3: Workflow

III. Results

The single neuron block as well as each network layout was simulated varying the initial oxygen concentration in the medium (0.2 mM, 0.16 mM, 0.12 mM and 0.06 mM) to analyse the dependency of the outputs of the platform on this variable.

A. *Single neuron*

The single neuron block was simulated for ten minutes for the four initial media O_2 concentrations. The outcomes of the single neuron model show that the electrophysiological behavior of the neuron is consistent with the expected dependency on the local oxygen concentration. Specifically, Fig. 3 shows the membrane potential over time in blue, while the orange plot describes the variations of the oxygen concentration at the boundary between the medium and the neuron. Potential is expressed in mV and concentration in mM.

As expected, the neuron has an intense firing activity when a higher concentration of oxygen is available, and it decreases its electrophysiological activity as O2 levels decrease.

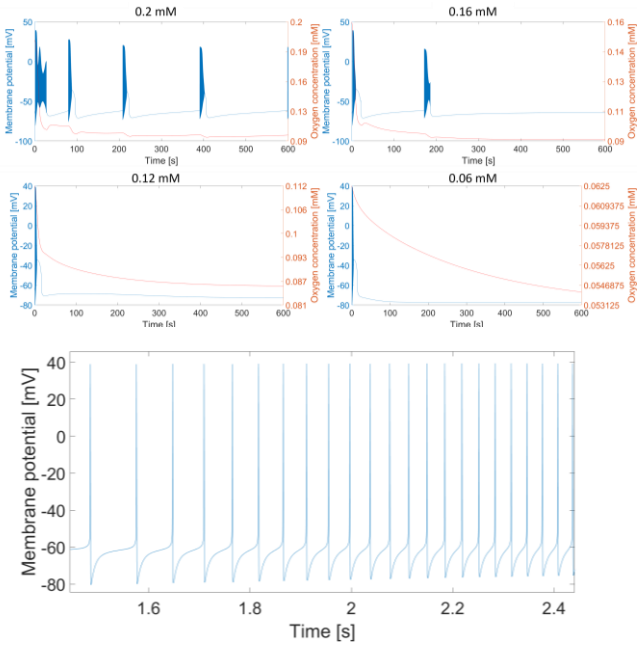

Fig. 4: Output of the single neuron block with different initial oxygen concentrations and detail of the membrane potential

Moreover, during intense firing activities (i.e., the close action potentials in the insert in Fig. 4) oxygen concentration rapidly drops off. On the other hand, Fig. 4 also shows that during the recovery time after a period of intense firing, the neuron does not produce action potentials and the oxygen concentration increases.

The cell consumes O2 for fueling its metabolism and for sustaining the activity of its Na-K-ATP pumps, responsible for the depolarization and repolarization of the membrane potential. In fact, the oxygen concentration, starting from the set initial value, rapidly decreases at the beginning of the simulation since it diffuses within the medium and reaches the neuron.

B. *Networks firing rate*

The networks generated according to Section II were simulated for ten seconds, and the membrane potential signals obtained were processed for identifying spikes (i.e., the membrane potential overcoming a threshold) and calculating the mean firing rate of each network as the number of spikes divided by the time of simulation.

The results of the statistical analysis of the mean firing rate calculated for each network layout simulated with the four initial O2 concentrations are shown in Fig. 5. Interestingly, although the values of the mean firing rates are different among network layouts, no significances were identified between the initial oxygen concentrations of 0.2 mM and 0.16 mM, while a significant difference (i.e., p-value≤0.001) is identified between all the other initial concentrations.

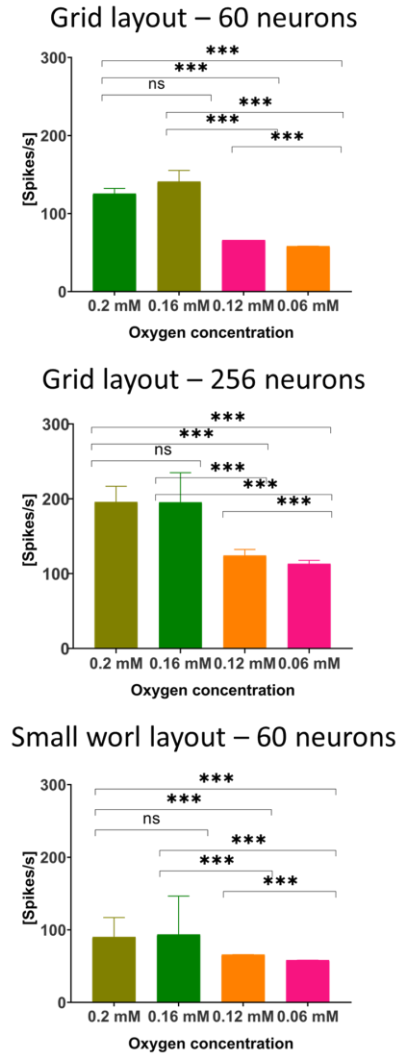

Fig. 5: Firing rate of the three network models as a function of initial O2 level (ns: non-significant; ***: p-value ≤ 0.001)

IV. Conclusion

In this work, a novel computational platform for mimicking the oxygen-dependent firing activity of neurons in monolayers is described. Ambient oxygen diffuses through the medium filling the culture plate, reaching the neurons. Each neuron is modelled as a unit that consumes the available local oxygen. The outputs of the simulations show the oxygen dependency of the electrophysiological activity of the neuron. In particular, neurons start to experience an hypoxic environment when the oxygen drops to the lowest levels used in the simulations.

The computational platform was developed with a modular and scalable architecture, allowing for further analyses and for the tuning of other desired parameters.

Future improvements of the work are ongoing and regard the validation of the platform using experimental data obtained from neuronal cultures seeded on MEA chips (e.g. publicly available datasets [19]). Such data will be analysed for extracting the local firing rate of the in vitro neural networks, to be compared with ones extracted from the platform. Also, a connectivity analysis will be conducted, assessing a correlation coefficient (e.g., the Spike Time Tiling Coefficient [20]) between the channels of the MEA. This will allow the identification of functional connectivity patterns that could be reproduced in a neuronal network within the computational platform. Once validated the platform will be improved for modelling 3D geometries, and in particular brain organoids [21]–[23], which are vessel-free, thus particularly O2 limited, which in turns limits cell viability and electrophysiological behaviour. Future improvements will consider also to increase the number of neurons within networks, to integrate a model of the glial cells and to implement neuron plasticity mechanisms.

The platform represents a powerful tool for the simulation of different models of neurons, synapses and neuronal networks and for studying the effects of the local oxygen concentration and other modulators (e.g., neurotoxins) on the output signals.

***Abstract*—Automatic drugs delivery during anesthesia can lead to faster sedation, increase patient's safety, and reduce the burden on anesthesiologists. This preliminary study proposes a Model Predictive Control (MPC) algorithm to control the induction and maintenance of the states of hypnosis, analgesia and neuromuscular blockade by means of automatic infusion of three drugs: Propofol, Remifentanil, and Atracurium. The study is conducted in a simulated environment based on a non-linear model describing the patient physiology that includes synergic effects among drugs and interpatient variability, as well as measurement noise and a variable surgical stimulation disturbance. Simulations on 24 virtual subjects show fast and safe induction of anesthesia. In terms of median [5th, 95th] percentiles, the MPC algorithm maintained hypnosis in a suitable range for 98.9 [93.7, 99.3]% of the time, analgesia for 100 [65.4, 100]% of the time, and neuromuscular blockade for 100 [100, 100]% of the time.**

***Keywords*—Automatic drug delivery, Clinical anesthesia, Closed-loop control, Model Predictive Control.**

I. INTRODUCTION

Automatic control of general anesthesia during surgeries has attracted attention due to its potential benefits to patients and for the medical personnel. It improves patients' safety by continuously monitoring vital signs and by modulating drug injections consequently, which may speed up the recovery process and reduce side effects, [1]; additionally, it helps the reduction of the workload of the anesthesiologist, although their presence in the operative room is still a necessity.

General anesthesia has three main effects: hypnosis, analgesia, and neuromuscular blockade (NMB). Hypnosis is the loss of consciousness required to prevent intraoperative awareness and memorization; analgesia is the suppression of physiological responses to nociceptive stimulation to prevent the perception of pain; NMB is the blockage of neuromuscular activity that results in paralysis. These outcomes are attained by the use of certain medications that the anesthesiologist carefully administers throughout the procedure. Propofol, in particular, is frequently used as a hypnotic. Remifentanil, a regularly used analgesic, is popular due to its quick onset of action, which reduces unfavorable opioid-induced side effects. When used together, Remifentanil and Propofol have a synergic impact on the patient's depth of hypnosis (DoH). Furthermore, curare-based drugs like Atracurium are frequently utilized for NMB.

The anesthesia procedure can be divided into three distinct stages: induction, maintenance, and emergence. The patient is brought from consciousness to the necessary hypnotic condition during the induction phase, which usually lasts 4-5 minutes. During the maintenance phase the surgery procedures take place. In this phase, it is necessary to maintain an adequate depth of anesthesia (DoA) despite the occurrence of disturbances, mainly due to nociceptive stimulation during the surgery. The final phase of anesthesia consists in awakening the patient by suspending drugs infusion.

Due to the intrinsic system complexity brought on by multiple inputs and outputs, non-linearities, noise effects, and coupling effects, the design of a closed-loop control system is a non-trivial task. Several solutions have been proposed for automatic single-input single-output DoH regulation, ranging from PID control [2], to machine learning based approaches, such as q-learning control, [3].

Among these different approaches, model predictive control (MPC) has emerged as a promising solution [4], [5], [6], [7]. MPC, that uses a model of the process, can handle multi-input multi-output (MIMO) systems, while satisfying a set of constraints, e.g. on system inputs and outputs. This is particularly useful in drug-delivery problems, in which the input variables (drug infusions) are constrained to be non-negative (as drugs cannot be "extracted" from the body). When an accurate model of the plant is available, MPC can reduce the impact of absorption delays or disturbances by embedding this information in the controller logic.

In this preliminary work, we designed a MPC algorithm, validated trough simulations, to simultaneously regulate the states of hypnosis, analgesia and neuromuscular blockade, by manipulating the infusion rates of Propofol, Remifentanil and Atracurium. The block-scheme of the control approach is shown in Fig. 1.

II. PATIENT SIMULATOR

In this work we use a state-of-the-art simulator of anesthesia that closely mimics the clinical and physiological body response to various drug dosing infusions [8]. The proposed patient simulator includes synergic interaction elements of general anesthesia. It considers three drug infusion rates input variables – i.e., Propofol $u_P(t)$, Remifentanil $u_R(t)$, and Atracurium $u_A(t)$ – and three output variables – i.e., bispectral index scale (BIS) linked to the DoH, Richmond Agitation Sedation Scale (RASS) linked to the analgesic state, and the NMB index – in 24 virtual subjects [8], i.e., 24 different set of parameters for the model.

Pharmacokinetic (PK) and pharmacodynamic (PD) models are used to characterize the link between drug infusion rate and

drug effect. The model for Propofol and Remifentanil includes a three compartments describing the distribution of the drug among blood, fast- and slow- exchanging tissues. Moreover, a further compartment is introduced to describe the drug transportation to the effect site. The effect site concentration is related to the drug effect by a nonlinear sigmoidal dose-effect response. Furthermore, Propofol and Remifentanil, have a synergic effect on the BIS level, lowering it in a non-linear way. The expression of BIS, a dimensionless index normalized between 0 (isoline) and 100 (patient fully awake and alert), as a function both Propofol and Remifentanil concentration in the effect site, is the following:

$$\text{BIS(t)} = E_{0_{BIS}} - E_{max_{BIS}} \frac{\left(\frac{U_P(t)+U_R(t)}{U_{50}(\Phi)}\right)^{\gamma}}{1+\left(\frac{U_P(t)+U_R(t)}{U_{50}(\Phi)}\right)^{\gamma}}, \quad (1)$$

where $E_{0_{BIS}} \approx 100$ is the baseline value representing the initial drug-free state of the patient, $E_{0_{BIS}} - E_{max_{BIS}}$ is the maximum reachable effect, γ determines the maximum steepness of the curve (i.e., the receptiveness of the patient to the drug), and C_{e50_P} and C_{e50_R} are the Propofol and Remifentanil concentrations necessary to reach half of the BIS maximal effect, respectively. Finally, $U_P(t)$, $U_R(t)$ are related to the effect site concentration of Propofol $C_{e_P}(t)$, and of Remifentanil $C_{e_R}(t)$ by means of the following equations: $U_P(t) = C_{e_P}(t)/C_{e50_P}$, $U_R(t) = C_{e_R}(t)/C_{e50_R}$. Finally $U_{50}(\Phi) = 1 - \beta\Phi + \beta\Phi^2$ where $\Phi = U_P(t)/(U_P(t)+U_R(t))$. Specifically, β describes the synergic effect of Propofol and Remifentanil: as β increases, the mixture of drugs becomes more powerful and induces a stronger hypnotic effect. The RASS metric, ranging from 0, patient calm and alert, to -5, unresponsive to voice and stimulation, is just influenced by the Remifentanil infusion as follows:

$$\text{RASS(t)} = E_{0_{RASS}} - E_{max_{RASS}} \frac{C^{\gamma}_{e_R}(t)}{C^{\gamma}_{e50_R} + C^{\gamma}_{e_R}(t)}. \quad (2)$$

The Atracurium PK-PD model has been developed in [9]. Its PK structure can be seen as a two-compartmental model and the PD model includes a second-order transfer function and nonlinear Hill function in series. Specifically, the NMB is normalised between 0 and 100, where 0 corresponds to full paralysis and 100 to full muscular activity:

$$\text{NMB(t)} = 100 \frac{C^{\gamma}_{e50_A}(t)}{C^{\gamma}_{e50_A} + C^{\gamma}_{e_A}(t)}, \quad (3)$$

where C_{e50_A} is the Atracurium concentration necessary to reach half of the NMB maximal effect, while C_{e_A} is the effect-site concentration of Atracurium. Every of the previously introduced parameters is patient-specific. Further details can be found in [8].

In order to increase the realism of the simulated scenario, further sources of complexity have been introduced into the simulations. Measurement noises affecting BIS and NMB have been modeled as in [10] and [11], respectively. Since RASS is an integer number estimated by the anesthesiologist, RASS measurements were rounded to the closest integer value. The measurement error introduced in this way is more realistic that a zero-mean Gaussian noise. The sampling period of these measurements is $T_s = 20$s.

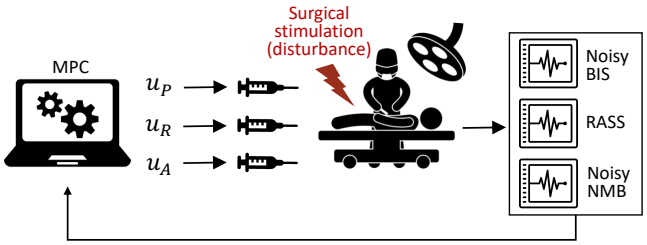

Fig. 1: Closed-loop control scheme.

Surgical stimulation has been added to the simulated scenario as an additive unmeasured disturbance on hypnotic state's output, that instantaneously increases the BIS level. Its shape has been taken from [12] and is common for all subjects, but its duration (linked to the surgical procedure duration) and magnitude (that depends on patient sensitivity) are patient-dependent. The shape, illustrated in Fig. 2, describes the three typical stages of a surgical intervention: a first arousal due to the surgical incision, a persistent phase associated to the surgical operation, and the final descending phase during the skin-closing procedure. Stimulation length is uniformly drawn in the range $[25,\ 35]$min while the maximum magnitude of the stimulation is uniformly drawn in the range $[+16,\ +24\%]$.

III. Methods

A. Control algorithm

At each control instant T_s, MPC finds the sequence of control actions that is predicted to achieve the "best system behavior" in a finite prediction horizon. Predictions are computed using a model of the process, whereas the "best system behavior" is assessed by minimizing a desired cost functional. According to the principle of the receding horizon, only the first action of this sequence is actuated; then, a new sequence is computed in the following control instant, using the new available measurements. This policy reduces the effect of

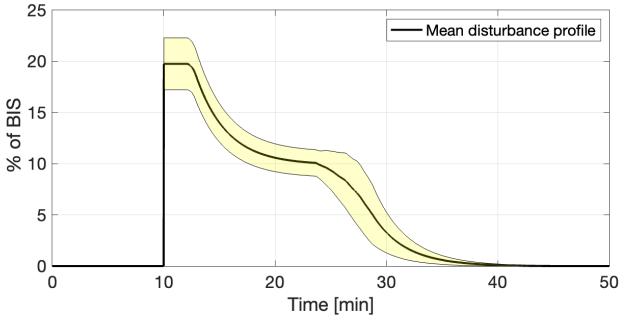

Fig. 2: Simulated disturbance profile variability due to surgical stimulation. The nominal curve is reported as the black line, while the variability interval of one standard deviation is reported as the yellow band.

errors due to model mismatches and the impact of unexpected disturbances affecting the system.

We employed a linear MPC formulation by relying on a linearized, averaged and discretized version of the model described in Section II. The model has been linearized around a suitable equilibrium operating point (x_{eq}, u_{eq}) that permits to maintain steady-state the desired output values: $\text{BIS}_{eq} = 50$, $\text{RASS}_{eq} = -4$ and $\text{NMB}_{eq} = 15\%$. Such equilibrium point has been computed using the trimming procedure implemented in the "Model Analyzer" application in Simulink.

The so-derived linearized model can be represented in state-space form as:

$$\begin{cases} \bar{x}(k+1) = A\bar{x}(k) + B\bar{u}(k), \\ \bar{y}(k) = C\bar{x}(k) + Md(k), \end{cases} \tag{4}$$

where:

- $\bar{x}(k)$ is the deviation of the state vector from the equilibrium state x_{eq};
- $\bar{u}(k)$ is the deviation of the input vector $u(k) = [u_P(k), u_R(k), u_A(k)]'$ from the inputs u_{eq} that guarantees the steady-state;
- $\bar{y}(k)$ is the deviation of the output vector $y(k) = [\text{BIS}(k), \text{RASS}(k), \text{NMB}(k)]'$ from the steady-state vector $y_{eq} = [\text{BIS}_{eq}, \text{RASS}_{eq}, \text{NMB}_{eq}]'$;
- $d(k)$ represents the output disturbance (i.e., surgical stimulation).

The optimization problem in MPC consists in minimizing, at each control instant, the following quadratic cost function:

$$J(k, y(\cdot), u(\cdot)) = \sum_{i=0}^{N-1} ||y(k+i) - y_0||_Q^2 + ||u(k+i) - u_0||_R^2. \tag{5}$$

It consists of two terms. The first penalizes the ℓ_2-norm of the difference between the future outputs of the model and the reference set-point $y_0 = y_{eq}$. The second term penalizes the ℓ_2-norm of the difference between future drugs infusion rates and a target set-point $u_0 = u_{eq}$. The matrices $Q \in \mathbb{R}^{3\times3}$ and $R \in \mathbb{R}^{3\times3}$ are non-negative weight matrices setting the trade-off between the two penalty terms in (5). They were set by trial and error on an average virtual patient to $Q = diag(10, 1, 5\%)$ and $R = diag(0.1\ [\text{min/kg/mg}]^2, 0.01\ [\text{min/kg/}\mu\text{g}]^2, 100\ [\text{min/kg/}\mu\text{g}]^2)$. The prediction horizon, N, is here set to 100.

System outputs are predicted via forward simulation from an estimate of the current system state, $\hat{x}(k)$. This estimate is obtained by means of a Kalman Filter, with the measurement noise modeled as in Section II.

Let $\mathcal{U}(k) = [u(k), \ldots, u(k+N-1)]'$ be the sequence of control actions that the MPC has to compute and $\mathcal{D}(k) = [d(k), \ldots, d(k+N-1)]'$ be the predicted disturbance profile. The optimal control problem solved by MPC is:

$$\min_{\mathcal{U}(k) \text{ s.t. } \mathcal{U}(k) \geq 0} J(k, \hat{x}(k), \mathcal{U}(k), \mathcal{D}(k)). \tag{6}$$

Drugs infusion rates are constrained to be non-negative. The constrained optimization problem is solved by using an interior-point algorithm. Once the optimal sequence $\mathcal{U}(k)$ is computed, only the first control action of this sequence is applied, following the receding horizon policy. The optimization problem is then repeatedly solved to compute the control actions to be applied.

B. Disturbance detection

Surgical stimulation is a challenging disturbance as it increases instantaneously the BIS level. To improve the rejection of this disturbance, we assumed to know its shape and its average length, while the magnitude of this disturbance, that depends on the patient sensitivity to the stimulus, is estimated in real-time. When a sudden change of slope (i.e., at least 15% BIS in 20s) is inferred, confirmation of the start of the surgery is requested to clinical staff. Assuming that the information is verified, the nominal disturbance profile shown in Fig. 2 (black line) is announced to the MPC algorithm ($d(k)$ in (4)) with amplitude scaled so that its maximal height is set equal to the measured change in BIS.

IV. Performance assessment

Our ultimate objective is to keep BIS, RASS and NMB indices within their clinical safe range by automatically adjusting Propofol, Remifentanil and Atracurium infusion rates achieving a proper degree of DoA. Moreover, according to [13], the adequate interval of the BIS index for anesthesia is [40, 60], the desired RASS is [-4, -5] and the NMB is to be maintained in the interval [10, 20]%. To evaluate the performance of the closed-loop control of DoA, a suitable set of performance indices is proposed:

- Time to Target (T2T): time required to reach the target range for the first time;
- BIS-NADIR: the lowest value of BIS observed during the induction phase;
- Time in Range (TIR): percentage of time spent in target range during the maintenance phase for BIS, RASS and NMB.

Results will be reported as median [5^{th}, 95^{th}] percentiles.

V. Results and Discussions

Fig. 3 reports the medians (blue lines) and interquartile ranges (black dotted lines) of the trajectories of drugs infusions, along with the trajectories of BIS, RASS and NMB, obtained in simulation on the 24 virtual patients.

The general guideline for the induction phase recommend to reach a good anesthetic state (i.e., the output variables within their safe range) in less than 4-5 minutes. It is also important to avoid drug over-dosing in this phase, as undershoots in the BIS index may be responsible for life-threatening hypotension. We achieved a T2T of 1.3 [1.3, 2.1]min for BIS, 1.3 [0.9, 1.3]min for RASS and 1 [1, 1]min for NMB, meaning that a good anesthetic state is generally reached in less than 5 minutes. Fig. 3 shows that proper induction of anesthesia is achieved safely, with a BIS-NADIR value of 47 [42.7, 51.5] (i.e., inside target range). Moreover, the disturbance rejection is satisfactory, the control response is fast and the indices stay

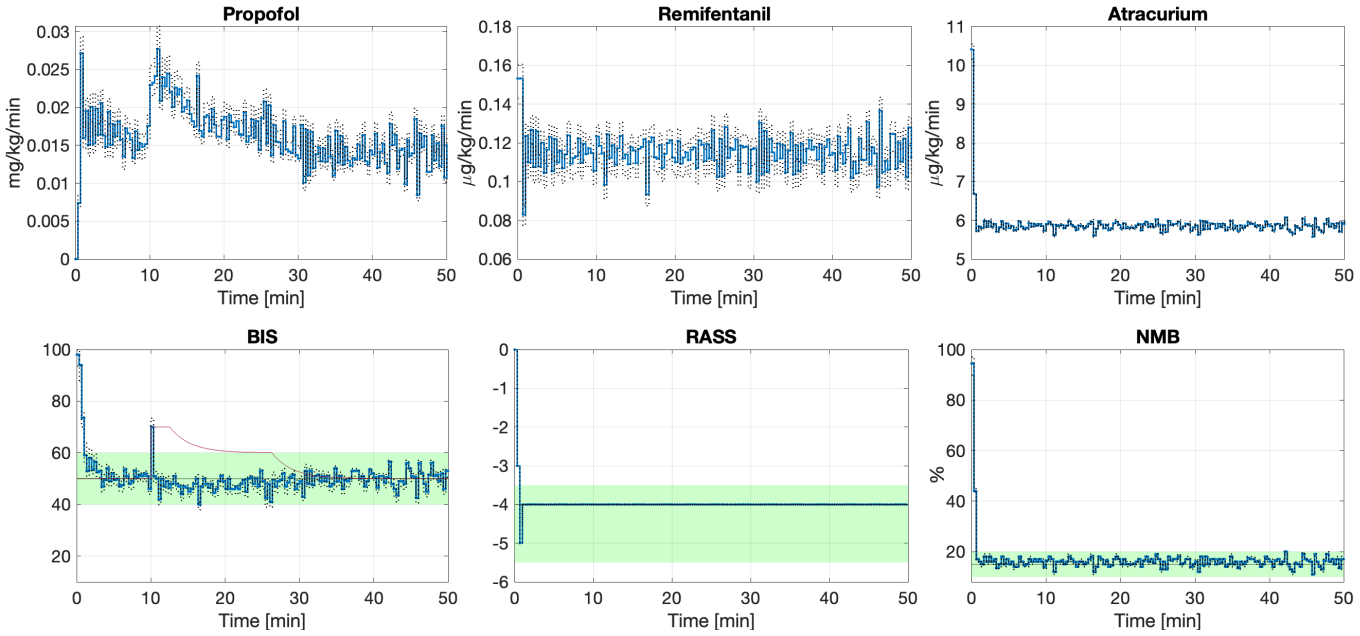

Fig. 3: Simulations of the MPC algorithm for the regulation of BIS, RASS and NMB by manipulating the infusion rates of Propofol, Remifentanil and Atracurium, respectively in the simulated patients. The green bands represent the target ranges for the three outputs. The red line on the BIS panel is the nominal disturbance profile. In each panel are reported the medians (blue lines) and interquartile ranges (black dotted lines).

inside the appropriate interval highlighted in green. TIR is 98.9 [93.7, 99.3]% for BIS, 100.0 [65.4, 100.0]% for RASS and 100.0 [100.0, 100.0]% for NMB. Disturbance on BIS was effectively detected and rejected. This was possible thanks to the a priori information on this disturbance (i.e., the nominal disturbance profile).

VI. Conclusions

In this article, a MIMO MPC algorithm is developed to accomplish the automatic control of the depth of anesthesia. The algorithm is developed and tested in silico. The simulated scenario is realistic, thanks to non-linearities introduced by the pharmacodynamics of the drugs, noise effects on BIS and NMB signals, differences in intra- and inter-patient parameters, and surgical stimulation disturbances. The approach proves to achieve accurate and safe control in both the induction and maintenance phases. Satisfactory disturbance rejection is achieved by using a priori knowledge on the surgical stimulus. The achieved control performance, as well as the infusion rates, are consistent with what has been reported in previous literature, [6], [7]. Future developments will involve the use of specialized infusion drugs to control various output variables associated with hemodynamics, while also accounting for other system factors like delays in the BIS signal.

***Abstract*— Detecting residual awareness in patients in a prolonged Disorder of Consciousness (pDoC) is a crucial issue in neurorehabilitation. Autonomic functions have been shown to correlate to the severity of brain injuries. Thus, we investigated whether metrics derived from non-linear Heart Rate Variability (HRV) analysis could be used to differentially diagnose patients with a pDoC. A prospective observational study was performed consecutively enrolling 209 patients with a severe brain injury. Resting-state ECG recordings were collected and nine metrics related to HRV complexity were correlated with the presence/absence of a pDoC. Then, the discriminatory capabilities of HRV complexity were evaluated. Lower HRV complexity was found to be associated with pDoC and SampEn, FuzzyEn, MultiScaleEn and Katz Fractal Dimension resulted capable of discrimination between patients with and without a pDoC. Complexity of HR, viewed as change in HRV at different time-scales, was found to be associated with presence of consciousness. With this work, we confirmed the mutual correlation between autonomic functions and consciousness alterations, providing complementary information for the implementation of low-cost clinical decision support tools in patients with a pDoC.**

***Keywords*—Disorder of Consciousness; Heart Rate Variability; NeuroRehabilitation.**

I. Introduction

Consciousness detection in patients with a severe Acquired Brain Injury (sABI) is challenging. These patients, after the coma phase, can transit to a state of prolonged Disorder of Consciousness (pDoC) which includes the Unresponsive Wakefulness State (UWS) and the Minimal Conscious State (MCS) [1]. This condition may persist or cease achieving a full recovery emerging from the MCS (E- MCS). Such heterogenous conditions, combined with consciousness fluctuations in the short or long term, can make neurological diagnosis complex and prone to misclassification. Nevertheless, the Coma Recovery Scale- Revised [2] with appropriate staff training and repetitive assessments lowers the cumulative misdiagnosis rate, even if falling under specific clinical conditions. To cope with such issue, the latest international guidelines for diagnosis of patients with pDoC have recommended the use of both clinical and instrumental evaluations to minimize the risk of misdiagnosis [3].

Within the possible instrumental evaluations, electrocardiography (ECG) provides a non-invasive way to investigate the functioning of the Autonomic Nervous System (ANS). Specifically in patients with a pDoC, it has been proposed that ANS may modulate large-scale brain patterns, attempting to balance sympathetic/parasympathetic homeostatic balance and to restore consciousness levels [4]–[6]. This two-way functional link between central nervous system (CNS) and ANS has been hypothesized in the Central Autonomic Network (CAN) model [7]. Currently, the work of Riganello et al. provided evidence of how heart rate variability (HRV), and in particular its complexity, can be used as a diagnostic marker of patients' neurological outcomes [5], [6], [8]. Similarly, complexity indexes of HRV have been shown to distinguish with a 90% accuracy UWS from MCS in a dataset of 30 acute sABI patients (16 MCS, 14 UWS) [8].

Given the aforementioned findings, our hypothesis, was that HRV complexity may be relevant also within rehabilitative contexts in non-sedated pDoC patients. Moreover, considering that the cardiac system works on multiple time scales (e.g., short time-responses, emotional influence, circadian rhythms) non-linear measures of HRV (NL-HRV) are among the most appropriate technique to analyse such signals. Such measures, compared to classical frequency or time-domain metrics, define the complexity of the signal at different time scales, instead than focussing on specific frequency ranges or time intervals. For these reasons, we extracted different complexity measures from ECG signals at admission to an Intensive Rehabilitation Unit (IRU) and correlated with the presence of a pDoC.

II. Materials and Methods

A. Study design and data collection

This analysis was performed in the framework of the PRABI study [9]. Inclusion criteria were: patients admitted to IRCCS Fondazione Don Carlo Gnocchi (FI) IRU from 06-01-2021 to 12-01-2022; diagnosis of a sABI; adults (age > 18). Approval from the local Ethical Committee was obtained (N. 16606OSS) and enrolment was done following the Helsinki Declaration. Patients have been included after obtaining a written consent signed by a legal guardian. Based on five consecutive CRS-R administration, the best evaluation was adopted to formulate a clinical diagnosis of consciousness (UWS, MCS or e-MCS). Twenty minutes of ECG recording was performed by electrodes applied to the chest at a sample rate of 128 Hz. Tachogram was extracted using the Python library NeuroKit2 and it was visually inspected for missing beaks [10]. After extraction of R-peaks, ectopic beats were interpolated.

B. HRV and entropy

Approximate entropy adopts non-negative numbers to define the complexity of a time series. In particular given a time series $S(i) = \{s(1), s(2), s(N)\}$, take m consecutive points to form $S(i) = \{s(i), s(i+1), \dots s(i+m-1)\}$ and define the distance between $S(i), S(j)$ as follows

$$d[S(i), S(j)] = max_{k=0,1,\dots,m-1} |s(i+k) - s(j+k)|$$

Then, for a given threshold r, evaluate the number of distances smaller than r divided by the total number of distances (N-m+1) recorded as $C_m^r(i)$.

After taking the natural logarithm of $C_m^r(i)$ and calculating the average across all I, the quantity $\phi_m(r)$ can be defined. Then the dimension of the m coefficient is increased to $m+1$ and the approximate entropy is computed as follows:

$$ApEn(m, r, N) = \phi_m(r) - \phi_{m+1}(r)$$

Improvements on the concept of ApEn derive from the enforcement of the condition $i \neq j$ in the calculation of the ApEn. The latter results in the calculation of the Sample Entropy (SampEn) as follows

$$SampEn(m, r, N) = ln(\phi_m(r)/\phi_{m+1}(r))$$

In this work, the m and r parameters are set to m = 2 and r = 0.2 as in [11]. In order to perform a more robust phase-space reconstruction, a fuzzy membership function is used to measure similarity of vectors. In particular, the phase-space reconstruction performed was on the time series $S(i)$ by creating a set of f-dimensional ($f \leq N-2$) vectors as follows

$$X_i^f = s(1), s(2), \dots, s(i+f-1) - u_f(i) \quad with \quad i = 1,2, \dots . N-f+1$$

and $u_f(i)$ the average of the f-dimensional vector. Then, after calculating the maximal Euclidean distance between X_i^f and X_j^f defined as D_{ij}^f, the degree of similarity A_{ij}^f can be derived using the fuzzy membership.

$$A_{ij}^f = e^{\left(-\frac{\left(d_{ij}^f\right)^n}{r}\right)}$$

The fuzzy entropy can be then computed via

$$FuEn(f, r, n, N) = ln\phi^f(n, r) - ln\phi^{m+1}(n, r)$$

with, $\phi^f(n, r)$ defined as follows

$$\phi^f(n, r) = \frac{1}{N-f} \sum_{i=1}^{N-f} \left[\frac{1}{N-f-1} \sum_{j=1, j\neq i}^{N-f} A_{ij}^f \right].$$

Shannon's entropy can be easily defined by

$$ShanEn(n) = -S^{2(n)} log_2\left(S^{2(n)}\right).$$

Lastly, Multi Scale Entropy (MSE) generalizes the entropy concept to different time-scales by including an initial coarse graining step [14]. Via a scale factor τ, ranging from 1 to *s*, the initial time-series S is under sampled following,

$$y_i^\tau = \frac{1}{\tau} \sum_{i=(j-1)\tau+1}^{j\tau} s(j) \quad with \quad j = 1,2, \dots ., round(N/\tau)$$

to then compute the SampEn for each coarse-grained time series at different scale factors

$$MSE(\tau, m, r) = SampEn_{y_j^\tau}(m, r, N) \quad with \quad \tau = 1,2, \dots, s$$

Then the composite (CMSE) and refined (RMSE) version of the MSE are computed following Azami et al. [15] and the open-source implementation of the Neurokit2 Python toolbox as well as the Higuchi and Katz fractal dimension (HFD, KFD respectively, [16]).

C. Statistical analysis

Outcome was set as presence/absence of a pDoC. HRV complexity metrics entered multivariate logistic regressions adjusted by age and sex, given the known influence of such factors on cardiac cycles [17]. All analyses were performed on SPSS (Vs 26, Chicago, SPSS Inc.) and a p-value <0.05 was considered as statistically significant.

TABLE I: LOGISTIC REGRESSION DOC/NODOC

Variable	*OR*	*95%CI*	*p-value*

Multivariate analysis of NL-HRV measures corrected by age and gender
Legend. Reference is set to absence of a DoC (e.g. OR<1 indicates that an increasing independent variable correlates with absence of a DoC).

III. RESULTS

Two hundred fifteen patients (112 males) were included in the study with median age of 65 years [interquartile range, IQR = 21]. Seven patients were excluded from the analysis due to missing data. Out of 208, 122 patients were diagnosed with a pDoC via the CRS-R scale (median CRS-R value of 9 points [IQR = 8]). The patients' aetiologies resulted distributed as follows: 62 patients with a traumatic brain injury, 18 anoxic, 39 ischemic, and 89 patients suffering from a haemorrhagic lesion. Univariate analysis on the NL-HRV entropy features resulted in higher entropies indicating a better consciousness state (Table 1).

Approximate entropy (odds ratio, OR = 0.327, p = 0.001, median pDoC = 0.82 [IQR = 0.81], No-Doc = 1.12 [IQR = 0.79]), Sample Entropy (OR =0.456, p = 0.003, median pDoC = 0.65 [IQR = 0.93], No-DoC = 1.05 [IQR = 1.04]), Fuzzy entropy (OR = 0.349, p = 0.005, median pDoC = 0.54 [IQR = 0.56], No-DoC = 0.75 [IQR = 0.85]) and Multiscale Entropy (OR = 0.382, p = 0.009, median pDoC = 0.57 [IQR = 0.79], No-DoC = 0.88 [IQR = 0.67]) were all found to be negatively associated with the presence of a pDoC (Table 1 and Fig. 1). Also, a higher Katz fractal dimension was found to be significantly correlated with a favourable diagnosis with a median of 2.68 [IQR = 1.62] for the No-DoC group and a of 2.11 [IQR = 0.89] for the pDoC group.

Approximate Entropy was found to be the one with the

strongest odds ratio (OR = 0.328, 95%CI=0.168-0.640, p=0.001). Discrimination capability of the occurrence of a pDoC has been reported via Receiver Operating Characteristic (ROC) curves (Fig. 2). In particular, ApEn resulted the feature better identifying patients with a DoC with an AuC = 0.647 (Fig. 2, Table 2). Nevertheless, SampEn, FuzzyEn, MSE and KFD all resulted capable of providing significant information on the discrimination between patients with and without a pDoC (p<0.01, Table 2).

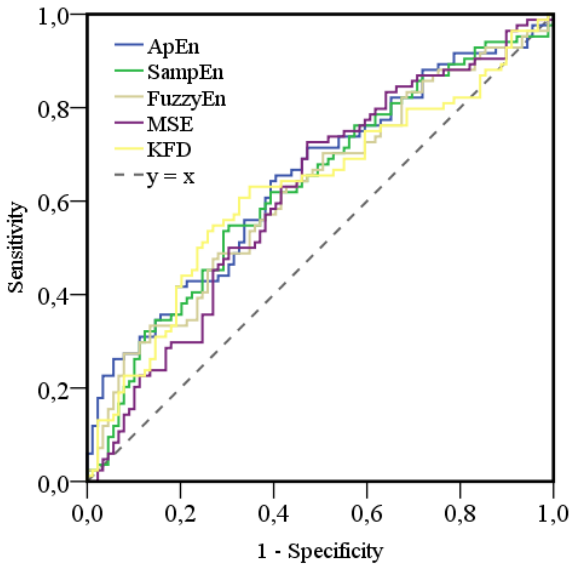

Figure 2. Receiver Operating Characteristic (ROC) curve for the complexity estimators which were found to be significant in univariate and with respect to pDoC/No-DoC.

IV. Discussion

Complementing consciousness diagnosis with instrumental evaluations would allow for a precise individualized rehabilitation management. To discriminate among patients with UWS and MCS, multifactorial approaches, including different instrumental evaluations, have been proposed [15]–[18]. The ECG signal, a non-invasive and inexpensive technique, is a proxy of the residual functionality of the ANS-CNS interplay. In particular, in patients with a brain injury it has been reported how HRV measures differentiate TBIs with elevated autonomic activity. Also, reduced HRV [19] and HRV MSE [20] were found to be predictors of mortality in TBI patients. The connection between consciousness, attention and HRV has been documented in a seminal study by Riganello et al., in which the likelihood of responding to visual/auditory stimuli was increased when the HRV low-frequency peak is around 0.1 Hz [21]. Specifically for the diagnosis of consciousness levels, complexity indexes were found to be capable of discriminating two groups of 16 MCS patients and 14 UWS patients sedated [8]. Furthermore, positive correlations were suggested between HRV entropy indexes, computed for long- and short-time scales, and fMRI-derived activation of brain areas involved in the CAN.

We extended on previous literature by providing a screening of different entropy measures in a notably larger cohort of sABI patients. Such bigger sample size enabled us to derive multivariate correlations of entropy measures with respect to the presence of a pDoC. Furthermore, given the importance of the assumptions made when performing each entropy estimates, we provide a comparison between different techniques together with the evaluation of typical fractal measures. Furthermore, entropy measures are strongly dependent on developmental parameters, calling for an aware choice of parameters when deriving such measures. Lastly, non-stationarities can either be due to artifacts or due to actual brain functioning. Among the different entropy measures adopted, Shannon entropy is the one most affected metrics by non-gaussian probability distribution function (PDF) of a time-series x(t), given the Jim-Paradigm mentioned in the work of Petty [22]. In our case, HRV being an absolute quantity and being affected by long-term non-stationarity is a candidate for a misleading use of Shannon entropy. Coherently, it is the one entropy measure with lowest significance with respect to the occurrence of a DoC. Moreover, the presence of long-term non-stationarities in HRV measures can affect the estimation of Shannon entropy given that the latter does not include any concept of distance (spread) in the x-space, measuring only the amount of information in the amount of information in the y-space of the PDF of x(t) [23]. ApEn, SampEn and FuzzyEn are known to decrease with increasing r, but in our case was kept fixed as in Riganello et al. to minimize such effect. ApEn values resulted higher in absolute value with respect to SampEn and FuzzyEn, common when investigating long signals [24].

Katz's algorithm is known to be less sensitive to noise with respect to Higuchi's method [13], coherent with the better performances obtained by KFD compared to HFD. Beyond, up to our knowledge this is the first study which, with such a large sample size, allows for multivariate correlations with the outcome, including known HRV confounding factors as age and sex [14]. Surely, the AuC achieved in this work is moderate. However, one has to take into account that each

variable is considered univariately as a predictor, without training any Machine Learning model and that the aim of the work was to specifically investigate the discrimination capability of HRV complexity. Coherently with a larger sample size and the inclusion of neurophysiological and neurobehavioral predictors, the AuC of a multivariate predictive model is expected to increase. With this work, we provided evidence that HRV complexity can be of fundamental help to complement a multifactorial diagnosis of consciousness. Such autonomic markers of consciousness may be used in absence of clear behavioural responses to improve consciousness diagnosis in patients with pDoC. Furthermore, HRV-derived markers, integrated with centrally derived neural correlates of consciousness and clinical assessments could be used to deploy decision support tools for diagnostic and prognostic purposes in patients with pDoC. Lastly, by providing a systematic evaluation of different complexity metrics, a preliminary insight on the best performing variables for the estimation of HRV complexity in patients with a pDoC was obtained.

***Abstract*—The modelling of neural circuits with single cell resolution is progressively becoming a reliable benchmark to simulate the neurophysiological correlates of brain activity and to investigate brain dysfunctions. The physiological and pathological conditions in fact can be explored through single neuron models that can simulate the salient electrophysiological properties of biological neurons. One of the main issues of the realistic modelling of brain circuits is related to the connection strategy: to properly define the network connectome it is of utmost importance to take into account morpho-anatomical constraints dictated by neuronal cito-architecture. We have developed a strategy to generate realistic neuronal networks with single-cell resolution based on the creation of geometrical probability density functions mimicking extension and orientation of neuronal axons and dendrites. The first benchmark of the modelling pipeline allowed to create a full-scale point neuron model of the mouse CA1 hippocampus. The modelling strategy has been applied to the CA3 region of the mouse hippocampus allowing to generate a full network with limited computational costs suggesting that the present approach can be reliably translated to other brain areas.**

***Keywords*—Hippocampus, CA3, CA1, network activity, neuronal modelling.**

I. INTRODUCTION

THE research on computational models of brain circuits has increased tremendously and the implementations of large-scale brain circuits at single neuron resolution is becoming instrumental for Neuroscience research [1,2]. The use of such technologies could in fact lead to innovative therapeutics and diagnostic tools for in silico medicine [3,4]. In the last decades, a significant number of mathematical models has been proposed to explore different spatio-temporal scales of neuronal microcircuits. The construction of these models is bound to a series of approximations which scale up with the size of the network. The major factor is the size of the connectome [5], which affects the computational performance and shapes the input-output relationship of the circuit. Although single cell properties have been tailored and refined for several neuronal classes, the strategy adopted to generate the network connectome is still a critical issue [6,7]. According to i) data availability, ii) computational effort and iii) level of biological realism, different connection strategies have been proposed and tested: from statistical algorithms [8] to sophisticated methods strictly adhering to morphological and anatomical constraints [9]. The choice of the connectivity strategy strongly depends on the computational effort especially when more than hundreds of thousands of neurons must be connected. The estimation of connection probability through isotropic or distance-based probability clouds provides remarkable results especially when combined with some morphological rule [10]. Unfortunately, the use of realistic morphologies in large networks can be hardly sustained given the limited number of available data, which in turn requires to replicate randomly individual morphologies to reproduce biological variability. Here, we present a connection strategy based on the generation of probability density functions for neuronal processes. The strategy has been benchmarked on the mouse hippocampus by developing a statistical/geometric approach to customize local connectivity. Starting from morpho-anatomical constraints obtained from morphological data, the proposed method allowed to generate a network connectivity of the CA1 and CA3 regions of the mouse hippocampus that are consistent with experimental findings on real circuits at single cell resolution [11].

II. RESULTS

Here, we propose a strategy for modelling full-scale networks based on morpho-anatomical constraints. The algorithm has been validated on CA1 and CA3 mouse hippocampal regions and is organized in sequential steps that are detailed below.

A. Cell placement

The 3D neuronal coordinates for both CA1 and CA3 regions have been downloaded from the Blue Brain Cell Atlas database (https://bbp.epfl.ch/nexus/cell-atlas/). The repository provides annotated references in the Common Coordinated Framework (CCF) for all the layers of both regions divided in excitatory and inhibitory populations without further classification of neuronal subtypes. We have therefore extensively analyzed the literature on hippocampal single cell morphologies to identify the excitatory and inhibitory subclasses and to provide a strategy to generate a connectivity matrix. The neurons were divided into 13 classes (2 exc, 11 inh) for CA1 and 14 for CA3 (2 exc, 12 inh) [12,13]; Table1. The resulting scaffolds were obtained with the BSB (Brain Scaffold Builder) framework [14] and their graphical representation are shown in Figure 1 [https://pypi.org/project/mayavi].

B. Neuronal morphologies and orientation

The activity of large-scale neuronal network comprising several hundred thousands of cells and millions or billions of synapses can only be simulated by using “point neurons”, Integrate-and-Fire neuronal models with single compartment. Point neurons preserve most of the electrophysiological properties while discarding detailed morphological descriptions to reproduce the electrotonic response of the

neuronal membrane. Here, geometrical shapes have been created only to compute the connectivity matrix. Given the simplified nature of this approach, we have assumed that neurons belonging to the same class share similar geometrical features. We have analyzed single cell morphologies from public repositories (neuromorpho.org, http://mouselight.janelia.org/, https://portal.brain-map.org) to identify an average shape to represent neuronal subtypes.

The geometrical shapes associated to each neuron represent a probabilistic density function that mimic the volume occupancy of axons and dendrites. In our approach, we have assumed that neurites could be represented as a combination of ellipsoids and cones, whose parametrization were obtained from the average axonal and dendritic extensions derived from data analysis (see Fig. 2,3). To maintain cell-to-cell variability preserving the desired parametrization, normal distributions for all the geometric descriptors were created and the ellipsoids and cones dimensions were randomly sampled within the distributions.

The orientation of geometrical probability density functions was performed by measuring, through an iterative scanning algorithm, the relative distances between soma position, inner layers, and outer regions (CA3 and Subiculum for CA1 neurons; CA1 and Dentate Gyrus for CA3 neurons) and tilting the ellipsoids and cones according to their relative position within hippocampal layers and respecting the morpho-anatomical constraints derived from the literature. For example, basal and apical dendrites of Pyramidal Cells (PC) are oriented towards SO and SLM, respectively, while axons of CA3 PC run along SO and SR (see Fig. 2).

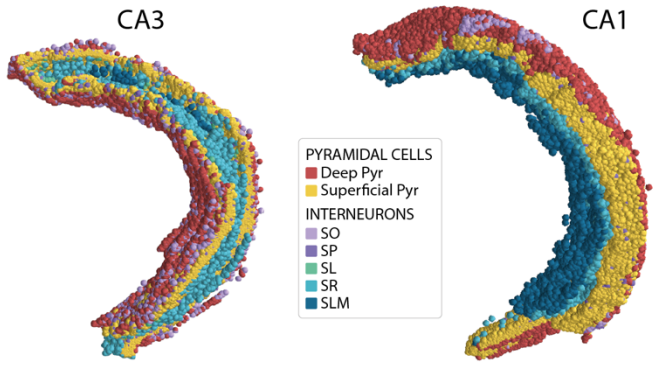

Fig. 1: Neuronal placement. Excitatory and inhibitory cell positioning according to the CA3 (left) and CA1 (right) region layer subdivision provided by the Blue Brain cell Atlas. Colored dots represent excitatory or inhibitory neurons that were divided according to their positioning within the CA1 and CA3 layers.

Geometrical morphologies mimicked the cross-section volumes of pre-synaptic axons and post-synaptic dendrites depending on the desired shape. The ellipsoids were modelled by assuming an orthonormal system of eigenvectors $\mathbf{v_1}$,$\mathbf{v_2}$,$\mathbf{v_3}$ associated with the eigenvalues λ_1, λ_2, λ_3 of a 3x3 symmetric positive matrix M.

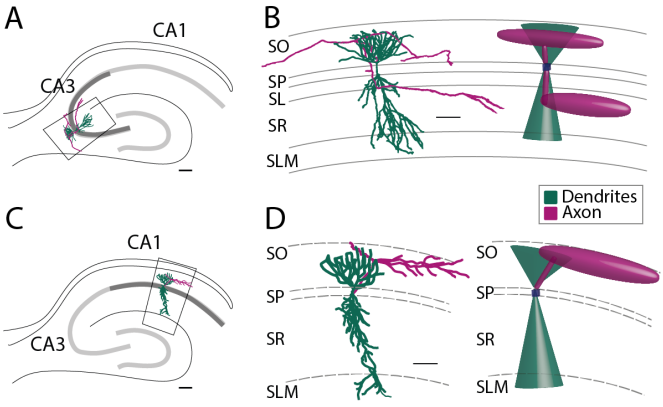

Fig. 2: Pyramidal neurons. (A) Scheme of a transversal section of the mouse hippocampus. Thick gray line represents the Pyramidal layer of CA3 area. (B). *Left.* Realistic morphology of a PC (dendrites in green, and axon in violet), oriented within a region of a transversal CA1 hippocampal slice (inset of A). *Right*. The probability density functions are represented as two cones and four ellipsoids (color code matches the colors of realistic morphology). (C) Similarly to A, scheme of a transversal section of the mouse hippocampus. The thick gray line represents the Pyramidal layer of CA1 area. (D). Similarly to B, a realistic morphology of a PC (dendrites in green and axon in violet) oriented within a region of a transversal CA1 hippocampal slice (inset of panel C). The corresponding probability density functions are represented on the right respecting the color code. Scale bars in μm (100 in A and C, 50 in B and D).

Considering $V = [v_1, v_2, v_3]$ then

$$V^T M V = \begin{bmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{bmatrix} = D[\lambda_1, \lambda_2, \lambda_3]; \qquad \text{Eq. 1}$$

is a diagonal matrix with the eigenvalues of M and the normalized vectors $\mathbf{v_1}$, $\mathbf{v_2}$, $\mathbf{v_3}$ are called the principal axis of M. Given an arbitrary base of orthonormal vectors $\mathbf{u_1}$, $\mathbf{u_2}$, $\mathbf{u_3}$ (the ellipsoid orientation vectors) forming the matrix U and a diagonal matrix of arbitrary eigenvalues D (semiaxis lengths), it is possible to obtain the symmetric matrix Q with

$$Q = UDU^T \qquad \text{Eq. 2}$$

The orientation vectors were selected according to the morpho-anatomical landmarks derived from the analysis of experimental morphologies in public repositories. The probability density function could then be modelled as tridimensional points scattered according to the following parametric equations:

$x = \lambda_1 cos\vartheta sin\varphi,\ y = \lambda_2 cos\vartheta sin\varphi,\ z = \lambda_3 cos\varphi$ Eq. 3

where $0 \leq \vartheta \leq 2\pi$ and $-\pi \leq \varphi \leq 0$.

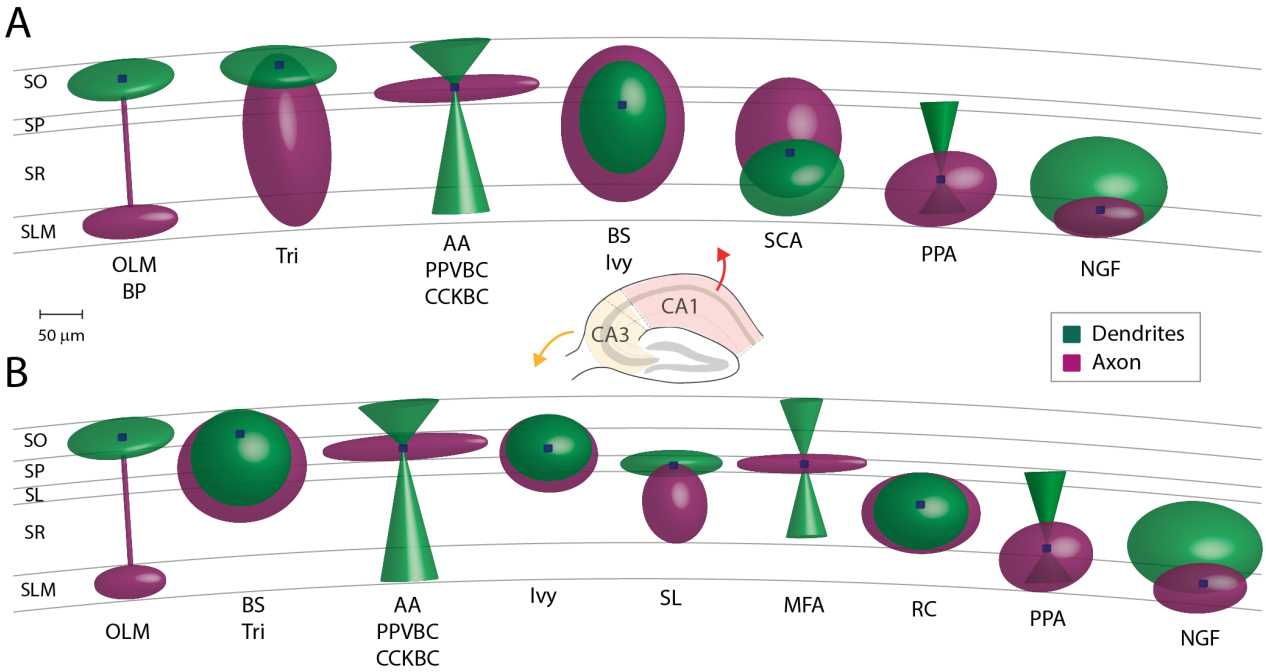

Fig. 3: Probability density functions of GABAergic interneurons. A. The 11 classes of CA1 interneurons described in table 1 have been represented with 7 shapes. B. The 12 classes of CA3 interneurons described in Table 1 have been represented with 9 shapes. Black squares indicate the preferential position of the cell soma while green and violet shades represent dendrites and axons respectively.

Conical probability density functions have been modeled as point cloud volumes with extent and orientation determined by parametric features and morpho-anatomical constraints. Assuming **u** and **v** are orthogonal vectors lying in the plane of the base, the scattered points in a conical volume are calculated with the following equation:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{pmatrix} O_x + \frac{h}{H}dx \\ O_y + \frac{h}{H}dy \\ O_z + \frac{h}{H}dz \end{pmatrix} + \begin{pmatrix} r \cdot \frac{h}{H} \cdot cos\vartheta \cdot u_x \\ r \cdot \frac{h}{H} \cdot cos\vartheta \cdot u_y \\ r \cdot \frac{h}{H} \cdot cos\vartheta \cdot u_z \end{pmatrix} + \begin{pmatrix} r \cdot \frac{h}{H} \cdot sin\vartheta \cdot v_x \\ r \cdot \frac{h}{H} \cdot sin\vartheta \cdot v_y \\ r \cdot \frac{h}{H} \cdot sin\vartheta \cdot v_z \end{pmatrix} 0 \leq h \leq H, 0 \leq \vartheta \leq 2\pi, 0 \leq r \leq R$$

Eq. 4

where $H = |P - O|$ is the height of the cone, O is the apex, P is the center point of the base, R is the radius of the cone base, [*dx,dy,dz*] are the vector component of H. The scattered points of the cone were created by randomly sampling h, theta and r in their respective ranges.

C. Neuronal connectivity

The geometrical morphologies were converted into axonal convex hulls and dendritic point clouds and an iterative algorithm intersected a single presynaptic axonal hull with all dendritic point clouds belonging to a particular neuronal class. Given the size of the benchmarked network (see Table 1) which could lead to an intensive computational load, the range of possible intersections was limited to axon and dendrites sharing putative volumes. This dimensional reduction was performed by calculating the bounding boxes for all geometric shapes and running the intersection algorithm to neurites with overlapping bounding boxes. The pairs of connected neurons were obtained by computing whether at least one dendritic point was included in an axonal convex hull. All neuronal pairs sharing one or more dendritic points were included in the empirical calculation of potential connection pairs. This initial evaluation was then reduced by estimating the putative number of connection pairs combining the number of pre and post synaptic neurons in both classes with the synaptic connection probabilities obtained from the public repository Hippocampome.org.

D. Benchmark of the modeling strategy

The proposed strategy has been benchmarked by generating two of the main regions of the mouse hippocampus, CA1 and CA3, each containing about 300'000 neurons. All the algorithms to the identify landmarks, to generate neuronal morphology and to intersect probability density functions were custom developed in Matlab (The Mathworks inc.) and then converted to python language. The time required to calculate the network connectivity depended i) on the number of points in each cloud, ii) the number of potential intersections and iii) the numerosity of each neuronal class. The codes were parallelized on a supercomputer (http://www.labcsai.unimore.it) equipped with an Intel Xeon

20 core 6230 2.1 GHz with 40 processors) to create the CA1 and CA3 circuits (each one with ~300k neurons and ~1 billion synapses).

.

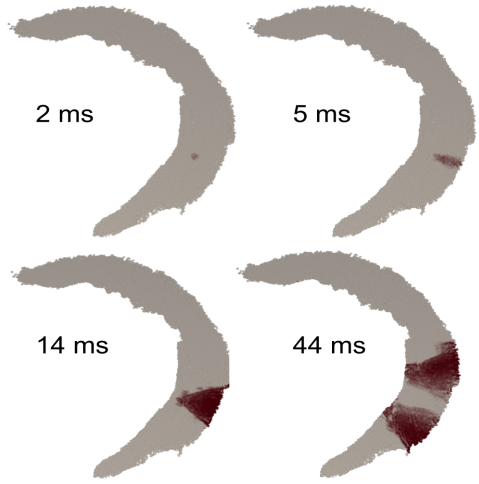

Fig. 4: HPC simulation results. The CA1 network model was stimulated to activate 240 neurons at time 2 ms after stimulation onset (upper left panel). All neurons are shown in grey. The neurons that fired an action potential within a 1 ms time window were plotted in dark red. The panels show the progression of the activation wave through the network at 5, 14 and 44 ms after stimulus onset.

E. Network simulation

The present connectivity strategy has been tested on the CA1 region by verifying the correct implementation of the directionality in Pyramidal-to-pyramidal activity propagation along transversal hippocampal slices. The CA1 simulation including PCs and inhibitory interneurons was set up on the supercomputer Piz-Daint of the Swiss HPC CSCS facility using the Cray X40 Compute nodes. Each node has two Intel® Xeon® E5-2695 v4 @ 2.10GHz (18 cores) and 64GB of RAM. The neuronal placement and connection matrices were loaded on the NEST simulator with Python API. All neuronal types were modeled as point neurons using the Hill & Tononi [15] neuron model available in NEST as it offers the possibility to receive AMPA, NMDA, and GABA mediated synaptic models. Synapses were endowed with short-term dynamics properly tuned according to the available literature using Tsodyks & Markram model. Neuronal models were not calibrated and tests were only performed to assess the technical feasibility of the overall implementation. To speed up the network setup, the neuronal placement and connection matrices were loaded into compressed datasets in a single HDF5 data file of 388 Mb. For these initial tests, we run simulations on a single HPC node. A simulation was set to use a single processor for the network setup and 18 threads to run the simulation. The network setup time was 65 secs and it took 373 secs to simulate 500 ms of network activity. Figure 4 shows the simulation results for the CA1 network model. After the stimulus onset, a front of active neurons spreads along the CA1 in both directions.

III. CONCLUSION

We have presented a generalized bottom-up strategy to generate networks of point neurons based on morpho-anatomical constraints that has been benchmarked on two mouse hippocampal regions. This data-driven method based on the construction of geometrical probability density functions mimicking axonal and dendritic shapes and extension, is particularly suitable in conditions of poor or absent data on cell morphologies which hamper the possibility to adopt more realistic strategies like touch algorithms requiring complete morphologies for all neurons. At the same time, connection strategies like random connectivity have been shown to produce networks connectivity with homogeneous distance connectivity and number of connections per neuron uniformly distributed, which has been shown to be unrealistic [8,11]. The proposed strategy will be integrated as a function of the BSB as a method to connect neuronal classes in a custom created circuit, providing an additional tool to generate network connectivity of large-scale circuits.

***Abstract*— The brain at birth is characterized by a default state of competition among the senses [1], and integrative abilities are acquired only later in life, based on experience. Recently, Crosse and colleagues [2] in a bisensory reaction time task, with auditory (A) and visual (V) stimuli, presented alone or together (AV), in a random sequence, showed that children's reaction times (RTs) to congruent AV stimuli did not differ significantly from unisensory RTs, but differences emerged between ASD and neurotypical (NT) subjects. In this work, we implemented a neurocomputational model to simulate the RTs and analyse the behavioural responses of ASD children (6-7 years of age) and their NT counterpart. The model suggests that the comparable RTs found in unisensory and multisensory conditions could be interpreted by the default competition among the senses; this default state can be implemented via mutual inhibition between primary sensory areas; and the shift toward the classical multisensory facilitation, observed in adults, is the result of the inhibitory cross-modal connections becoming excitatory after an extended multisensory experience. Moreover, model results suggest that differences between ASD and NT children are due to a stronger cross-modal inhibition in 6-7 year-old ASD children. Finally, this neurocomputational model allowed investigation of the temporal profile of interactions among stimuli of different sensory modalities. These findings link the perceptual framework delineated by several empirical results to a plausible neural implementation.**

I. Introduction

MULTISENSORY integration (MSI) is the mechanism exploited by the brain to deal with information from different sensory systems, and optimizing its responses in case of redundant multimodal cues compared to the individual unisensory components, when presented separately. The principles ruling MSI in the spatial domain, like the inverse effectiveness and the multisensory enhancement in case of congruent multisensory stimuli, have been known for a long time [3], [4]. In the temporal domain great effort has been dedicated to identify the conditions for a multisensory facilitation (the so-called temporal binding window, TBW) [5], [6], but only recently the competition among stimuli incongruent in time has been analysed: Cuppini et al. [7] addressed MSI in the temporal domain for healthy adult subjects. Additionally, MSI is not innate: the brain at birth is characterized by a default state of competition among the senses, and integrative abilities are acquired only later in life, based on sensory experience [1].

In the last decade, numerous studies dealing with MSI focused on its alterations in subjects with neurodevelopmental disorders. Among these, individuals with Autism Spectrum Disorders (ASD) have shown a lack of benefit from multiple sources of information as their neurotypical (NT) peers do [8]–[12]. These deficits have been observed in case of simple AV detection task, involving low-level stimuli [2], [13], but also with audiovisual (AV) speech stimuli, thus suggesting that perceptual deficits may be responsible for higher order core symptoms characterizing ASD [12].

Recently, Crosse and colleagues [2] implemented a bisensory reaction time task to characterize the MSI maturation, in NT and ASD, from childhood to the adult age, and analyse the switch cost (the difference between RTs in case of stimuli preceded by a different sensory modality, switch trials, and RTs in repeat trials, when the preceding stimuli are of the same modality). In their experimental setup, auditory (A) and visual (V) stimuli were presented in random sequence, alone or together (AV), and subjects were required to respond (pressing a button) as soon as they perceived a stimulus. They showed that children's reaction times (RTs) to congruent AV stimuli did not differ significantly from unisensory RTs. Similarly to [1], also these authors suggested that this behaviour could be ascribed to a default competitive interaction among sensory modalities. Postnatal multisensory experience is thought to craft cross-sensory projections between sensory cortices, promoting the maturation of integrative abilities and shift the competition to facilitative cross-modal interactions. Authors highlighted that this shift is delayed in ASD children.

Despite the numerous developmental studies, reporting reduced multisensory abilities in younger children, there is little evidence of such competitive cross-modal architecture. Moreover, to our knowledge, there is no study investigating the mechanisms underlying MSI in the temporal domain for children and/or for any pathological condition. Therefore, here, we used a computational modelling framework to reproduce the data of Crosse et al. [2], investigating the nature of cross-modal interactions in the youngest subjects (6-7 years of age), characterizing the differences between NT and ASD children, and the mechanisms underlying MSI in the temporal domain.

A. Data analysis

To identify the neural mechanisms to be implemented in the network, first we analysed the empirical results of [2], based on the age group, in the case of unisensory and multisensory stimulations.

As it can be seen in Fig. 1, data of 6-7 year-old subjects do not show a multisensory behavioural facilitation. Indeed, responses (RTs) were not significantly faster in the multisensory condition compared to the unisensory ones: in NT children (Fig. 1A), RTs in AV repeat trials were comparable with RTs in the visual repeat condition; in ASD children (Fig. 1B), RTs in AV repeat trials were comparable with RTs in the auditory repeat condition. Moreover, RTs in case of multisensory switch trials, do not differ neither from

AV repeat, nor from unisensory repeat condition. This pattern of behaviour not only denotes the absence of a multisensory facilitation, but it suggests an active competition between the two sensory modalities: the fact that behavioural responses in the multisensory repeat condition are comparable with RTs in the fastest unisensory repeat condition, suggests that in case of AV stimulation, the two sensory channels compete, and only one of them can drive the response and determine the RTs. In agreement with [1], [2], these results strongly suggest the existence of an initial cross-modal competition between the sensory modalities. During the development, this competition should be superseded by the classical multisensory facilitation, as the result of the multisensory experience a subject was exposed to.

In our model, this default cross-modal competition was implemented via inhibitory cross-modal projections, as shown in Fig. 2. These synapses produce a fast competition between sensory modalities, and, balancing the integration occurring in the M region (due to the excitatory feedforward connections projecting on it), nullify any multisensory facilitation.

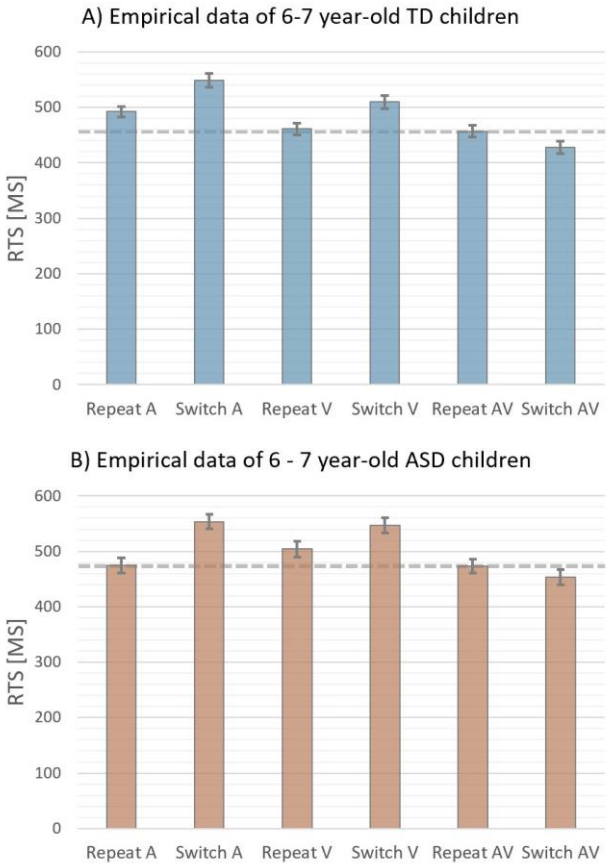

Fig. 1: Analysis of unisensory and multisensory RTs for both NT and ASD children of 6-7 years of age. A) In NT children of 6-7 years of age, RTs in the multisensory repeat trials were comparable with RTs in the visual repeat condition. B) In ASD children of 6-7 years of age, RTs in the multisensory repeat trials were comparable with RTs in the auditory repeat condition. It is evident that multisensory RTs were not faster than the faster of the unisensory conditions, but exactly comparable to it. This behavioural data could only be explained by a competition between the two sensory modalities.

II. Methods

A. Model architecture

The model has been realized to simulate the behavioural task implemented by [2], which focuses on multisensory interactions in the temporal domain: subjects (either adults or children, NT or ASD) were required to respond to auditory and visual stimuli, alone or combined, presented in a random sequence, with an inter-stimulus-interval (ISI) varying between 1 s and 3 s. Given the experimental set-up in [2], we do not require either multiple units sensitive to different spatial positions in each sensory area, nor do we need multiple sensory regions sensitive to different input features.

The model we developed is represented in Fig. 2. The network is composed of three layers.

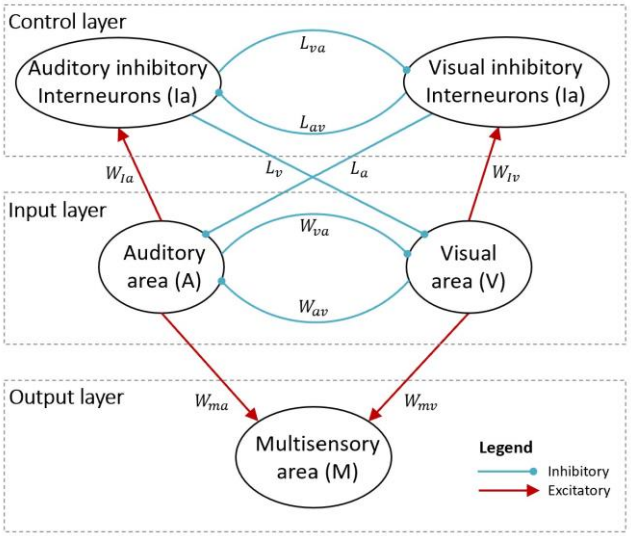

Fig. 2: Model structure. A and V represent the auditory and visual regions, responsible for the first sensory processing, and implementing the input layer. They exchange direct inhibitory synapses (W_{va} and W_{av}), implementing a cross-modal competition. M is the multisensory output region, excited by the input layer, through feedforward connections (W_{ma} and W_{mv}). It is responsible for generating the simulated reaction times (RTs) to the external stimuli. I_a and I_v are unimodal inhibitory areas, excited by the input layer (through W_{Ia} and W_{Iv}) and implementing a control mechanism via feedback inhibitory synapses (L_a and L_v) and a winner-takes-all mechanism (L_{va} and L_{av}).

A and V represent the auditory and visual regions, respectively, responsible for the first sensory processing of external stimuli, and implementing the "input layer". A and V exchange reciprocal inhibitory synapses, W_{va} and W_{av}, with a fast dynamic, implementing the default cross-modal competition.

M is the multisensory output region ("output layer"), responsible for generating the simulated reaction times (RTs) to the external stimuli. M, which receives the converging excitatory projections (W_{ma} and W_{mv},) from the two areas in the input layer, may correspond to multisensory associative cortices, including, for example, the Posterior Parietal Cortex (PPC).

Ia and Iv are unisensory inhibitory areas representing a "control layer". They are excited by the input layer (through W_{Ia} and W_{Iv}) and implement a cross-sensory competition between the two sensory modalities, characterized by a slow dynamics: if stimulated by an input of the corresponding sensory modality, these modality-specific inhibitory interneurons produce a long lasting inhibition of the input region processing external stimuli of the other sensory modality, via the inhibitory feedback projections (L_a and L_v), and the winner-takes-all mechanism (L_{va} and L_{av}). It is worth noting that, since the dynamics of this mechanism is slow, the processing of the current stimulus is affected by the previous

one, when of the opposite sensory modality. This competitive layer can be implemented through higher order regions, for example located in the medial Prefrontal Cortex (mPFC) or the Posterior Cingulate Cortex (PCC).

B. *Assessment of network performance*

First, as described above, to discriminate between alternative architectures for the network, we performed an analysis of the data collected by [2], based on the age group, in the case of unisensory and multisensory stimulation.

Once we identified the cross-modal inhibition as the more plausible neural architecture to explain these behavioural data, we performed several simulations to test the network behaviour. To this end, we presented sequences of unisensory (A or V) and congruent AV stimuli, in randomized order. The onset, duration, and presentation rate (ISI) of the stimuli were chosen to mimic the experimental setup of [2], whose data are compared to our results. Specifically, external stimuli are excitatory inputs with a duration of 60ms, presented at a rate of every 2s (the mean ISI in [2]). The activity elicited in the output region was compared with a fixed threshold, φ (10% of the maximum neurons' activity), to evaluate the simulated RTs, computed as the time interval between the instant of input presentation, and the instant when the evoked activity in the output area reaches the threshold. These results were analysed separately based on the respective input modality.

III. Results

In the following we present our results, critically analysing the model behaviour. This allows us to understand (i) what mechanisms are responsible for behavioural data in children and (ii) how such mechanisms differ in ASD.

TABLE I: Synaptic weights

NT children			
$L = 3$	$L_{a_NT} = 0.09$	$W_{av_NT} = -0.45$	$W_{ma_NT} = 1$
$WI = 1.4$	$L_{v_NT} = 0.07$	$W_{va_NT} = -0.45$	$W_{mv_NT} = 1.72$
ASD children			
$L = 3$	$L_{a_ASD} = 0.13$	$W_{av_ASD} = -0.8$	$W_{ma_ASD} = 1.1$
$WI = 1.4$	$L_{v_ASD} = 0.05$	$W_{va_ASD} = -0.8$	$W_{mv_ASD} = 1.3$

A. *Testing model simulations against empirical data*

Once we identified the cross-modal inhibition as the main mechanism to be implemented, the next step was to determine the exact parameters' values that allow to reproduce RTs reported in [2], for both ASD and NT children at 6-7 years of age. To this aim, several sets of parameters were tested, and the simulated RTs were compared with the experimental median RTs extracted from the population of real subjects.

Fig. 3 illustrates the comparison between simulated and real RTs, obtained with the best set of parameters for all the six input configurations, for both ASD and NT children. It is worth noting that, among all the parameters, only the synaptic weights differ between the two groups, and are reported in Table I.

In particular, model results suggest that differences between ASD and NT children can be explained by a stronger cross-modal inhibition in 6-7 year-old ASD children, as can be noted from the more negative value assumed by W_{va} and W_{av} in the ASD simulations (Table I). We made this assumption based on the delayed maturational trajectories characterizing ASD abilities [9], [14]: since the maturation of perceptual abilities is delayed in ASD, we could assume that cross-modal connections are more negative in ASD children of 6-7 years of age compared to their NT peers.

As it is evident from Fig. 3, the model provides a good fit with empirical data of [2].

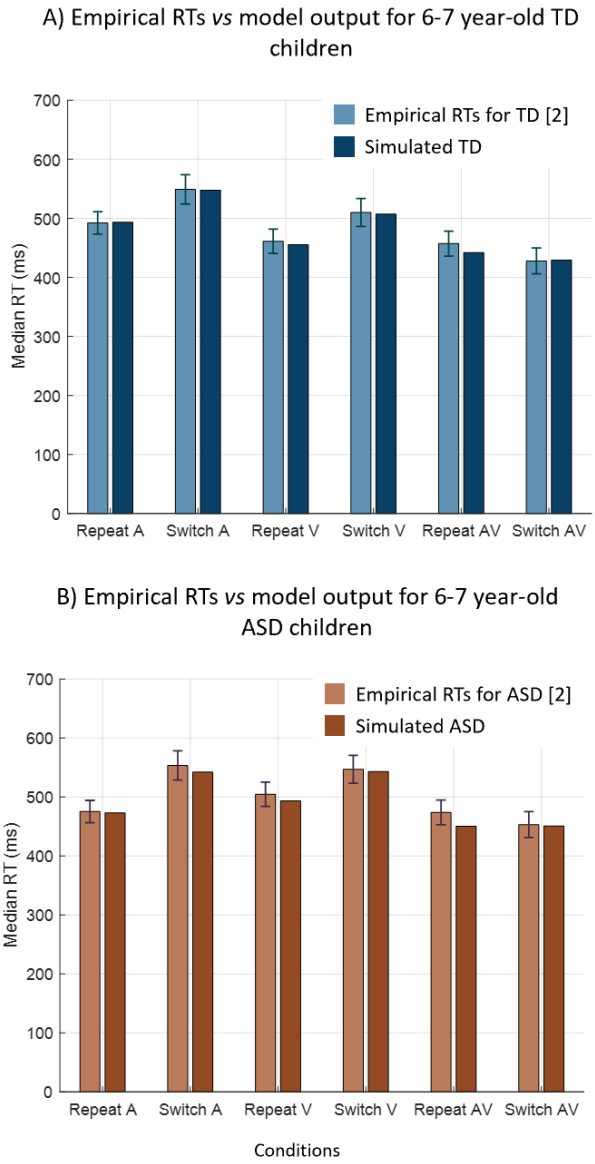

Fig. 3: Simulated RTs vs Median RTs of the subjects' population. For each stimulus configuration (A and V Repeat, A and V Switch, AV Repeat and Switch) RTs obtained with the model were compared with the experimental median RTs extracted from the population of real subjects. To set the basal configuration of parameters, no noise was added (neither on the input, nor on the synapses).

B. *Model's behaviour*

To clarify how each implemented mechanism contributes to the model's behaviour, in Fig. 4 we report the activities elicited in the NT network's regions in four exemplary conditions of unisensory (A) and multisensory (AV) repeat and switch.

Comparing the auditory repeat and switch conditions (Fig. 4A and 4B), we can notice that the activation elicited in the model by the second stimulus (A) is lower in the switch case. This is due to the inhibitory effect exerted by the prior input (V): the visual inhibitory interneuron, excited by the preceding visual stimulus, inhibits the auditory input region through the

feedback projections, characterized by a slow dynamic (i.e. the effect acts over a long period of time). The consequent lower activity produces a delayed activation of the multisensory region, resulting in longer RT.

Similar results were found for visual repeat/switch trials.

In case of multisensory stimulation, in addition to this slow inhibition that the prior input exerts on the processing of the current AV stimulus, the A and V components of the AV input reciprocally compete, by means of the direct inhibitory cross-modal synapses. This results in a lower activity elicited by an AV stimulus in the input layer (Fig. 4C and D) compared to the case of unisensory stimulation. This inhibition counterbalances the integration occurring in the M region, mediated by the excitatory feedforward projections. The presence of cross-modal inhibitory synapses is critical to explain the behavioural data. Indeed, without this mechanism a cross-modal input would produce RTs much faster than those found in [2].

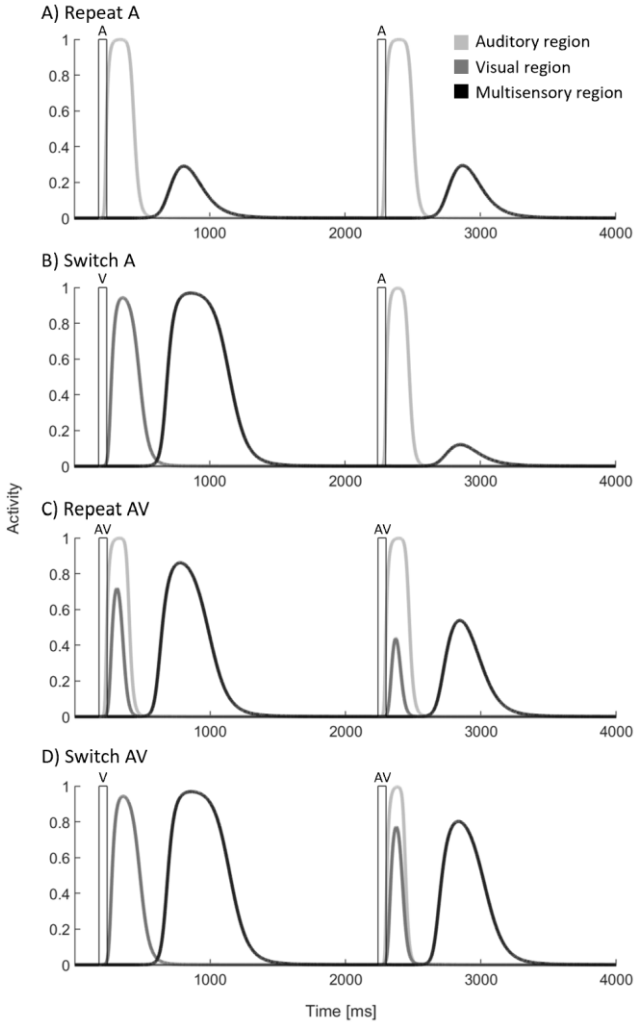

Fig. 4: Example of the network behavior, in the case of a A) Repeat A, B) Switch A, C) Repeat AV and D) Switch AV conditions, for NT children. Rectangular wave represents the external visual stimuli presented with an ISI of 2000ms. Light grey lines describe the activation of the auditory region, dark grey lines describe the activation of the visual area. Black lines represent the activity elicited in the output region in response to this stimulation.

IV. Conclusion

In this work, we developed a biologically plausible neurocomputational model of perceptual abilities and sensory interactions in children. This model should be thought of as a "engineering" tool, to test and interpret current empirical knowledge, elucidating the neural mechanisms in play.

In the first part of our work, we investigated the nature of cross-modal interactions in children. Empirical evidence [1] identified a default state of cross-modal competition in kittens, which could potentially represent a mechanism preserved also in human brain. Indeed, recent children's behavioural data [2] are consistent with such a competitive architecture. In our model, we linked these empirical results with a plausible neural implementation, in which the default competition is realized via inhibitory cross-modal projections.

In the second part, we tested how altered perceptual mechanisms could contribute to ASD phenotype and we suggested that the slower maturation of perceptual abilities in ASD would result in a stronger cross-modal competition in these children compared to their NT peers.

Overall, the importance of this work is that it provides with a deeper insight into perceptual function, dysfunction and behaviour in children. One field expected to benefit from this in the near future is the neurorehabilitation: by elucidating the underlying neural mechanisms, plausible neural networks will allow to make predictions, design specific interventions and explain their effects.

Functional Connectivity of the EEG in epilepsy: a single case study

G. Chiarion[1], L. Mesin[1]
[1] *Mathematical Biology & Physiology, Dept. Electronics and Communications, Politecnico di Torino, Turin, Italy*

***Abstract*—This paper introduces some of the most used methods in the literature to explore network connections in the brain from electroencephalogram (EEG), based on functional connectivity (FC) metrics and topological indexes from graph theory. A publicly available dataset of EEG of epileptic children is studied. We trace in a single case all fundamental steps required to develop an adapted method for seizure prediction: extraction of FC indices, topological analysis by graph theory and prediction by machine learning. Specifically, some FC indexes (cross-correlation, phase-locking value and mutual information) are estimated to explore the information flow. Then, topological measurements (i.e., strength, clustering coefficient, characteristic path length and efficiency) are used to characterize the resulting connections. To discriminate inter-ictal and pre-ictal EEG epochs, we processed these topological indexes with different classifiers (k-Nearest-Neighbor, Support Vector Machine and Discriminant Analysis). Pseudo-Quadratic Discriminant Analysis classifier performed best to predict an epileptic seizure, with a mean accuracy up to 75% and a True Negative Rate of 80% suggesting, at least for the specific patient considered, a variation of brain connectivity before the onset of a seizure.**

***Keywords*—EEG, Connectivity, machine learning, seizure prediction.**

I. INTRODUCTION

Recent neuro-scientific studies, mostly based on functional magnetic resonance imaging (fMRI), had disproved the hypothesis that each human brain function is only associated to a specific area, evidencing that most of them result from coordinated activity between separated regions. Thus, spatially distant brain regions may share functional properties [1]. This is the focus of functional connectivity (FC), which explores the interconnections of spatially distant regions of the brain. It is defined as a statistical dependence among remote neurophysiological events [2] and accounts for determining which sets of neurons are appointed to carry out a precise function. Many efforts are devoted to deepen this research path. Indeed, neuronal interactions and their inter-dependence are fundamental for cognition [3] and the accomplishment of different tasks, e.g., in movement coordination [4]. Deficits in FC are associated to different diseases. For example, in autism, they reflect into a lack of social interaction and empathy [5]. Global changes to the functional organization of the brain network were found following stroke [6]. Moreover, connectivity between hippocampus and prefrontal cortex was found disrupted in psychiatric and neurodegenerative disorders [7].

The most known technique used so far in this context is fMRI, which allows to map the anatomical connectivity of a neural network by means of diffusion tensor imaging [8], [9]. However, fMRI lacks in time resolution and therefore cannot be entrusted with detecting short time events, which can instead be investigated by electroencephalography (EEG), which is a low-cost technique allowing to study FC among cortical brain regions and providing different information with respect to fMRI [10]. Many applications of EEG have been documented, e.g., in the study of schizophrenia and bipolar disorder [11], investigation of the level of consciousness [12], dyslexia [13], encephalitis [14], epilepsy [15]. Specifically, an epileptic seizure is a transient manifestation of abnormally high or synchronous activity of neurons in the brain [16], with symptoms like cognitive, emotional, affective, autonomic or motor problems.

To assess FC, different bivariate metrics can be used; indeed, a common practice is to combine different metrics to assess FC and draw a more meaningful scene of the network [17], [18].
Once obtained a network of connections, a key for understanding its topology is given by graph theory, providing different methods to post-process FC indexes, very useful in many applications [11], [19]. Different topological indexes are then introduced and applied. Here, we explore the topological structure of functional connections in an example application to the prediction of epileptic seizures, in which inter-ictal and pre-ictal time windows are discriminated by a machine learning approach applied to the indexes extracted from them.

II. FC METRICS

In neuroscience, there is a rich and evolving literature about the methods to quantify neuronal interactions [1].

In the following paragraphs, some popular FC metrics are described. The FC indexes estimated between pairs of EEG channels are collected in an adjacency matrix (AM). It has dimensions $N_{ch} \times N_{ch}$ and can be written as $A = \{a_{ij}\}_{i,j=1,\dots,N_{ch}}$, where a_{ij} is the FC index between channels i and j and N_{ch} are the total number of channels.

a) Cross-correlation: The simplest measure of synchronization between two discrete univariate time series x_n and y_n is ***cross-correlation***, defined as:

$$c_{x,y}(\tau) = \frac{1}{N-\tau} \sum_{i=1}^{N-\tau} \left(\frac{x_i - \overline{x}}{\sigma_x} \right) \left(\frac{y_{i+\tau} - \overline{y}}{\sigma_y} \right) \qquad (1)$$

where the time series are assumed to be real, i labels the i^{th} sample, x_i and y_i are the i^{th} samples of the two time series, $\bar{x}$

and $\bar{y}$ are their means, σ_x and σ_y are their standard deviations, N is the number of samples of the two time series and τ is the delay.

b) Mutual information: ***Mutual information*** is based on information-theoretic concepts [20], specifically on *Shannon entropy* [21]. It measures how much one random variable tells us about another one. A high mutual information indicates a large reduction in uncertainty on a variable once another is known, and zero mutual information between two random variables means that they are independent.
Mutual information between two random variables X and Y is defined as

$$I(X,Y) = H(X) + H(Y) - H(X,Y) \tag{2}$$

where $H(X)$ and $H(Y)$ are the entropies of X and Y, respectively, and $H(X,Y)$ is the joint entropy:

$$\begin{aligned} H(X) &= -\sum_{i=1}^{M_x} p_x(i) \log(p_x(i)) \\ H(Y) &= -\sum_{i=1}^{M_y} p_y(i) \log(p_y(i)) \\ H(X,Y) &= -\sum_{i=1}^{M_x} \sum_{j=1}^{M_y} p_{x,y}(i,j) \log(p_{x,y}(i,j)) \end{aligned} \tag{3}$$

p_x and p_y represent marginal probabilities, $p_{x,y}$ is the joint probability; M_x and M_y are the numbers of the states of X and Y, respectively.

c) Phase Locking Value: Phase synchronization problem has first been taken into account in [22] and [23] to surmount some limitations of linear methods, which are not able to separate amplitudes and phases in the interrelations between two signals.

The phase synchronization can be measured using the ***Phase Locking Value*** (PLV) which is defined as

$$PLV(t) = \left\| \frac{1}{n} \sum_{t=1}^{n} e^{i[\Phi_1(t) - \Phi_2(t)]} \right\| \tag{4}$$

where n is the number of samples, $i = \sqrt{-1}$ and $\Phi_k(t)$ is the instantaneous phase of the k^{th} signal.
The value of PLV ranges from 0 (i.e., the signals are completely decoupled) to 1 (i.e., the signals have constant phase lag and are coupled).

III. Indexes of the network patterns

Many indexes have been proposed to characterize the topological organization of networks represented by a graph [24], finding many applications in the interpretation of EEG [25]. The following topological indexes are considered in this paper. They are defined in terms of the coefficients

a) Global Strength (S): it is the sum of the weighted connections to a node:

$$\begin{aligned} S &= \tfrac{1}{N_{ch}} \textstyle\sum_{i \in N} S_i \\ S_i &= \textstyle\sum_{i \in N} w_{ij} \end{aligned} \tag{5}$$

where $N = \{1, 2, \ldots, N_{ch}\}$ and w_{ij} is the weight of the edge from node i to node j. It provides an overall characterization of how much the network is connected.

b) Clustering coefficient (CC): The global weighted CC of the network [26] is defined as:

$$\begin{aligned} C &= \tfrac{1}{N_{ch}} \textstyle\sum_{i \in N} C_i \\ C_i &= \tfrac{2}{k_i(k_i-1)} \textstyle\sum_{j,k} (w_{ij} w_{jk} w_{ki})^{1/3} \end{aligned} \tag{6}$$

where the triangle weights w are scaled by the largest weight in the network

$$w_{ij} = w_{ij} / \max(w_{ij}) \tag{7}$$

and C_i is the clustering coefficient of the i^{th} node. It is a measure of the degree to which nodes in a graph cluster together [27].

c) Global efficiency (GE): It is defined as [28]

$$E = \frac{1}{N} \sum_{i \in N} E_i = \frac{1}{n} \sum_{i \in N} \frac{\sum_{j \in N, j \neq i} d_{ij}^{-1}}{N_{ch} - 1} \tag{8}$$

where E_i is the efficiency of node i and d_{ij} is the shortest path length between nodes i and j

$$d_{ij} = \sum_{w_{uv} \in g_{i \leftrightarrow j}} w_{uv} \tag{9}$$

where $g_{i \leftrightarrow j}$ is the geodesic path between nodes i and j (with $d_{ij} = \infty$ for disconnected pairs). It measures the efficiency of the network to exchange information.

d) Characteristic path length (PL): The PL is defined as

$$\lambda = \frac{1}{N_{ch}} \sum_{i \in N} L_i = \frac{1}{N_{ch}} \sum_{i \in N} \frac{\sum_{j \in N, j \neq i} d_{i,j}}{N_{ch} - 1} \tag{10}$$

where L_i is the average distance between the node i and all other nodes. As for the previous index, it is also a measure of information transport in the network (with opposite trend with respect to the efficiency), as a short average path length between nodes indicates a better overall connection.

IV. Case study

Tests on real data were made using the *CHB-MIT Scalp EEG Database*, publicly available in Physionet [29]. The dataset is a list of 1 hour scalp EEG signals (sometimes the duration of the recordings can vary), grouped by patients (22 subjects from 1.5 to 22 years old). Not all the recordings nor the patients present ictal phases. Our tests were focused on one subject: the number 3, a 14 years old female patient. Four signals showing one seizure each were analyzed: recordings chb03_04, chb03_34, chb03_35 and chb03_36. In the following, we refer to these EEG traces as Signal 1, Signal 2, Signal 3 and Signal 4, respectively.

A. Pre-processing: filtering and artifact removal

A preliminary processing was applied on our data to attenuate the effect of noise. A portion of data centered on each seizure was selected: specifically, we included EEG traces from 15 minutes before to 10 minutes after the seizure. A broad 5^{th} order IIR Chebychev band-pass filter 0.1 - 80 Hz was applied. Anticausal double pass filtering was used to avoid any phase distortion. To remove EOG artifacts, as eye blink and eyeball movements, data have been pre-processed using

the Automatic Artifact Removal (AAR) toolbox [30]. Specifically, Second Order Blind-source Identification (SOBI) [31] algorithm was applied to decompose EEG into components [32] and the one with the lowest fractal dimension (computed by the Sevcik's method [33]) was removed.
At last, data have been segmented in epochs 5s long, overlapped by 80%. FC metrics has been computed on each of these epochs.

B. FC metrics evaluation

All the metrics have been evaluated in different frequency bands: δ: 0.5-4 Hz, θ: 4-8 Hz, α: 8-12 Hz, $\beta 1$: 12-20 Hz and also in a broad frequency band M1 (0.5-20 Hz). Once computed the metrics and obtained the correspondent weighted AMs, topological properties were measured. Since there is no consensus in literature on the optimal threshold to extract the significant connections [34], no threshold (absolute or proportional) was applied to the AMs. Indeed, the application of a different arbitrary threshold could lead to ambiguous and different results, also when the same metric is used [35].

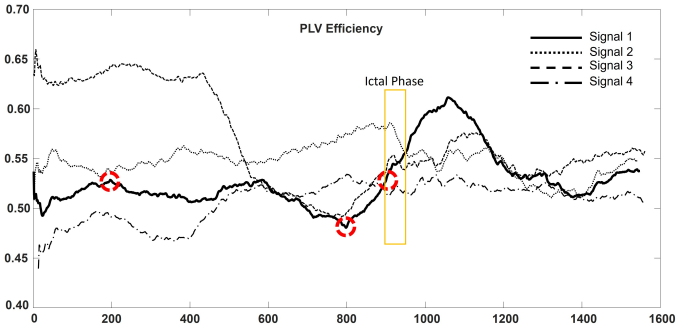

Fig. 1: Trend of efficiency applied to the adjacency matrix of the phase-locking value (PLV) calculated for 4 registrations of the same patient from 15 minutes before to 10 minutes after the seizure. The values are evaluated in windows of 5 s each with a 80% overlap, and then filtered by a causal moving average of 2 minutes.

C. Prediction of seizure onset

a) Dataset definition: The topological indexes described above were used to predict the onset of a seizure through a classifier. The dataset used for the classification was organized as a matrix $N \times M$, where the rows correspond to the 5 s epochs in which the signal was split (with 80% overlap, as explained before) and each column M_j represents a global topological metric. For each of the four signals, a moving average window of 30 s was applied, and two parts were extracted: the first 5 minutes, far from the seizure, considered as inter-ictal and labelled as "0"; the last 5 minutes before the seizure, considered as pre-ictal and labelled as "1". The final dataset had 2400 rows (600 elements for each signal) and 61 columns (3 Metrics, 4 Topological Indices, 5 Frequency Bands and the last column is the ground truth).

b) Classification methodology: All the available machine learning classifiers implemented in Matlab were trained using 5-fold cross-validation and default parameters. The classifiers were then sorted by validation accuracy and the top 3 were chosen to be tested and optimized: Support Vector Machine (SVM), k-Nearest Neighbor (kNN) and Discriminant Analysis (DA).

Leave-One-Trace-Out approach was chosen to train and test the classifier performance, using each time the data from 3 out of 4 signals (1800×61 dataset) to train the classifiers and the remaining to test the generalization of the model (600×60 dataset).

For SVM, different kernels have been tried: linear, Gaussian radial basis function and polynomial. Based on accuracy, the best results were achieved using a polynomial kernel with a mean accuracy of 64%. It's important to notice that the mean performances are heavily degraded by the first signal as test. In fact, the accuracy in this particular case is only of 46% and True Negative Rate (TNR) of 9%. Excluding this signal as test set brings the mean accuracy to 70% and TNR to 77%.

When using kNN, different distance metrics have been tried: Euclidean, Chebychev and cityblock. Based on accuracy, the best results were achieved using cityblock metric, with a mean accuracy of 59%. Also with this classifier, the average performance degraded due to the test on the first signal; excluding it, the mean accuracy was 62% and TNR increased to 72%.

Concerning DA, different types of analysis have been tried: linear, pseudo-quadratic and diag-quadratic. Based on accuracy, the best results were achieved using pseudo-quadratic DA, with a mean accuracy of 70%. The first signal had poor performance in the test, and excluding it made the mean accuracy increase to 75% and TNR to 80%. This classifier was the best in terms of performance with respect to the others tested.

Finally, an analysis of the distribution of the outputs of the classifiers was performed, considering our Leave-One-Trace-Out approach. Also in this analysis it is evident how the first signal behaves differently, since the vast majority of its predictions as test set are ones. By using the DA classifier, a 30 samples long uninterrupted true positive consensus region between signals is found, from 300 s to 270 s before the seizure onset. By choosing 50 predicted positive events in a 1 minute window as threshold, the classifier would uniquely recognize the ictal phase in all the signals, with the exception of the first.

V. Conclusion

FC and topological metrics can be useful tools to explore brain network connection in different conditions. Epilepsy is a neurological disorder characterized by the emergence of seizures, in which the brain activity becomes abnormal. The seizure is characterized by high or synchronous activity of neurons [16], which could be triggered by an anomalous connectivity pattern. Thus, comparing the functional connections in normal conditions and close to the seizure onset could be of relevance for the prediction of an incoming seizure [36]. We explored the possible variation of global topological indexes in the pre-ictal with respect to the

inter-ictal phase, by considering EEG epochs close (up to 5 minutes before) and far (10 to 15 minutes before) from the seizure, respectively. A single patient was considered, with a view to developing a method adapted to the specific subject. Discriminant Analysis can distinguish fairly well epochs recorded during the two phases, using topological indexes of different FC metrics. Thus, the evaluated topological indexes contain some information about the modification of brain activity in preparation to the onset of the seizure. Moreover, these results are consistent in different signals of the same subject, as the classifier was trained on data including some seizures and then applied on those concerning a different one. The classification performance were quite low for the first signal, regardless of the type of classifier used. Notice that, according to the author of the dataset, the first signal was acquired in the afternoon, while the other three were recorded in the late night. We can presume that the patient was awake during the acquisition of the first signal, while she was sleeping during the other recordings, thus affecting the characteristics of the signals.

***Abstract*—In recent years, computational models have been clinically used for the prediction of the exchanges of main electrolytes, breakdown products, and body fluids during haemodialysis. If correctly trained, such models can lead to a therapy customization, mainly needed for ESRD patients characterized by multiple comorbidities. The multi-compartmental, multi-solute model developed during DialysIS and InterACTIVE-HD 2.0 frameworks allows to accurately predict the patient's response in the same sessions used for the model training but also in independent sessions, using only the clinical data recorded at the beginning of the session. Here, the reported results refer only to the centre of Lugano: hence, a comparison of the DialysIS and InterACTIVE-HD 2.0 datasets in terms of characteristics and predictive performance has been performed. The stable model's performance over time confirms the correctness of the path, even if further investigations are needed.**

***Keywords*—Hemodialysis, Patient-specific model, Predictive model, Clinical decision support systems.**

I. Introduction

In recent years, computational models have been used to predict the clinically observed trends of the main electrolytes, breakdown products, and body fluids volumes during haemodialysis. Either one, two or three-compartmental models have been developed, focused on the description of either a single (accurately but ignoring its complexity) or multiple solutes (for a limited dataset) [1]–[7]. Now, the use of models based on patients' characteristics is gaining ground, in order to customize the treatment, in particular for elderly ESRD patients that are characterized by multiple comorbidities [8]. According to this objective, a patient-specific model has been developed, improved, and optimized over the course of two projects (DialysIS first and InterACTIVE-HD 2.0 later) involving several patients in treatment in Italian and Swiss centres. More in detail it is a multi-solute three-compartmental model whose customization is achieved through the identification of parameters modulating – specifically on the basis of patient's characteristics – mass and fluid balance across dialyzer, capillary, and cell membranes [9]. This model, after being trained with three sessions, allows a proper simulation of each patient's response to the treatment, in terms of mass and fluids distributions within modelled compartments (intracellular, interstitial, and intravascular). Input were the initial clinical data and the output generation require less than a minute. A so performing tool could support the clinical decisions, improving the treatment efficiency as well as the patients' quality of life. Hence, a comparison of the DialysIS and InterACTIVE-HD 2.0 datasets in terms of characteristics and predictive performance has been performed.

II. Methods

A. Inclusion criteria

DialysIS project (2013–2016): enrolled patients are 18 or older, with a dialysis vintage higher than three months, and arteriovenous fistula as vascular access. They undergo standard HD (SHD) or hemodiafiltration (HDF). No further non-inclusion criteria were defined.

142 patients were enrolled from Nephrology and Dialysis Units of the Sant'Anna Hospital (Como, Italy), A. Manzoni Hospital (Lecco, Italy), Regional Hospital of Lugano (Lugano, Switzerland), and Circolo Hospital and Macchi Foundation (Varese, Italy).

InterACTIVE-HD 2.0 project (2020–2023): as for DialysIS for the age and then:

- dialysis vintage higher than 6 months;
- arteriovenous fistula or central catheter as access in a ratio similar to 7:3;
- residual renal function less than 10ml/min;
- patients with pacemakers less than 15% of the whole.

Moreover, it is suggested that at least one third be diabetic patients and that a balanced male/female ratio be maintained. Patients who have undergone major surgery or trauma in the three months preceding the beginning of the project were excluded a priori.

145 patients were enrolled from Nephrology and Dialysis Units of the Kantonsspital Graubünden (Chur, Switzerland), Sant'Anna Hospital (Como, Italy), Regional Hospital of Lugano (Lugano, Switzerland), ASST Valtellina e Alto Lario (Sondrio, Italy), and Circolo Hospital and Macchi Foundation (Varese, Italy).

B. Data acquisition

The data were acquired in accordance with the guidelines

approved by the ethics committees.

DialysIS data acquisition was performed over a two-week span of treatments (i.e., 6 HD sessions for each patient), while for InterACTIVE-HD 2.0 project the acquisitions were carried out either in 3 consecutive phases for the centres of Lugano and Como, and in 2 consecutive phases for the centres of Chur, Sondrio, and Varese. Each set of acquisitions last at least 1 month form the previous one.

Both projects' data acquisition integrates the clinical records, collected by means of hospital information system (HIS), patient-specific parameters measurements, and plasmatic electrolyte and catabolites concentrations.

The clinical records, allowing stratified analyses, included:

- gender and age;
- height and weight (at start and at the end of the session);
- pathologies leading to Chronic Kidney Disease;
- existing comorbidities and eventual drug doses (if taken) to control it;
- dialysis therapy (i.e., SHD or HDF);
- dialysis vintage;
- prescribed dry weight and weight loss;
- dialysis duration.

On the other hand, other parameters have been directly measured by machine sensors for each session, with different frequencies, as reported below:

- every minute: effective treatment time, ultrafiltration flow rate and ultrafiltration volume, dialysate flow rate and temperature, blood flow rate, dilution flow rate, body temperature, relative blood volume, pressures of arterial and venous lines, and trans-membrane pressure;
- every 15/20 minutes by using the machine' blood pressure cuff: systolic and diastolic blood pressure, and heart rate;
- every 30 minutes: plasma and dialysate conductivity.

For InterACTIVE-HD 2.0 project, the simultaneous use of smart devices (i.e., smartwatch ASUS VivoWatch SP and L.I.F.E Italia S.r.l. sensorized garment) was also planned for a more continuous and less invasive measurement of certain parameters, such as systolic and diastolic blood pressure, heart rate, and saturation, with the final aim of also predicting hypotensive episodes.

Blood composition instead has been analysed by means of either hemogasanalysis or central laboratory, at different time-steps, as reported in Table I.

The dialysate composition has been measured at the beginning of every session in DialysIS framework, while also at the end of every session for InterACTIVE-HD 2.0 project.

Moreover, patient hydration status has been analysed at the beginning of the first and the last sessions by using a Bio-Impedence-Analysis (BIA) in DialysIS framework, while also at the end but only of the first session for InterACTIVE-HD 2.0 project.

Moreover, during each session, for both projects, any complication has been registered.

C. Data transmission

Differently from DialysIS project, during InterACTIVE-HD 2.0, all the data recorded from the dialysis machine have been digitalized and stored in a Dialysis Unit DB, where integrated with clinical record, BIA, and laboratory data. Collected data were then anonymized and transferred in a .json file to be transmitted to the project online DB. The anonymous DB is accessible to the registered users through the project platform.

D. Proposed approach for the clinical use of the model

The developed model can be trained with 3 consecutive sessions (ID). In the training phase, the model needs as inputs all the data reported in the Sub-section B, returning the set of patient specific parameters that allow to minimize the overall error during the considered session. This first step takes only few minutes per session.

Hence, 3 different sets of patient-specific parameters are obtained and each one differently modulates mass and fluid balance across dialyzer, capillary, and cell membranes, according to the patient's characteristics during each session.

The next step is to average these 3 sets in order to obtain a set of parameters representative of the patient, avoiding peculiar values related to a single altered session. In this manner, it is possible to run the model in predictive mode (PRED), giving in input the patient parameters and the patient's conditions at the beginning of the session to be simulated. In less than 30s, the model gives as output the patient's response to the treatment, in terms of mass and fluids trends and distributions within modelled compartments.

TABLE I: BLOOD COMPOSITION – ACQUISITION FREQUENCY

Parameter	*DialysIS*	*InterACTIVE-HD 2.0*
pH	∀hour	∀hour
pO2	∀hour	not planned
pCO2	∀hour	∀hour
Hematocrit	∀hour	∀hour
Hemoglobin	∀hour	∀hour
[Electrolytes]	∀hour	∀hour
Glycemia	∀hour	∀hour
[Urea]	∀hour	∀hour
[Mg^{2+}]	start + end	∀hour
[Phosphates]	start + end	∀hour
[Albumine]	start + end	∀hour
$Calcemia_{TOT}$	start + end	start + end
[PTH]	(start + end)^{1st}	(start + end)^{1st}
[B2M]	(start + end)^{1st}	(start + end)^{1st}
[Creatinine]	(start + end)^{1st}	∀hour
BNP dosage	not planned	(start + end)^{1st}

Electrolytes stand for Na^+, K^+, Cl^-, Ca^{2+}, and HCO_3^-. ∀ stands for every session, while 1st for the only first session of each acquisition phase.

E. Performance evaluation

Hence, it will be firstly performed a comparison of baseline characteristics of the 2 sets of patients undergoing SHD/HDF, enrolled for the two frameworks. For Lugano, Como, and Varese centres, involved in both the project a direct comparison is possible.

Dataset were compared in term of gender, age, dialysis age, therapy distributions, initial electrolytes and urea concentration, as well as in term of presence of either cardiopathy or diabetes or hypertension.

The performances of the model are evaluated in terms of normalized Root Mean Squared Error (nRMSE), as in Eq. (1).

$$nRMSE = \sqrt{\frac{1}{N} \times \sum \left(\frac{y^2_{i,mod} - y^2_{i,cl}}{y^2_{i,cl}} \right)^2} \quad (1)$$

The subscript i stands for the i[th] of N acquisition time-points, while CL and MOD refer to the clinically measured data of interest and to the model simulated ones, respectively; y is the variable of interest, i.e., electrolytes' hematic concentrations.

F. Statistical analysis

DialysIS and InterACTIVE-HD 2.0 patients' baseline characteristics and nRMSEs have been compared via a Wilcoxon rank sum test.

Moreover, InterACTIVE-HD 2.0 inter-phase performance variability has been evaluated via a Kruskal-Wallis test.

III. Results

Being the InterACTIVE-HD 2.0 project still running, the preliminary results were here presented for the Lugano centre, involved in both the projects and having already completed all the acquisitions.

A. Baseline characteristics

The baseline characteristics of the enrolled patients for DialysIS and InterACTIVE-HD 2.0 projects in Lugano are shown in Table II, where quantitative values are reported as median (IQR). Statistical differences have been highlighted in InterACTIVE-HD 2.0 column: * when $0.01<p\leq0.05$, ** when $0.001<p\leq0.01$, and *** when $p\leq0.001$.

TABLE II: Baseline characteristics

Parameter	*DialysIS*	*InterACTIVE-HD 2.0*
Gender	13 M – 7 F	15 M – 10 F
Age	73 (58, 80)	81 (68, 85)
Dialysis age	49 (38, 61)	73 (49, 110) *
Therapy	120 HDF	209 HDF – 81 SHD ***
$[Na^+]_{in}$	137 (135, 138)	139 (137, 138) ***
$[K^+]_{in}$	4.70 (4.40, 5.30)	4.80 (4.40, 5.30)
$[Cl^-]_{in}$	105 (103, 106)	102 (99, 106) ***
$[Ca^{2+}]_{in}$	1.13 (1.09, 1.17)	1.10 (1.04, 1.17)
$[HCO_3^-]_{in}$	22.6 (21.0, 23.8)	21.4 (19.5, 23.0) **
$[Urea]_{in}$	17.5 (13.9, 20.9)	16.9 (12.7, 21.2)
Cardiopathy	85%	92%
Diabetes	35%	56%
Hypertension	85%	88%

Age is reported in years, while dialysis age in months; concentrations are reported in mmol/L.

B. Performances of the model

Relatively to DialysIS project, it was possible to run PRED model on 16 patients (out of 20 enrolled in Lugano).

Instead, for InterACTIVE-HD 2.0 project, PRED model successfully runs for 242 sessions out of 290 monitored, excluding only 2 patients on the 25 enrolled in Lugano.

The performances of the model ($nRMSE_{\%}$) are reported as boxplots in Figure 1. A distinction is made between ID mode (i.e., the first 3 sessions used for model training by the minimization of the deviation of model outputs from the clinical data – ID_{123}), PRED mode in the same sessions the model has been trained ($PRED_{123}$), and PRED mode in independent sessions ($PRED_{456}$).

In ID mode, the model simulates accurately all the electrolytes and urea plasmatic concentrations, with an average median nRMSE of 2.66% related to DialysIS and 4.49% related to InterACTIVE-HD 2.0 ($p\leq0.01$, except for HCO_3^-). In general, a greater dispersion is observed for InterACTIVE-HD 2.0.

In PRED mode, the model maintains its predictive accuracy, with no differences between the training sessions and independent ones: regarding DialysIS project, the nRMSE average increase with respect to ID mode is equal to +2.50 and +2.87 percentage points, respectively; instead, in the case of InterACTIVE-HD 2.0 project, this increase is equal to +3.31 and +4.81 percentage points, respectively.

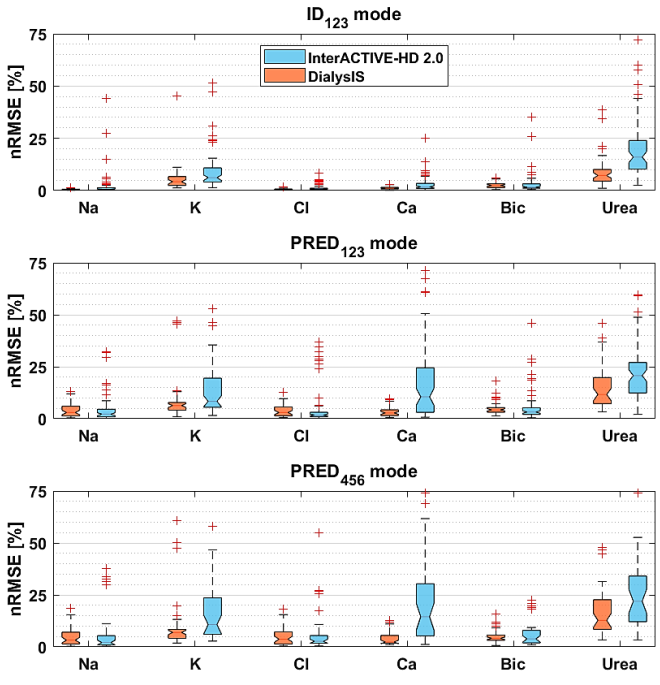

Fig. 1: nRMSE boxplots

Along the InterACTIVE-HD 2.0 project, the protocol included multiple acquisitions over time; specifically, in the

case of Lugano centre, clinical data acquisitions have been done on a 7-month span. The performances of the model in this timeframe are reported as nRMSE% boxplots in Figure 2.

It can be observed that for Na^+ predictive performances are maintained in this time span, and the same can be said for Ca^{2+} but at a higher level of error. For, Cl^- and HCO_3^- there's a gradual but constant loss of predictive performances, particularly evident at two months ($p \leq 0.01$). Finally, in spite of their high variability, K^+ and urea is predicted in an almost stable manner over time.

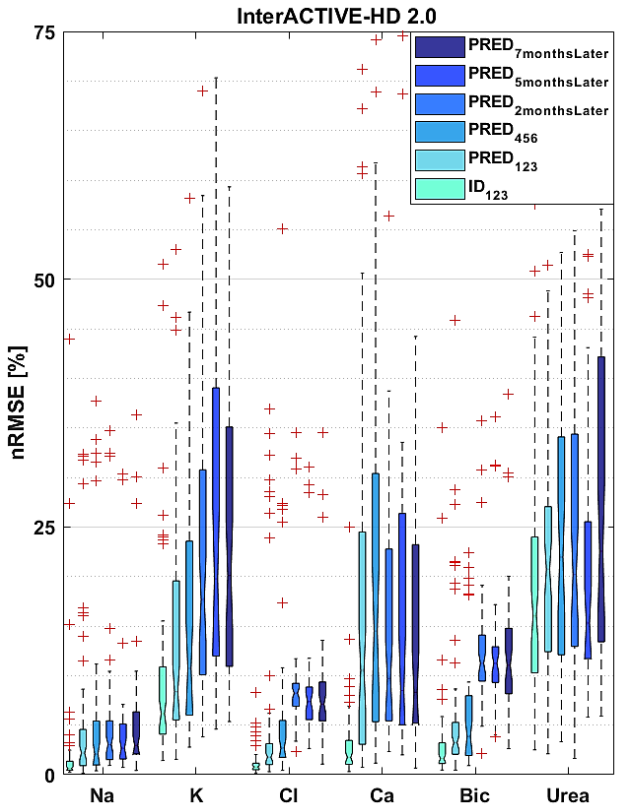

Fig. 2: InterACTIVE-HD 2.0 nRMSE boxplots – Performance over time

IV. Discussion

The two populations of patients enrolled for DialysIS and InterACTIVE-HD 2.0 in Lugano are in general superimposable in terms of baseline characteristics; however, some differences have been evidenced by the statistical analysis:

- InterACTIVE-HD 2.0 dialysis age distribution is much higher than DialysIS one ($0.01 < p \leq 0.05$), with some patients undergoing dialysis for at least 21 up to 243 months (against 3 up to 95 months);
- for InterACTIVE-HD 2.0, also SHD patients have been included, while before there were only HDF ones ($p \leq 0.001$);
- $[Na^+]_{in}$ distribution for InterACTIVE-HD 2.0 results shifted to higher values with respect to DialysIS ($p \leq 0.001$);
- $[Cl^-]_{in}$ distributions for InterACTIVE-HD 2.0 results more variable, particularly downwards, with respect to DialysIS ($p \leq 0.001$);
- $[HCO_3^-]_{in}$ measured values have similar values, but differently distributed ($0.01 < p \leq 0.05$).

The performance evaluation highlighted that:

- the dispersion observed for InterACTIVE-HD 2.0 ID nRMSEs seems to be not correlated to the differences of initial clinical data, but is attributable to a sub-set of patients probably characterised by greater intra-patient variability that the model cannot track; a different training approach should be used.
- in the case of $PRED_{123}$ and $PRED_{456}$ modes, the prediction of Na^+, Cl^- and HCO_3^- is better for InterACTIVE-HD 2.0, while for K^+, Ca^{2+} and urea there's a loss in accuracy: this loss is greater where there were observed already high errors in ID mode.

Finally, the predictive performances over a 7-month span in the InterACTIVE-HD 2.0 framework, suggest a recalibration of patient-specific parameters at least every two months to obtain even better results.

V. Conclusion

It is necessary to expand the set of patients on which to run the predictive model in order to obtain consistent results, as well as to stratify the results so as to identify that subset of patients simulated worse and thus suggesting specific model improvement.

Acknowledgement

The used data were recorded during DialysIS (Dialysis therapy between Italy and Switzerland) project funded by the cross-border cooperation program INTERREG IT/CH 2007-2013, Grant ID 33570710. Two of the authors (C.B. and G.C.) have been financed by the INTERACTIVE-HD2.0 project funded by the cross-border cooperation program INTERREG IT/CH 2014-2020, Grant ID 1441882.

Smart Titration of Long-Acting Insulin in Insulin-Naïve Type 2 Diabetic Subjects

J. Bonet[1], R. Visentin[1], M. Vettoretti[1], A. Facchinetti[1] and C. Dalla Man[1]
[1]*Department of Information Engineering, University of Padova, Padova, Italy*

***Abstract*: Insulin-naïve subjects with type 2 diabetes (T2D) begin their therapy with a low initial insulin dose (IID) which is gradually increased to reach the optimal insulin dose (OID) and optimal blood glucose target (OBG). However, for those individuals with a high insulin need (HIN), the STANDARD IID recommended by American Diabetes Association (ADA) guidelines may not be sufficient for achieving OBG in a timely manner. To address this limitation, we propose a SMART IID strategy and assess its possible benefits and risks on blood glucose control during the insulin titration period.**

A 52-week basal insulin titration trial was performed on 300 in-silico insulin-naïve subjects of the T2D Padova simulator, to determine their subject-specific OID. Based on the final OID, subjects were classified as having HIN or low insulin need (LIN).

A logistic regression model was developed to classify subjects as HIN or LIN based on certain characteristics available at the start of the trial. The subjects classified as HIN by the model were then assigned to a higher IID (SMART). A second 52-week titration trial was conducted using the SMART IID on the subjects classified as HIN. To assess effectiveness and safety of SMART IID, we compared time above 180 mg/dL (T_a), time in target 70-180 mg/dL (T_t), time below 70 mg/dL (T_b), and cumulative number of hypoglycemic events (NH) in the two experiments at 90, 124, 180, 270 and 365 days, with 124 being the time to reach the OBG.

Results found that T_a was always significantly lower and T_t was always significantly higher with SMART IID than STANDARD titration ($p<0.001$). Although statistically significant, the differences in T_b at 3 months and in NH at 90 and 124 days were considered to be clinically negligible.

***Keywords*— logistic-regression model, machine-learning, simulation, diabetes therapy.**

I. Introduction

Type 2 diabetes (T2D) is a chronic disease characterized by high blood glucose levels (hyperglycemia) due to both an impaired pancreatic insulin secretion and a concomitant inability of insulin to properly control glucose utilization and production, known as insulin resistance.

With the progression of the disease (advance-stage T2D), patients may need exogenous insulin to control glucose metabolism: rapid-acting insulin (e.g., lispro [1]) before and after meals to prevent post-prandial hyperglycemic events, and long-acting insulin (e.g., degludec [2]) to keep plasma glucose level within the normal range between meals and overnight.

According to American Diabetes Association (ADA) standards of care [3], T2D insulin-naïve patients (i.e., subjects that start using exogenous insulin to treat diabetes) are usually initiated to basal insulin therapy with a low initial insulin dose (IID), typically 10 U (STANDARD), which is then adjusted weekly or twice a week, depending on fasting plasma glucose (FPG), to reach the optimal blood glucose (OBG) while avoiding hypoglycemia.

The procedure of determining the optimal insulin dose (OID), called insulin titration, is time consuming, particularly for individuals with high insulin resistance that results in a high insulin need (HIN). To speed up this phase, we developed a logistic regression model to predict the insulin need for insulin-naïve T2D subjects based on measurable characteristics. Then, a SMART titration rule, applied to HIN individuals, was proposed to rapidly achieve OBG.

To validate this method, the Padova T2D Simulator [5] was modified to create a population of insulin-naïve T2D subjects [6]. Then, the modified simulator was used to simulate both the STANDARD and SMART therapies, and the outcomes were compared in terms of common used glucose control metrics.

II. Methods

A. Subjects and Protocol

The data used in this study were generated using the University of Padova T2D Simulator (T2DS) [5], which consists of a sophisticated nonlinear model describing the glucose–insulin–C-peptide system dynamics and a population of *in silico* T2D subjects, each one represented by a different realization of the model parameter vector.

The T2DS was originally equipped with early-stage T2D virtual subjects (resembling those described in [7]-[9]) and, therefore, was not able to reliably predict the system dynamics in subjects with advanced-stage T2D. To overcome this issue, the T2DS was tailored on inulin-naïve T2D subjects, using the population tuning method presented in [6] and the data reported in [10].

The resulting *in silico* population consisted in 300 *in silico* insulin-naïve subjects (102 females) with body weight (BW) of 86 [77-97] kg (median [25th-75th] percentile), age of 51 [37-65] years and body mass index (BMI) of 31 [29-34] kg/m^2.

The *in silico* subjects underwent two experiments. The first one was a standard oral glucose tolerance test (OGTT), in which subjects ingested a 75g of glucose and plasma glucose, insulin and C-peptide concentrations were measured at fasting (t=0 min) and both 120 and 180 minutes after the glucose intake (Table I). The second experiment was a STANDARD 52-week basal insulin titration trial to find the subject-specific optimal insulin dose (OID) of degludec, starting with an IID of 10 U. In particular, the insulin dose was adjusted twice per week (+2U or -2/-4U) depending on the deviation of measured FPG from the target range of [70-90] mg/dL. The OID was defined as the degludec dose administered at week 52. Once OID was estimated in each subject, we labelled the subjects based of their insulin needs: high (HIN) if OID ≥44U, corresponding to the median value of OID distribution, and

TABLE I
BASELINE CHARACTERISTICS

G_0 (mg/dL)	G_{120} (mg/dL)	G_{180} (mg/dL)
159 [142-179]	234 [215-270]	224 [203-252]
I_0 (µU/mL)	I_{120} (µU/mL)	I_{180} (µU/mL)
59 [25-88]	258 [182-355]	210 ([152-305]
Cp_0 (pmol/L)	Cp_{120} (pmol/L)	Cp_{180} (pmol/L)
839 [629-1106]	1870 [1586-2176]	1823 [1563-2134]

Median [25th-75th] percentile of fasting (subscript 0) and postprandial (subscripts 120 and 180, i.e., 120 and 180 minutes after glucose intake) plasma glucose (G), insulin (I) and C-peptide (Cp) concentrations.

low (LIN), otherwise. Time in target [70-90] mg/dL (T_t), time above 180 mg/dL (T_a), time below 70 mg/dL (T_b) and cumulative number of hypoglycaemic events (NH) were also calculated both in HIN and LIN.

B. The Logistic Regression Model

We developed a logistic regression model to classify insulin naïve T2D subjects as HIN or LIN, based on some measurable features. Model equation is:

$$logit(P) = ln\left(\frac{P}{1-P}\right) = \beta_0 + \sum_{j=1}^{N} \beta_j X_j \quad (1)$$

where P is the probability that a subject is classified as HIN, $\beta = [\beta_0\ \beta_1 \ldots . \beta_N]$ is the vector of model coefficient with β_0 the intercept and β_j the coefficient related to the specific *j*-th feature and X_j are the input features. For our purpose, we considered as input features sex, BW, BMI, age, and the baseline plasma glucose, insulin and C-peptide concentrations measured at fasting (subscript 0), 120 minutes (subscript 120) and 180 minutes (subscript 180) after glucose intake (Table I).

Once the model is identified, the estimated probability of HIN was obtained as:

$$\hat{P} = \frac{\exp(logit(P))}{1+\exp(logit(P))} \quad (2)$$

Then, a subject was classified as HIN or LIN accordingly to the following decision rule:

$$\begin{cases} \text{HIN} & if\ \hat{P} > P_{th} \\ \text{LIN} & if\ \hat{P} \le P_{th} \end{cases} \quad (3)$$

where P_{th} is the threshold probability, optimally determined during model training as detailed in the next section. For each subject was also determined the lower bound (l_b) of the 95% CI of the estimated probability ($\hat{P}$), which was then used to determine an intermediate starting dose for HIN subjects (see *Clinical Assessment* section equation 10).

C. Model Training

We first split the dataset into training (70%) and test sets (30%) (Figure 1).

Model parameters were determined using the maximum-likelihood estimator on the training set [11].

In order to select an optimal feature set, an exhaustive feature selection was performed (i.e., all the possible feature combinations were evaluated, so that a total of 8191 models were considered) using a 100-bootstrap-resampling of the training-set. This strategy consisted in generating, at each iteration, an "internal training set" obtained by sampling with replacement from the training set, so that the cardinality remains the same, and an "internal test set" made up by the non-sampled data (*out of bag set*).

All the candidate models were trained on the 100 internal training sets. Then, we discarded models that did not satisfy the following conditions:

1) all the features being statistically significant (based on the Wald-Test [12]) in at least 70% of the internal training sets;
2) the average deviance being significantly different from that provided by the null model (based on the likelihood ratio test [13]).

Subsequently, for those models who passed the previous selection step, the area under the receiver operating characteristic curve (AUC-ROC) was computed on the internal test set. The best model was selected as the one with the highest average AUC-ROC value.

Finally, we used a *grid-search* approach to determine the best P_{th}, defined in (3), as:

$$P_{th} = argmax_P(mean(Sensitivity) * mean(Specificity)) \quad (4)$$

with *Sensitivity* and *Specificity* calculated in each internal test set as:

$$Sensitivity = \frac{TP}{TP+FN} \quad (5)$$

$$Specificity = \frac{TN}{(TN+FP)} \quad (6)$$

with *TP* the number of true positive, *FN* the number of false negative, *TN* the number of true negative and *FP* the number of false positive.

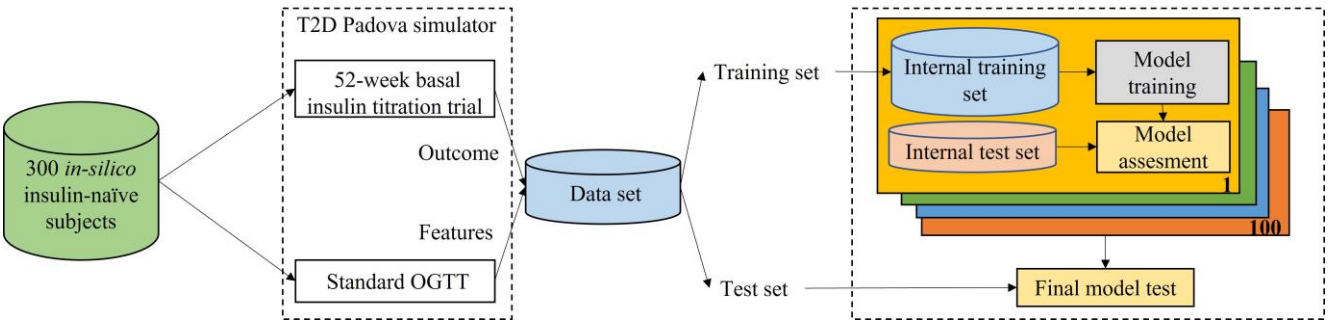

Fig. 1. Schematic representation of the training and test algorithm.

D. Model Testing

The selected model was then applied to the test set and, in addition to AUC-ROC, *Sensitivity* and *Specificity*, defined in (5) and (6), the following performance metrics were calculated:

$$Precision = \frac{TP}{TP+FP} \quad (7)$$

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \quad (8)$$

$$F1-score = \frac{2TP}{2TP+FP+FN} \quad (9)$$

E. Clinical Assessment

To assess the clinical impact of the classification model on glucose control optimization, the subjects classified as HIN underwent a SMART 52-week basal insulin titration trial. In particular, for each HIN subject, IID was set to:

$$IID = \begin{cases} 44U \ if \ l_b > P_{th} \\ 20U \ otherwise \end{cases} \quad (10)$$

As anticipated in the Methods, section B, the second equation was used to guarantee patient's safety whenever the uncertainty of the estimate was not negligible. The titration scheme and the target glucose range were the same used in the STANDARD protocol.

T_t, T_a, T_b, NH were calculated after 3-6-9-12 months and when OID is reached (TOBG, equal to 124 days in median during the SMART titration) and compared with those obtained in HIN subjects following the STANDARD titration (i.e., with IID of 10U), to assess the benefit and possible risk of the proposed titration rule.

F. Statistical Analysis

The comparisons were done using the paired Student T-test [14], for normally distributed metrics, and the paired Wilcoxon test [15]. Normality of distributions was assessed with Shapiro-Wilk test [16]. The significance level was set to α=0.05. Results are reported as mean ± standard deviation (SD), in case of normally distributed variables, and median [25^{th}, 75^{th}] percentile, otherwise.

III. Results

A. Model Performance

Among the candidate logistic models, the selected one predicts the insulin need based on subject's glucose and C-peptide measurements:

$$logit(P) = -5.2351 + 0.0742 \cdot G_0 - 0.0389 \cdot G_{180} + 0.003 \cdot Cp_0 - 0.0038 \cdot Cp_{120} + 0.0036 \cdot Cp_{180} \quad (9)$$

It classified the *in silico* subjects with a sensitivity of 87%, specificity of 91%, precision of 91%, accuracy of 89%, F1-score of 0.89 and AUC-ROC of 0.94.

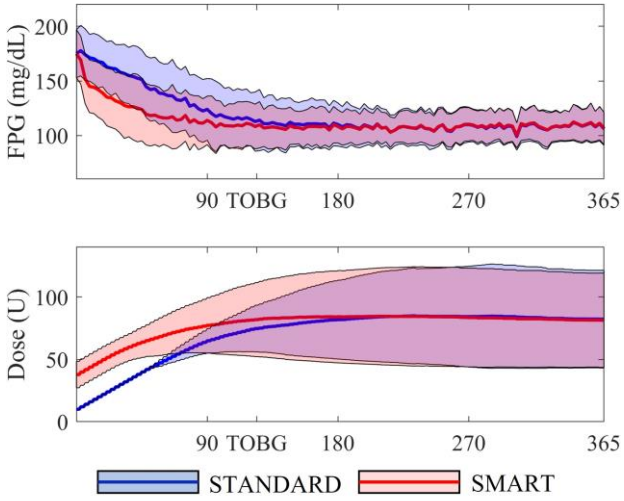

Fig. 2. Mean ± SD time courses of FPG (upper) and insulin dose (lower panel) during STANDARD (blue) and SMART titration (red).

B. Clinical Assessment

Figure 2 shows the simulated FPG and the administered insulin doses during the titration period. As expected, with the SMART titration scheme, the OBG is achieved 30 [0-86] days earlier than with the STANDARD algorithm, thanks to the higher IID. The performance metrics of the SMART vs. STANDARD algorithms, calculated as cumulative measurements at 3-6-9-12 months after the start of insulin titration and when OID is achieved, are compared in Figure 3. For all the considered time intervals, T_a was significantly lower and T_t was significantly higher during SMART than STANDARD titration ($p<0.001$) [17]. On the other hand, SMART titration led to significantly higher T_b ($p=0.001$) and NH ($p=0.005$) in the first 3 and 6 months of the trials, respectively. However, despite statistically significant, the difference in T_b at 3 months was clinically negligible (0% [0-0.08]%), with only one subject showing T_b during SMART higher than 1% with respect to the same metric calculated during the STANDARD therapy [18].

Similarly, the differences in NH at 90 and 124 days (TOBG), despite statistically significant, were 0 [0-1] and 0 [0-1.8].

IV. Conclusions

To achieve the OBG in a timely manner even in HIN subjects, we developed a logistic regression to predict the subject-specific OID as high or low before starting insulin titration, using glucose and C-peptide measurements obtained from an OGTT conducted before the titration. The model exhibited high specificity and precision and had a low number of false positives. This allowed for classification of subjects as HIN or LIN, enabling the initiation of insulin therapy with the most appropriate IID based on the subject's insulin needs. Specifically, this study shows that the SMART therapy in HIN subjects allows reaching the OID about one month in advance compared to the STANDARD method and shows a statistically significant improvement of T_t and reduction of T_a during the trial, with no relevant increase of T_b and NH in the first few months [18][3].

The main limitation of the proposed classification method is the need of plasma glucose and C-peptide measurements obtained before and after a standard OGTT, which requires subject's hospitalization. In the future, it is intended to refine

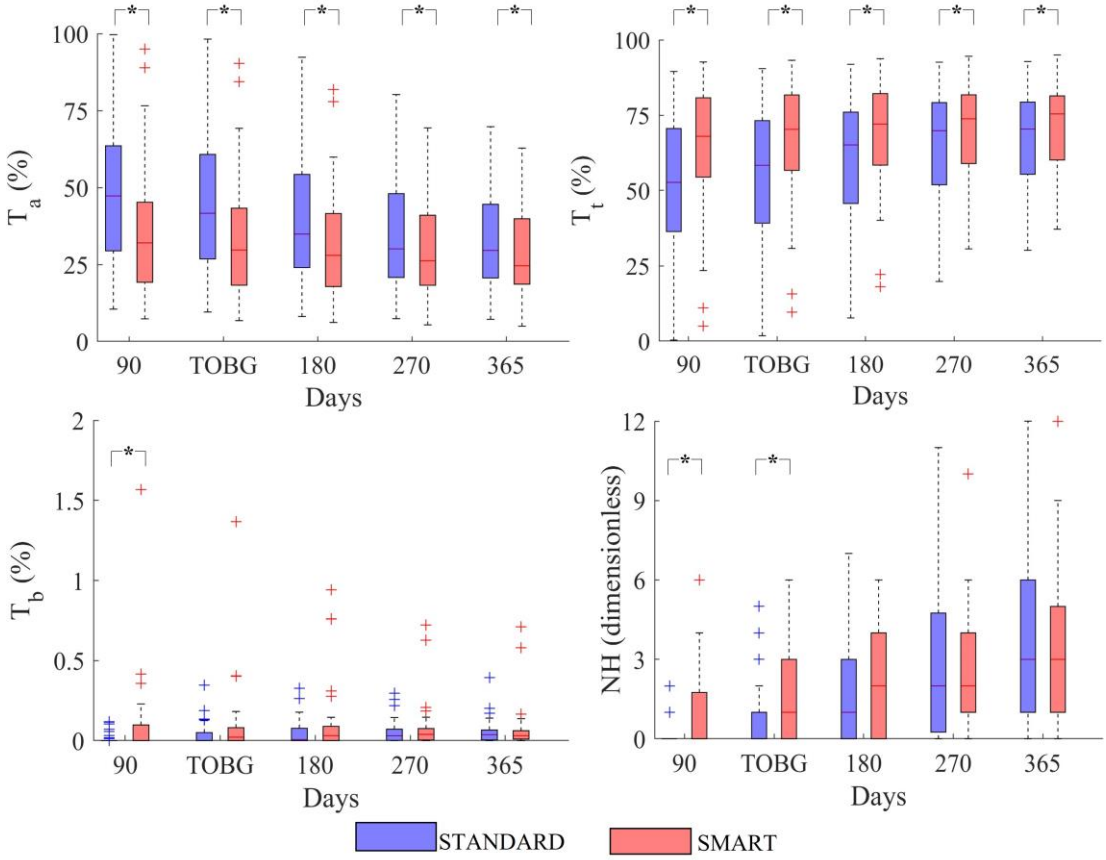

Fig. 3. Boxplot of T_a, T_t, T_b and NH during the STANDARD (blue) and SMART titration (red boxes) at 90, 180, 270, 365 days and TOBG. Asterisks denote statistically significant differences between STANDARD and SMART titration, according to either paired T-Student test or paired Wilcoxon test.

the model to achieve the same classification performance using data from wearable or minimally invasive devices. Another limitation is that the method uses a binary classification (LIN vs HIN) which is relatively coarse and could be refined by incorporating a multi-class classification algorithm to further personalize the IID.

Nevertheless, this study demonstrated that, in principle, IID of an insulin naïve T2D subject can be optimized based on a limited number of measurable characteristics, reducing the duration of the insulin titration phase without increasing the risk of hypoglycemia.

***Abstract*—As humans, being sociable is fundamental to our existence, and communication underpins all of our interactions. Implicit communication accounts for a large portion of the information flow, and humans are adept at interpreting the unspoken from the actions of others. In the last three years, we studied the kinematics modulations that naturally occur when transporting objects and how they can reveal item characteristics to an external observer. The findings on human behavior guided us into developing robotic applications to automatically detect some features of the carried objects from the motion and, on the other hand, communicate the same information by exploiting the robot embodiment. In the current publication, we present a critical review of the state-of-the-art along with a description of the open issues and challenges.**

***Keywords*—Human-robot interaction, motion kinematics, implicit communication, object properties detection**

I. INTRODUCTION

In recent years, the use of robots in different fields, including industry, healthcare, and education, has increased. However, challenging barriers remain in place for integrating robots into our society. The difficulties in having direct and clear communication with an artificial agent stand out among the others. Standard communication mediums in robotics are based on speech [1], or explicit gestures [2], [3], while more recent approaches investigate new technologies such as augmented reality headsets [4], [5]. Nevertheless, an often overlooked channel of communication is the implicit one. Indeed, as humans, we communicate only partially through words; we heavily rely on subtle cues to collect from our peers a spectrum of information, ranging from internal status to intentions or needs [6]. Coordination emerges from the interaction precisely because of the implicit signals [7], giving rise to a series of mutual synchronization and anticipation phenomena that drastically reduce the need for complex verbal instructions and the resulting delays [8]. More precisely, implicit communication refers to all those modulations that occur in our gestures independently of our will or consciousness. In the presence of another person, these signals may be emphasized with a social purpose to make the action even more predictable and readable by a collaborator: this is called signaling [9]. Within our research, we have chosen to investigate a scenario where robots and humans often need to work together: the handling and transport of objects. In these situations, nonverbal communication plays a crucial role in conveying information about the transported object [10], such as its weight, fragility, spillability, potential danger, or assembly state. Through various methodologies and perspectives, we aim to explore ways in which the implicit communication associated with object handling can be applied to interaction with robots, drawing inspiration from natural human behaviors.

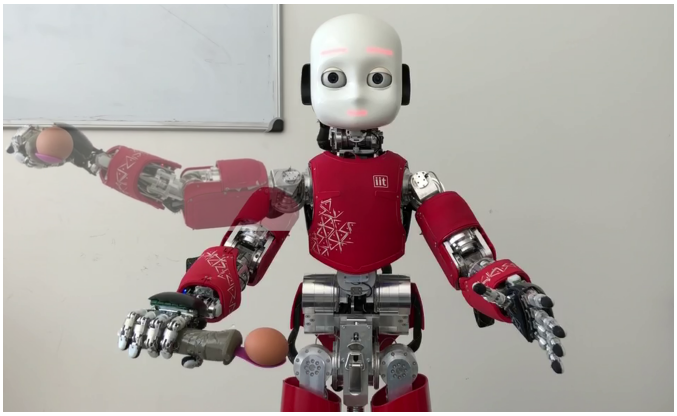

Fig. 1: Example of a careful action performed by the robot iCub, which is able to transport an egg by modulating appropriately the velocity profile during the motion

In Section II, we present the strategies humans adopt to handle objects which differ in weight or delicacy required by analyzing and modeling human motion. These observations guided us in exploring methods to infer properties relying on human kinematics. In Section III, we expose the dual challenge of generating expressive movements on a robot while being task-oriented (see Figure 1 for a motion proof of concept). Finally, in Section IV are gathered insights on how implicit modulation influence and affect the interaction. Conclusions follow.

II. RECOGNIZING OBJECT PROPERTIES FROM HUMAN MANIPULATION

Previous literature addressed implicit communication referred to objects, focusing on the intention of the action [11], the position and the timing of the handover [12], the carefulness in the motion [13], the spillability of containers [10] or more extensively on the weight [14], [15], [16], [10]. To study the strategies adopted by humans to transport

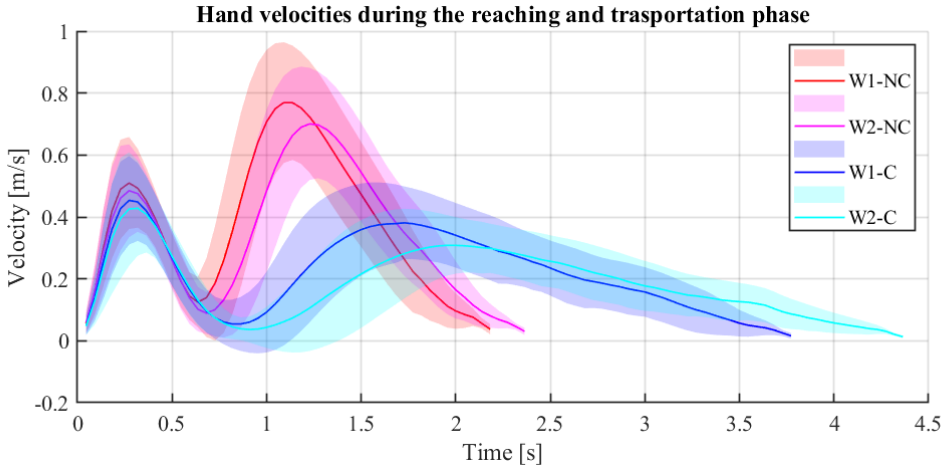

Fig. 2: Hand mean velocities and standard deviation, in transparency, are associated with reaching (first peak) and transportation movements (second peak) of four different glasses. The two cups containing water (W1-C and W2-C) are in blue, while the other coups not requiring care in their motion (W1-NC and W2-NC) are in red. The weight difference between W1 and W2 was 500 grams.

objects with different characteristics, we exploited a multimodal dataset involving four transparent plastic cups with two possible levels of weight (*W1:* 167 or *W2:* 667 grams) and associated carefulness. The carefulness was characterized by the presence of water to the brim or by its absence, leading to the definition of Careful (*C*) and Not Careful (*NC*) manipulations. Figure 2 summarizes the findings relative to human kinematics, measured with a motion capture system, during the transportation of the four objects typologies. While reaching the object, represented by the first peak of velocity, humans' motion is uniform for all the glasses, either full, empty, heavy, or light. The strongest modulation appears instead during the transport of the glasses. We can notice how the velocity peak is lower when transporting the *W1-C* and *W2-C* glasses, and the velocity profile follows a different shape. Indeed, the velocity is bell-shaped for glasses without water, while the careful transport movements present an anticipated peak with a prolonged deceleration phase, especially for the full, heavy container. Participants were especially cautious in the final phase of the movement, gently leaning the glass so as not to spill the content. In the initial phase of the movement, the velocity derivative is significantly steeper for empty glasses, indicating higher acceleration in moving the object only slightly modulated by the weight.

These results confirmed the hypothesis that human motion is strongly affected by the item's characteristics, particularly for the care adopted, and this modulation could be exploited for an automatic inference process. Therefore, we investigated which sensor could extract accurate kinematic features and which classifier could enable an online implementation of the architecture; details on this research are described in [17], [18]. As a critical summary of the results, motion descriptors could be extracted online with the iCub robot camera computing the optical flow of the scene. This approach allows for the most spontaneous interaction with the robot, but it presents some limitations that may need to be considered, depending on the application scenario. In particular, the perception of human motion with the robot camera, even if robust to some occlusions, should take place as much as possible in robot view sight. In addition, the proposed approach assumes that object transportation is the main motion in the scene and therefore is well described by the optical flow; if the person is walking in the room while handling objects, then an additional segmentation of the arm is required. We could mitigate these limitations by integrating data from an inertial sensor worn at the wrist, which was available in the dataset and gave good results in the offline classification of the carefulness using a simple Long Short Term Memory (LSTM) neural network. The same model was exploited for classifying online the carefulness using the camera alone, with modified transportation tasks with respect to those in the training set, with an accuracy that reached up to 81.3%. Duarte et al. [13] achieved similar accuracy levels by modeling the motion carefulness with a Gaussian Mixture Model and tracking the object with a motion capture system.

We did not pursue the online weight classification, given the poor performances obtained offline with all the possible sensors. This result can be ascribed to the characteristics of the data. As shown in Figure 2, the difference between the two levels of weight is not striking and is overridden by water presence. However, we are optimistic that with a more weight-oriented training set, such classification could be achievable with the same approach.

III. GENERATING COMMUNICATIVE ROBOT MOVEMENTS

The problem of generating human-like movements has been addressed from different perspectives. Some strategies resort to optimizing motion primitives such as the jerk [19], [20]; others make use of animation techniques or exploit learning from demonstration (see respectively [21] and [22] for a review). Coming to implicit communication through robot actions, Venture and Kulić proposed a recent and complete survey

on expressive robot motions [23]; other studies explored the possibility of conveying the goal of the action [24], or the weight of the handled object [16]. As pointed out by Sandini et al. [6], the challenge of generating plausible motions with a humanoid robot can be even greater: from one hand, their shape can solicit the same coordination mechanisms emerging in humans, but it also creates an expectation of competency that may be easily disrupted. We questioned then the possibility of creating robotic actions, human-inspired without being a replica, able to convey a specific attitude in the gesture - in this case, the carefulness - with a strategy that could be reproduced easily on different platforms, even not humanoid. From the recognition of the action patterns presented in Section II, we saw how the velocity of the motion is relevant in its whole dynamic. Therefore, adopting equivalent velocity profiles for the robot end-effector could effectively express the carefulness of a specific action without undermining its effectiveness and instead make it more closely fitting the object properties. With these goals in mind, we resorted to Generative Adversarial Networks [25], [26] to generate velocity profiles belonging to *C* or *NC* classes. Indeed, these networks can produce synthetic data capturing the distribution of the training set and therefore accounting for the natural variance that affects human actions [27]. An advantage of this approach is the applicability to different robotic platforms, as only the end-effector velocity is controlled, without applying constraints to the rest of the kinematic chain; of course, this may also lead to a sense of uneasiness depending on the dynamic of the secondary joints. Another point to be stressed is that resorting to velocity norms, they are detached from any particular trajectory. Therefore, to be applied to transport movement from point A to point B, each profile needs to be appropriately rescaled. Since in the literature, there are proofs of time-invariance in the upper limb movements [28], [29], we opted to maintain the duration of the action over the magnitude of the velocity reached. In any case, we should assess the effect on the interaction of the velocity modulation.

IV. THE EFFECT OF IMPLICIT COMMUNICATION OF OBJECT PROPERTIES: TOWARD THE INTERACTION

In the previous Sections, we presented different perspectives and studies on implicit communication applied to robotics for the expression and detection of object properties. However, the effect of such approaches on the interaction has been investigated only to a limited extent. For instance, it has been shown that, provided a well-thought robot's action, humans use the estimated weight of the object for planning their lifting action [16]. Another study considered a handover scenario where a robotic manipulator adapted its grasping strategy depending on the object being passed and was positively evaluated through questionnaires [30]. Indeed, the evaluation of interaction outcomes is commonly performed with questionnaires, even though implicit measures to estimate motor contagion may be preferable since they allow measuring spontaneous adaptations [31]. Physiological measures such as skin conductance or electromyogram can be useful to estimate the level of ease of the participants but require a more invasive framework [32]. We conducted two studies to assess if the attitude of transport actions with different robotic platforms - humanoid and not - were perceived as careful or not as intended [33], [34]. Findings showed that participants perceived the care in the action when explicitly questioned about it. Moreover, there was significant coordination with the robot even if was not made necessary by the task; when the robot executed a careful action, participants slowed down their reaching or transport actions, taking more time to complete them. Interestingly, this also happened with a robotic manipulator having a kinematic chain significantly different from the human arm. Bisio et al. [31] showed proof of how motor contagion appears as long as a humanoid robot respects biological laws of motion. In our case, the motion plausibility was granted using human-inspired velocity profiles. Even with a robotic manipulator, participants could match their motor repertoire to the motions of the observed agent, showing emerging coordination.

V. CONCLUSIONS

We showed several methods and strategies to open an additional communication channel to interact with robots, exploiting implicit cues embedded in the movements. In our research, as the area of designated application, we focused on the innovative one of perceiving and transmitting the properties of objects involved in transport actions, focusing particularly on motion carefulness. This feature, as in other works [13], [10], was achieved with the modulation of a single physical characteristic: through the manipulation of glasses full of water. Future studies should assess which other factors contribute to making an item delicate to handle and how they affect the kinematics. In this regard, preliminary evaluations were pursued in [33].

The leading idea and the whole framework are inspired by human behavior and interaction abilities. This approach could be seen as a limitation for application areas with a more functional focus, such as pre-defined assembly tasks, where the speed of execution and strength of robots reach levels unimaginable for a human being. However, if we want to build robots able to share the social sphere with us, there is no other way but to be inspired by what happens on the biological level. Knowing how human-human interaction works should guide us in designing better artificial agents: coordination can emerge only from mutual understanding.

***Abstract*—*Introduction.* The connection between brain activity and cardiac variability, through the modulation of the autonomic nervous system, is a well-established phenomenon. However, the studies that have addressed the reciprocal influences between central and autonomic nervous system during resting state are still limited, especially in the context of pathophysiology.**
***Aim.* In the present work, the main objective was to explore the relationship between the central nervous system and cardiac variability at rest in an integrated multimodal analysis thanks to simultaneously acquired ECG and fMRI data.**
Moreover, we evaluated possible differences in adult-onset major depressive disorder (MDD), in which both brain function and cardiac variability alterations are evident, but in which there is still no idea of their reciprocal effects.
***Methods.* Thirty-three participants were included in the study (67.33 ± 9.63 years, 58% females), 16 diagnosed with adult-onset MDD and 17 healthy controls (HC) with comparable age and sex. fMRI analysis was integrated with the analysis of the heart rate variability through an HRV-driven fMRI analysis to study the BOLD responses to sympathetic and vagal autonomic changes.**
***Results.* Our findings allowed to identify activations and deactivations in brain regions that are some of the key nodes of the central autonomic network (CAN), a network of brain structures that are involved in the regulation of autonomic processes at high central level. The comparison between patients affected by MDD and HC subjects revealed that differences in brain correlates of cardiac variability are present in brain regions of the CAN.**
***Conclusions.* Combined HRV-fMRI analyses provided new findings on physiological brain-heart interactions and allowed to characterize the autonomic and central neurobiological bases of depression from a wider and more comprehensive prospective.**

***Keywords*—fMRI, HRV, central autonomic network, major depressive disorder**

I. INTRODUCTION

The connection between the brain and the heart is a well-established phenomenon and, according to the neurovisceral integration model, central-level neural circuits are involved in the regulation of peripheral cardiac activity, through the modulation of the autonomic nervous system (ANS) [1].
Among the studies that have identified direct and indirect pathways by which neural networks are linked to autonomic circuits, of relevance is the work of Benarroch, who described the existence of the central autonomic network (CAN) [2], which is a network of brain structures involved in control mechanisms essential for adaptation and survival, among which baseline ANS function and its modulation in response to changing environment. The most acknowledged forebrain structures of the CAN include the hypothalamus, insula, and amygdala, whereas recent functional neuroimaging studies have shown that also the medial prefrontal cortex (mPFC), thalamus, anterior cingulate cortex (ACC), hippocampus, precuneus and cerebellum are involved in ANS functions [3].
Although neuroimaging techniques alone have allowed to understand the human brain and its complex functions, unprecedented findings on brain functioning are being achieved more recently thanks to the integration of multiple modalities that allow to explore also the links of the brain with other systems of the human body.
However, the studies that have investigated the brain regions involved in the dynamics of heart rate variability (HRV), which indexes autonomic modulation, are still limited.
A deeper knowledge of this complex interaction both in physiology and in pathology can be obtained by integrating electrocardiography (ECG) with functional magnetic resonance imaging (fMRI).
fMRI is a very powerful tool that allows to study brain function, mapping both brain activity and the network of connections among regions in the entire brain. The basic concept underlying fMRI measurements is that an increase in neuronal activity, stimulating both higher energy consumption and increased blood flow, can be detected by measuring changes in oxygenation concentration (Blood Oxygen Level Dependent, or BOLD contrast).
Instead, ECG recordings enable to extract information on the HRV, which is the physiological phenomenon that consists in changes in the time intervals between consecutive heartbeats

to rapidly adjust to physical and psychological stimuli to maintain homeostasis. Heart rate is largely under the control of the ANS, composed by two constantly interacting branches, the sympathetic activity, which has an excitatory role, and the parasympathetic or vagal activity, which mostly performs an inhibitory control.

The various oscillators generate rhythmic fluctuations at different frequency ranges, which are divided into four bands: ultra-low frequency and very low frequency that are related to slow circadian rhythms, low frequency (LF) (0.04-0.15 Hz) and high frequency (HF) (0.15-0.4 Hz) [4]. The efferent vagal activity is the major contributor to the HF component, while more controversial is the interpretation of the LF component, which is considered a parameter that includes both sympathetic and vagal influences.

HRV has considerable potential to assess the role of ANS in healthy individuals and in patients with various cardiovascular and non-cardiovascular disorders, including psychiatric illnesses.

In this respect, major depressive disorder (MDD) is a disabling psychiatric pathology that, besides being a brain disorder, is often characterized by autonomic neural dysfunction, reflected in reduced HRV [5].

Within this context, the main objective of this study was to provide deeper insights on the relationship between brain activity and cardiac autonomic-modulated activity through simultaneous ECG and fMRI techniques, via an HRV-driven fMRI analysis.

Since this relationship is even less explored in the context of psychopathology, our second aim was to explore possible differences in patients diagnosed with MDD with respect to the control group. Indeed, MDD is a heterogeneous disease, in which both brain function and HRV alterations have been shown, but there is less idea of their reciprocal effects. Therefore, the study of the interaction between the brain and heart could provide new findings about the disorder itself.

II. METHODS

A. Participants and study protocol

The dataset analyzed was extracted from the clinical study conducted in the RADAR project, "Role of LSD1 in aging-dependent epigenetic drift leading to frailty-associated mood disorders", which was coordinated by Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico of Milan [6].

Thirty-three participants were included in the present analysis (67.33 ± 9.63 years, 58% females), 16 diagnosed with adult-onset MDD and 17 healthy controls (HC) with comparable age and sex. Clinical diagnoses were assessed using the Italian version of the Structured Clinical Interview for DMS-5 (SCID) and only subjects with MDD onset at age greater than 45 years were included in the patient group.

All subjects provided a written informed consent to the study protocol, which was conducted in accordance with the Declaration of Helsinki and approved by the Ethical Committee of Fondazione IRCSS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy.

The participants underwent a multimodal 3T MRI session including a simultaneous ECG-fMRI acquisition of 500 seconds during eyes-closed resting state condition.

B. fMRI preprocessing

Starting from raw fMRI data, fMRI preprocessing was performed by using HALFpipe standardized workflow, proposed by the ENIGMA Consortium for the elaboration of task-based and resting-state fMRI data [7]. Preprocessing implemented a consensus of preprocessing steps required for any fMRI study: re-aligment of fMRI volumes, coregistration with the anatomical image, segmentation, normalization and spatial smoothing.

As BOLD signals are generally noisy, we implemented an additional set of denoising pipelines with the aim of comparing them according to some quantitative metrics to identify which could be the more effective in both noise removal, resting-state networks identifiability and signal enhancement. Besides the minimal steps, according to the results of this comparison analysis, the mean signals from white matter and cerebrospinal fluid, and the mean global signal were regressed out.

C. HRV

In parallel to fMRI preprocessing, the ECG signal was pre-elaborated. The gradient artifact, which is due to ECG acquisition in fMRI environment, was removed through the artifact subtraction method and, next, ECG signals were filtered with a band-pass Hamming windowed sinc FIR filter with cut-off frequencies of 0.1-120 Hz, and a notch filter at 50 Hz to remove powerline interference.

R peaks were semi-automatically identified and HRV time series was computed as their difference in time. Moreover, an ECG-derived respiration signal was estimated by low-pass filtering the ECG at 1 Hz. The respirogram was extracted by sampling the respiration at each R peak time.

D. HRV-driven fMRI analysis

fMRI and HRV data were combined together to perform an HRV-driven fMRI analysis with the objective of studying the BOLD response corresponding to changes in HRV, due to both sympathetic and parasympathetic actions of the ANS.

We extracted time-varying HRV parameters that could represent sympathetic and parasympathetic activities, and their balance, to be used within a general linear model (GLM) in order to explain fMRI data. These regressors were computed starting from the tachogram and the ECG-derived respirogram that were inserted in a time-varying bivariate autoregressive model, which is a cross-spectral analysis used to highlight linear frequency relationships between the two different signals in input [8]-[9].

The explaining variable that corresponds to the sympathetic activity was computed as the time-varying power in the LF range of the power spectrum estimated from the tachogram alone, hence removing spectral contribution driven by respiration.

As regards vagal modulation, the corresponding regressor was

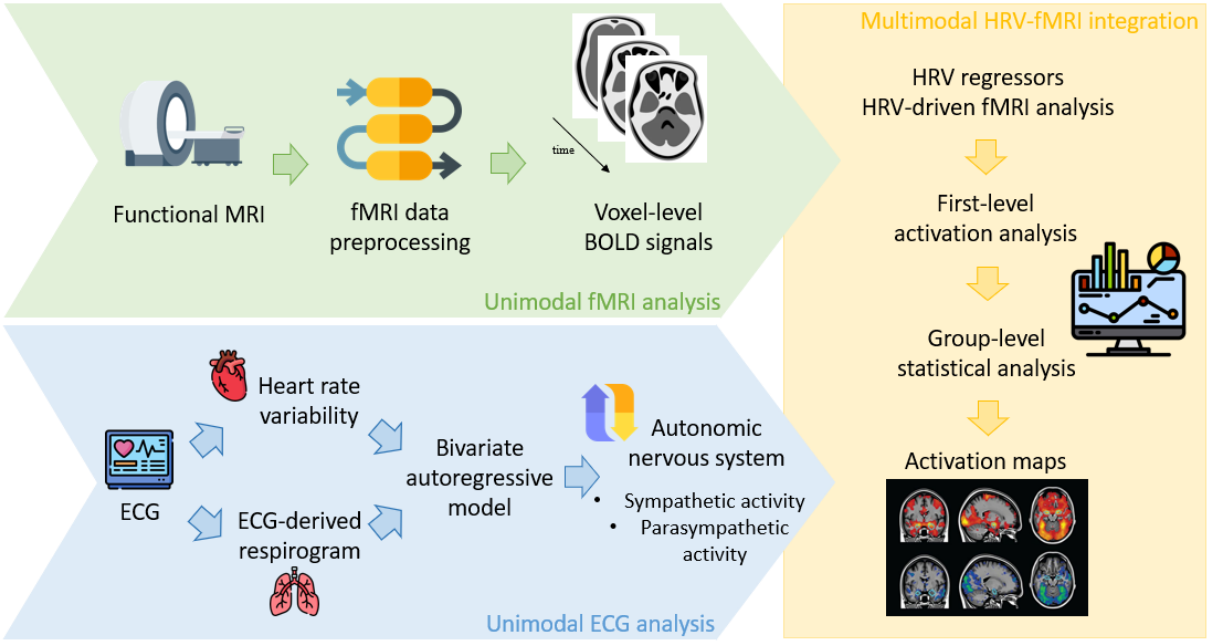

Fig. 1: Workflow.

calculated as the time-varying power in the spectrum that explains the respiration influence on cardiac variability. In resting state condition, this interaction is mainly related to respiratory sinus arrhythmia processes, hence it reflects the contribution of vagal activity at the respiratory rate (usually, falling in the HF range) [9].

Also the ratio between LF and HF power estimated time series was computed as regressor representing the sympathovagal balance of the autonomic nervous system.

The convolution with the canonical hemodynamical response function was applied to each regressor to take into account the intrinsic delay of the neurovascular coupling.

We performed subject-level HRV-fMRI activation analysis to identify cortical and subcortical brain regions with a significant BOLD response to different spectral changes in HRV, represented by the previously defined regressors. The design matrix was composed by the three HRV regressors and by six non-interest regressors that are the movement parameters estimated during fMRI volumes realignment phase.

After estimation of the GLM coefficients, inference on fMRI responses to LF, HF and LF/HF fluctuations was performed by creating contrasts that assess the contribution of the regressors of interest, alone or in combination, to the overall BOLD signal.

Group-level HRV-fMRI analysis was performed by making inference on the subject-level contrast maps representing the fMRI correlates of HRV analysis. Three group-level GLM analyses (for LF, HF and LF/HF) were performed. The GLM design matrix included age, sex, and diagnosis as covariates, plus a constant term used to evaluate the activation for the entire group. Inference on group-level fMRI responses and on diagnosis effects was based on T-tests on the corresponding regressor ($p \leq 0.001$). The clusters of voxels were then labeled according to AAL Atlas.

III. RESULTS

The HRV-driven fMRI analysis enabled the identification of brain regions with a BOLD response significantly correlated with ANS modulation.

Considering cardiac variability due to LF fluctuations, a group-level positive BOLD response was found in brain regions that belong to the CAN, such as left *precuneus* and bilateral *insula*, meaning that they have a positive hemodynamical correlation with LF power at group level. Instead, deactivation was found in left *middle frontal gyrus* and *inferior frontal gyrus* triangular part areas (see figure 2).

In the same condition, a higher BOLD response was discovered in the right *hippocampus/parahippocampus* in MDD patients than in healthy subjects, as shown in figure 3.

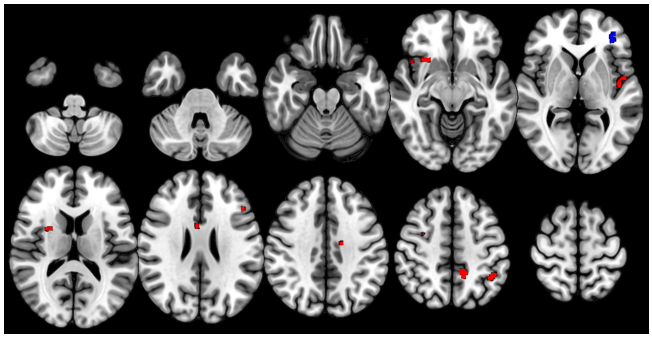

Fig. 2: LF: group-level positive (red) and negative (blue) BOLD responses.

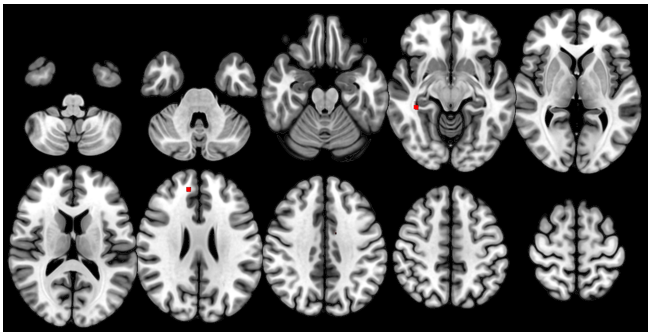

Fig. 3: LF: higher BOLD response in MDD group (red).

HF modulation induced a deactivation in the right *middle cingulate cortex*, right *lingual/precuneus/hippocampus* in the entire group at the net of age, sex and diagnosis effects, meaning that oxygenation, which is assumed to reflect neuronal activity, in these brain regions decreases in relation to an increase in vagal activity (see figure 4).
Bilateral *hippocampus*, bilateral *precuneus*, and right *parahippocampus* resulted to have a higher BOLD response associated to vagal activity variations in MDD group than in HC group, as shown in figure 5.

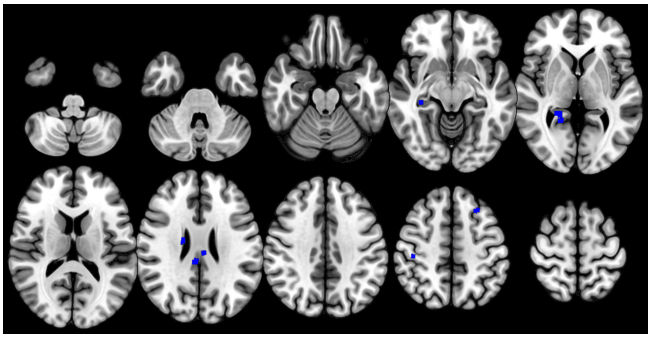

Fig. 4: HF: group-level negative (blue) BOLD response.

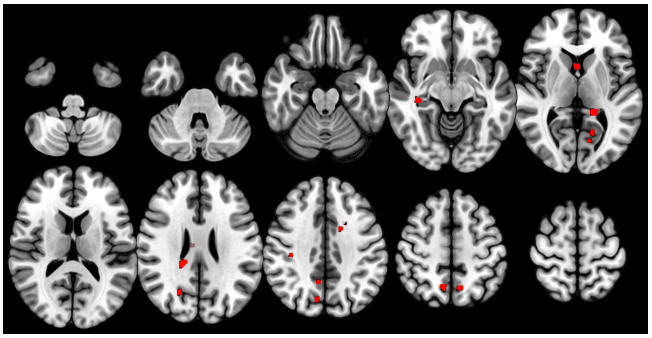

Fig. 5: HF: higher BOLD response in MDD group (red).

IV. CONCLUSIONS

In the present study, we have adopted a novel sophisticated multimodal methodological approach for the investigation of the resting state brain-heart interaction in healthy subjects and in individuals affected by adult-onset MDD.
The HRV-driven fMRI analysis allowed, using an entirely data-driven approach, to identify activation and deactivations of brain regions that have been shown to play a role within the CAN, involved in high central level autonomic processes.
Besides providing useful information on the physiology of central and peripheral nervous systems, we found alterations in their relationships in subjects affected by MDD.
The results suggest an overlap among brain circuits related to limbic, affective, cognitive, and autonomic dysregulations, supporting the idea of a common neurobiological source of multiple disease dimensions.
Further integrated HRV-fMRI analyses will provide a more comprehensive overview on the autonomic and central neural bases of MDD, bridging the gaps among its heterogeneous clinical features and allowing to characterize this disabling disorder from a new and different point of view.

ACKNOWLEDGEMENT

***Abstract*— As a result of neuro-vascular coupling, the functional effects of antipsychotics in human brain have been investigated using hemodynamic markers such as Cerebral Blood Flow (CBF) and Cerebral Blood Volume (CBV). However, the relationship between observed hemodynamic effects and the pharmacological action of antipsychotics has not been fully established. Here we wanted to investigate the relationship between the administered repeated dose of amisulpride, an atypical antipsychotic, and the changes in cerebral blood flow in the striatum. To investigate this relationship, we linked the plasma concentration to PET receptor occupancy and ultimately to the Arterial Spin Labelling's (ASL) CBF data from a placebo-controlled study in healthy volunteers, who received a repeated dose of amisulpride. To link the data, we developed a PK/PD framework which, starting from the dose administered, was able to predict the plasma drug concentration after a repeated dose, to predict the receptor occupancy (RO) in the targeted regions of the brain, and finally to link it with changes in cerebral blood flow in the striatum. The results showed a statistically significant monotonically increasing relationship between changes in relative to global CBF and receptor occupancies in the putamen (p-value < 0.001) and caudate regions of the brain (p-value < 0.01). These findings suggest that antipsychotics increase striatal perfusion, with a mechanism possibly mediated by D_2 receptors and represent further evidence supporting the hypothesized PK/PD model of antipsychotic effects on CBF measures founded on macaques by 'Sander et al, 2013'.**

***Keywords*—antipsychotics, amisulpride, receptor occupancy, dopamine**

I. Introduction

Antipsychotics are the preferred choice for the treatment of conditions such as schizophrenia and other psychiatric disorders with psychotic features. The main target of most of these compounds is the dopamine D_2 receptor where they act as antagonists or partial agonists [1]. The effects of antipsychotics in the brain have been investigated using different tools but their impact and mechanism of action on brain physiology is still not well understood. In this report we examine the effects of amisulpride, a second-generation antipsychotic and highly selective antagonist of dopamine D_2 and D_3 receptors [2]. Amisulpride has a dual range of applicability. At high doses (from about 400 to 600 mg/day) it is an effective neuroleptic [3] while at low doses (50–200 mg/day), amisulpride has been shown to have antidepressant properties [4]. Clinical effective doses and affinities of D_2 antagonists suggest that the antipsychotic effect arises when at least 60–70 % of these receptors is occupied by a drug of this class, whereas occupancies of more than 80% are associated with extrapyramidal side-effects [1]. The levels of striatal D_2 occupancy of amisulpride at higher doses (from 400 to 600 mg/day) are consistent with this model of antipsychotic action [5], [6]. The effect of D_2 blockade on resting perfusion levels or metabolism has been investigated in several studies, using PET and ASL [7], [8]. Results consistently show a rise of perfusion or metabolism in the basal ganglia, especially in the putamen. This effect can be attributed to an enhanced neurotransmitter turnover in the dopaminergic synapses inducing metabolic activity. However, since MRI does not measure neuronal activity directly, the neurochemical mechanisms underlying CBF changes after antipsychotics administration remain unclear. Up to date the only evidences linking hemodynamic changes induced by these drugs with dopamine receptors occupancy comes from animal literature, where a monotonic increase in regional Cerebral Blood Volume (rCBV) has been observed following injection of an increasing dose of the D_2/D_3 antagonist radiotracer [11C]raclopride in the striatum of two male rhesus macaques [9]. This result suggests that vascular responses to D_2R-like antagonists are coupled to changes in neuroreceptor occupancy.

The aim of the present work is to replicate this relation in human by developing a PK/PD framework capable to quantitively model the dose of amisulpride in plasma, the dopamine blockage (measured with PET imaging) and CBF changes (measured with MRI).

II. Materials and methods

A. Participants and study design

The data used for the current thesis were collected as part of a project organized by the Imperial College London in collaboration with King's College London, called 'Neuroreceptor regulation of brain structure and function'.

The aim of the project was to investigate the role of neuroreceptor agonism/antagonism on the brain, and it was approved by the West London & GTAC Research Ethics Committee. The experimental protocol consisted in a within-subject, cross-over, single-blinded placebo-controlled study design where healthy individuals received amisulpride or placebo. Healthy individuals were pseudo-randomized to receive the drug for a period of up to one week followed by placebo or to start with placebo and then receive the drug. A washout period of at least 10 days (or > 5 half-lives of the drug/active metabolites) was included in between interventions, in order to minimize any carry-over effects. The dose used for the study for the purpose of better tolerability was gradually raised: first day 200 mg, second day 300mg, and third to seventh day 400 mg. During the study the following assessments were made at several time-points:

- MRI (structural, MRS, ASL, fMRI) at baseline, after the first week of treatment and after the second week of treatment.
- PET [11C]-PHNO imaging at baseline and after the week of active treatment.
- Dopamine agonist/antagonist plasma levels after the first week of treatment and after the second week of treatment.
- Physical examination including weight, hip circumference, waist circumference at screening, baseline, after the first week of treatment and after the second week of treatment.

B. Pharmacokinetic analysis

In this study, sparse PK sampling was used; therefore, it was not possible to fully characterize the PK model on the basis of these data. In the literature, amisulpride PKs have been well described using a one-compartment open model with first-order absorption and elimination [10], [11]:

$$C_p(t) = \frac{Dose \cdot k_a}{V/_F \cdot (k_a - CL/_V)} \cdot \left(e^{\frac{CL}{V} t} - e^{k_a \cdot t} \right) \quad (1)$$

where Dose is the amount of drug, F the bioavailability, V/F (L) the apparent central volume, ka (1/h) the absorption rate constant, CL/V (L/h) the elimination constant rate defined as the ratio between oral clearance CL/F (L/h) and the apparent central volume. Since we had only one blood sample per subject it was not possible to directly estimate parameters for the population under study. To model the pharmacokinetic of amisulpride after a repeated dose administration we used as starting point, model parameters taken from previous studies conducted using amisulpride doses comparable with the one in our study [10], [11]. The simulation was implemented in order to model a repeated dose administration, with an oral administration every 24 hour for seven days. With a dose of 200mg for the first day, 300 mg for the second day and 400 from the third to the seventh day.

The results obtained by the simulation were compared with the measured data and those reported in literature by experiments with similar doses. The simulation was carried out using the MATLAB toolbox Simbiology®.

C. Direct Pharmacokinetic/Receptor occupancy model

The classical Hill equation was used to describe the relationship between drug plasma concentration and receptor occupancy. This equation is a direct model and assumes that free drug concentration equilibrates rapidly between the plasma, free brain, and target-bound compartments:

$$E = \frac{E_{max} \cdot C_p}{EC_{50} + C_p} \quad (2)$$

where C_p is the plasma concentration of the drug and EC_{50} the drug plasma concentration that achieves 50% of RO.
The PET RO occupancy data were available for only four subjects, so the model was firstly used to estimate the population EC_{50} parameters using the RO measured with PET and the plasma concentration at the time of PET scan. Once the model parameters were estimated, Eq. 2 was used to predict the RO for all the other subjects who did not perform the PET scans, by using measured plasma drug concentration.

D. Relationship between occupancies and CBF

Considering the ΔCBV/RO model proposed by Sander et al, 2013 [9]:

$$\Delta CBV = -N_2 \cdot B_{max,2} \cdot \vartheta(0)_{DA} \cdot \vartheta_{AM} \quad (3)$$

We tried to replicate this model but linking relative to global CBF changes (ΔCBF) to changes in receptor occupancies ($\Delta\theta$). We substituted the CBF to CBV inside the model using the relationship proposed by Grubb et al [12] which suggests a power law relationship between CBF and CBV:

$$CBV = c \cdot CBF^{\beta} \quad (4)$$

Combining Eq. 3 with Eq. 4, the final relationship between CBF changes and receptor occupancy:

$$\Delta CBF = \alpha \cdot \vartheta_{AM}^{b} \quad (5)$$

where $\alpha = \frac{-N_2 \cdot B_{max,2} \cdot \vartheta(0)_{DA}}{c}$ is a parameter that includes all the constant values inside the model of Sander, b is the inverse of the parameter β and ϑ_{AM} is the amisulpride RO.

III. Results

A. Statistical analysis

The mean drug plasma concentration was 291 ± 187 (234 ±114 *for male*, 343 ± 229 for female*)* the average age was 26

± 7.8, the average weight was 71 ± 14 kg. T-test revealed that there was no statistical difference in plasma concentration between female and male, even though female showed higher plasma concentration. Spearman rank correlation revealed that there was no statistical correlation of both weight and age with plasma concentration while it revealed a positive statistical correlation between relative CBF changes in putamen and plasma concentration ($R = 0.24$, $p\text{-value} < 0.05$) but this correlation was not significant for caudate.

B. PK/RO/CBF model

The pharmacokinetic simulation results showed that the model was able to correctly predict the kinetics of amisulpride after a repeated doses with the concentration being in line with the literature's results [13], [14], [15], [16]. Moreover, the majority of our subjects fall inside the simulated concentration curves showing that our data were in agreement with the

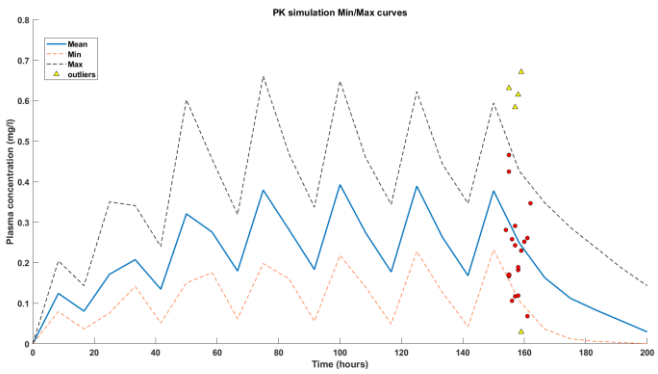

Fig. 1: Max, min and mean curves obtained with PK simulation

plasma concentration measured in previous studies (Fig.1). The subjects outside the range were considered as outliers and not considered for further analysis.

The fitting of PET RO data returned a EC_{50} value of 182.1 ng/ml for putamen and 117.7 ng/ml for caudate, both these values are in line with previous findings [5]. Given the plasma concentration of amisulpride across the subject, simulated RO ranged from 16.9 to 91.1% for caudate and from 11.6 to 86.9% for putamen. The *mean+/-SD* of amisulpride receptor occupancy was 62.3+/-17.2% for caudate and 52.9+/-17.7% for putamen and in agreement with expected D_2/D_3 occupancy of the drug with the given dosage.

Fig. 2 and Fig. 3 show the relationship between amisulpride receptor occupancies and ΔCBF changes for putamen and caudate. The models were statistically significant *(F-statistics = 19.2, p-value < 0.001)* for putamen and *(F-statistics = 8.25, p-value < 0.01)* for caudate. The exponent b of the power law model (Eq. 5) was 1.66 and 1.82 in putamen and caudate, respectively.

These results were concordant with the one founded by Sander et al on macaques [9] which returned a b = 1.7 for putamen and b = 1.4 for caudate in group 1 and b = 1.4 for putamen and b = 1.6 for caudate in group 2.

Thus, also in our case the data showed a monotonically increasing relationship between receptor occupancy and CBF changes and also in our case this relationship was regional dependent within the striatum, showing that the model better explained the putamen data compared to caudate.

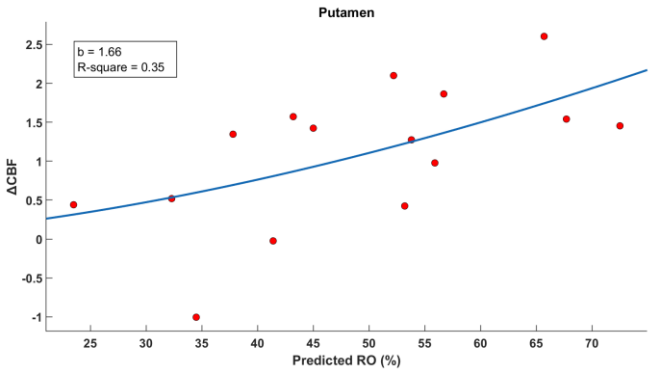

Fig. 2: ΔCBF vs amisulpride receptor occupancy for putamen, Data show a monotonically increasing relationship *(p-value < 0.001)*

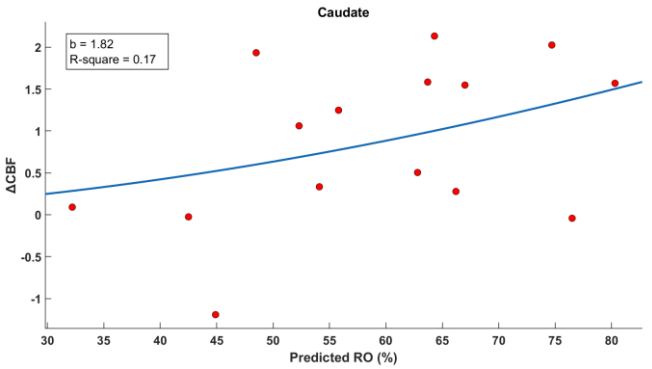

Fig. 3: ΔCBF vs amisulpride receptor occupancy for caudate, Data show a monotonically increasing relationship *(p-value < 0.01)*

IV. Discussion

In this study, we developed a PK/PD predictive framework to investigate the relationship between repeated clinical effective dose of amisulpride and cerebral blood flow of healthy volunteers in striatum. Results showed that the model accurately predicted the kinetics plasma drug concentrations after seven days of repeated administration. The ranges of concentrations obtained were in line with previous findings in literature [14], [15], [16], [17]. These results allowed us to evaluate the compliance of our subjects according to their plasma concentration data and to consider as outliers those subjects with a plasma concentration outside of the range Confounding variables such as gender, height, weight, and adverse events scores did not show a statistically significant effect on PK levels, even though mean plasma concentration of females has been reported higher than males [6]. Although it might a matter of statistical power, given the small sample.

The RO predictions obtained using the Hill equation model with the population EC_{50} parameter estimated were in line with expected value of RO given the corresponding plasma concentration [6]. The small number of PET scans limited the ability to conduct a more comprehensive analysis, such as

evaluating the relationship between the RO and dopamine receptors density distribution.

The results of the $\Delta CBF/RO$ model obtained integrating the CBF data inside the model proposed by Sander using the power law relationship between CBF and CBV, showed a monotonically increasing relationship between changes in CBF and amisulpride occupancies in caudate and putamen. The association between CBF changes induced by amisulpride and percentage of receptor occupancy matches earlier evidence in non-human primates showing large CBF increases after injection of the D_2 antagonist PET tracer [11C]raclopride in the same regions as the one investigated in this study [9]. These results suggest that the relationship between the physiological response to D_2 antagonist and D_2 availability described by 'Sander et al., 2013' in preclinical models also exists in humans.

To the best of our knowledge this is the very first time that this relationship has been detected in vivo in humans.

V. Conclusion

Understanding the link between neurochemical changes and brain function is crucial to uncover mechanisms underlying the effects of psychopharmacological treatment. In this work we investigated the case of amisulpride whose functional effect suggests a monotonic coupling relationship between neurovascular responses and dopamine D_2/D_3 occupancy in basal ganglia. We conclude that the perfusion changes in the basal ganglia uncovered by ASL under the administration of amisulpride were consistent with previous reports describing similar changes [17], [18]. This contributes into accumulating evidence that antipsychotics have similar effects on basal ganglia perfusion. However, the present findings were obtained using a combination of real and simulated data and we cannot exclude direct actions of dopamine on the vasculature that are uncoupled with neural activity. Therefore, the degree to which these non-neuronal effects contribute to the associations described here is not known.

Modeling Doxorubicin Treatment Effect in Multiple Myeloma

D. Andrean[1], F. Da Ros[2], M. Mazzucato[2], M.G. Pedersen[1], and R.Visentin[1]
[1] *Department of Information Engineering, University of Padova, Padova, Italy*[2]
[2] *Aviano National Cancer Institute, Aviano, Italy*

***Abstract*—Doxorubicin (DOXO) is commonly employed as chemotherapy drug to treat several kinds of cancer, including multiple myeloma (MM). Hence, a full characterization of DOXO pharmacokinetics/pharmacodynamics (PK/PD) is essential to maximize its efficacy while minimizing possible side effects. We recently proposed a mathematical model of DOXO PK in MM cells. Thus, as a natural succession, here we aim at modeling DOXO PD to describe its effects on MM cells.**

We monitored *in vitro* the MM cell proliferation in eight 2-week experiments, one under untreated conditions (control) and seven after a 3-h administration of DOXO at different concentrations (from 15 nM to 900 nM). A logistic growth and treatment response model, accounting for both cell proliferation and death rates, was developed and identified on each experiment to fit the collected cell count time series.

Results show that the proposed model is able to describe cellular growth both in untreated conditions and after DOXO treatment. We also propose a simple model to characterize the relationship between the administered DOXO amount and the corresponding drug-induced cell death rate parameter.

The proposed model is perfectly scalable to obtain a more precise descriptive implementation but also to develop a predictive framework that could lead to advancements in the current MM treatment paradigms.

***Keywords*—mathematical modeling, pharmacodynamics, in vitro, cancer.**

I. Introduction

MULTIPLE MYELOMA (MM) represents one of the most common types of blood cancer, affecting thousands of patients each year [1]. To this date it remains a treatable but not curable disease with a high death rate [2].

Chemotherapy drugs are common for tratment of MM, and, among them, Doxorubicin (DOXO) is well established and represents an effective MM therapy, often in combination with other drugs [3]. Mathematical modeling of pharmacokinetics (PK) and pharmacodynamics (PD) have proven a fundamental tool to guide new therapeutic protocols and to enlighten important phenomena regarding drug's effect [4], [5]. Moreover, coupled experimental/modelling approaches to study DOXO PK/PD have already proven useful, e.g., in breast cancer [5]. A similar approach was recently applied in MM too, with the development of a DOXO PK model [4]. To the best of our knowledge, this was the first attempt in the MM context.

In order to carry on the research in the field and to describe DOXO effects in MM cells, here we aim at modeling DOXO PD on a MM cell population.

Specifically, we start from an available model developed for breast cancer treatment [5], and properly modify it in order to describe the DOXO-induced cell death in a specific MM cell line.

II. Methods

A. Data description

Data used in the present work were collected at the Aviano National Cancer Institute, Aviano, Italy during *in vitro* experiments on MM cells.

MM1r cell lines (ATCC, http://www.atcc.or) were cultured in RPMI 1640 medium, supplemented with 10% fetal bovine serum (FBS) and penicillin/streptomycin. Cell cultures were subjected to different DOXO doses to observe the drug effect on vitality and cell growth. In particular, $5{,}6\times10^5$ cells were treated with different concentration of DOXO, i.e., 0 (control), 15, 20, 40, 50, 200, 450, 900 nM, for three hours. After 3 hours of drug exposure (t = 0 h), DOXO was removed and cells were seeded 10^4 cells/well in 96 well plate.

To monitor cell number, fluorescent CFDA-SE dye was used. In brief, cells were labeled with CFDA-SE 5 μM for 10 min and the emitted fluorescence was measured with TECAN. Fluorescence signal of each well was then converted in cell number taking advantage of a standard curve generated previously. This procedure was repeated every 24 h for 14 days.

Each experiment was repeated three times, starting on a different day of the week in order to possibly reduce the lack of measurement during the weekends, and to grant multiple samplings of the same relative time after DOXO removal (from 4 to 8).

Mean and standard deviation of cell count at each sampling time were calculated for each experiment and successively used as datapoints for model identification.

It is worth noting that, during each experiment, fresh culture media was added several times due to its consumption by the cells. This caused abnormal fluctuations and high uncertainty in some of the cell counts. An example of this phenomenon can be observed in Fig. 1 in the two measurements immediately before 300 h. Indeed, adding fresh media provided cells with a bolus of nutrients, thus likely promoting proliferation even in areas where the resource consumption was high enough to inhibit it. As such, this aspect, together with the known complex behaviors of MM cells when cultured *in vitro* [6], introduced some measurement uncertainty in time.

B. Doxorubicin response model

The PD model describing the MM cell response to DOXO administration is a simplified version of an available logistic

growth and treatment response model previously developed to describe DOXO effects on breast cancer [5].

The model assumes that the variation of cell count in time (*N*) is described by a single differential equation that includes a saturation term to account for the finite dimension of the culture well, which imposes an upper limit to the cell numerosity:

$$\frac{dN}{dt} = (k_p - k_d) * N * \left(1 - \frac{N}{\theta}\right) \quad N(0) = N_0 \qquad (1)$$

where k_p represents the proliferation rate, which determines how fast cells replicate, k_d is the drug induced death rate which models the drug effect on the population dynamics, θ is the maximum number of cells, and N_0 is the initial cell amount. The model assumes that k_p and θ are drug-independent parameters, while k_d depends on the DOXO dose.

C. Model identification

Model a priori global identifiability has been assessed using the Structural Identifiability Analyser (SIAN) software [7]. All the model parameters (k_p, k_d, θ) resulted globally identifiable since the proliferation and death rates are estimated separately.

The model of equation (1) was identified via nonlinear least squares estimator implemented in MATALB R2022a [8] using the *lsqnonlin* function.

The DOXO response model was identified on cell count datapoints, assumed affected by known standard deviation, empirically calculated from data as reported in section II-A. In particular, model parameters k_p, k_d, and θ were estimated in two separate steps.

The first step consisted in identifying the model on control experiment data (i.e., without DOXO administration). Since the proliferation rate is unaffected by the death rate in untreated conditions, only k_p and θ were estimated, while k_d was fixed to zero. Hence, the following cost function for nonlinear least squares estimation was minimized:

$$\hat{p}_{NLS} = argmin_p([y - G(p)]^T \sum_v^{-1} [y - G(p)]) \qquad (2)$$

where $p = [\theta, k_p]'$ is the parameter vector, y is the data vector containing the control experiment measures, $G(p)$ represents the model prediction and $\sum_v$ is the data covariance matrix, containing the sampled variances on the diagonal and zero elsewhere.

The second step consisted in identifying the model on treatment experiment data. In particular, a DOXO dose-dependent k_d was estimated for each treatment condition, while a unique θ was estimated by a Bayesian Maximum a Posteriori, with the statistical prior information taken from the previous θ estimated from control experiment data. Parameter k_p was fixed at the respective value estimated in the previous step. Therefore, model identification in this second phase was realized by considering the following cost function:

$$\hat{p}_{MAP} = argmin_p \Big([y - G(p)]^T \sum_v^{-1} [y - G(p)] + (p - \mu_p)^T \sum_p^{-1} (p - \mu_p) \Big) \qquad (3)$$

where $p = [\theta, k_d]'$ is the parameter vector, y is the data vector containing all the seven treatment experiment data time series, $G(p)$ represents the model prediction, $\sum_v$ is the data covariance matrix, and μ_p and $\sum_p$ are the a priori average vector and covariance matrix of model parameters.

It was observed that some experiments exhibited a cell count at time zero (N_0) unexpectedly higher than the following one at t=24 h (N_{24}). Thus, in order to improve model prediction, N_0 also was estimated in both control and treatment experiments. To note, including N_0 as additional model parameter to be estimated did not compromise a priori identifiability.

For each model identification, the estimated model parameters and the predicted cellular proliferation time course were analyzed. In addition, the model prediction 95% confidence intervals were calculated by bootstrapping data. For every experiment, each sample mean was randomly replaced by one of the single measurements used to calculate it. A new model identification was then performed on this resampled dataset. This process was repeated 500 times, for each experiment, to obtain a reliable confidence interval. It is worth noting that this procedure done in the control experiment also generated the mean and variance of the θ parameter that have been used as *a priori* information during the second-step of identification.

D. Death rate parameter fit

Model identification on different experiments led to a set of drug-induced death rate parameters k_d, one for each different DOXO concentration administered in a specific experiment.

As it will be shown in the Results section V, plotting the estimated k_d values as a function of DOXO concentrations suggests that death rate is linked to the applied drug dose following a saturation pattern. In particular, we described this relationship with a simple exponential model:

$$k_d = A * \left(1 - e^{-dose/B}\right) \qquad (4)$$

where $dose$ denotes the DOXO amount used in a specific experiment, A represents the maximum value of the death rate and B modulates the shape of the curve.

III. Results

A. Control experiment identification

Fig. 1 shows the model fit on control experiment data. In absence of DOXO treatment, the logistic model generally predicts the cellular growth well, except for the two samples before 300 h. To note, the experimental protocol required multiple refreshments of the culture media; in this regard, the immediate availability of nutrients caused the proliferation rate to increase rapidly and suddenly decrease the day after, due to the fast media consumption, thus causing the oscillation observed between 200 and 260 h.

All model parameters (θ, N_0, k_p) are estimated with good precision (Table 1), described in terms of percent coefficient of variation (CV). Interestingly, the k_p value is comparable with estimates obtained from breast cancer experiments [5].

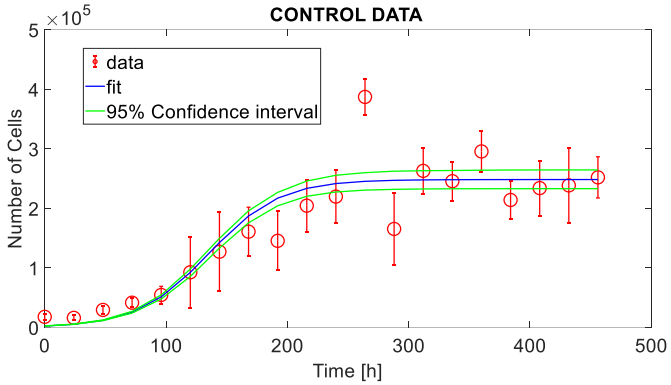

Fig. 1: Model fit on control experiment data. Cell count data are reported with red circles, with vertical bars representing the 95% confidence interval. Continuous blue line indicates model prediction, while green lines represent the 95% confidence intervals of the estimation, calculated with a bootstrap approach.

TABLE II: TREATMENT PARAMETER ESTIMATES

DOXO dose [nM]	θ [dimensionless]	N_0 [dimensionless]	k_d [h^{-1}]
15	236202 (3.99 %)	25657 (11.44%)	0.0179 (8.92%)
20	"	6355 (16.80%)	0.0208 (5.72%)
40	"	23722 (2.80%)	0.0317 (1.48%)
50	"	5726 (19.91%)	0.0330 (2.59%)
200	"	8039 (12.91%)	0.0482 (3.76%)
450	"	3684 (5.07%)	0.0479 (6.19%)
900	"	4579 (31.86%)	0.0549 (11.41%)

For each model parameter, the estimated value is provided together with its precision in terms of percent coefficient of variation (CV). Parameter θ is assumed independent from drug dose, i.e., a unique value is estimated, common to all the experiments. Parameter k_p is assumed fixed and equal to 0.0342, i.e. the estimate obtained from control experiment data.

B. *Treatment experiments identification*

Fig. 2 shows the model fit on treatment experiment data. In particular, the model is able to correctly describe the cell proliferation under DOXO treatment, also capturing the fact that any DOXO dose above 50 nM leads to a permanent stop of cellular proliferation.

Model parameters (θ, N_0, k_d) are estimated with good precision (Table 2). In particular, the estimated θ, common to all treatment experiments, is similar to the respective one obtained from control data; N_0 varies among experiments, accordingly with the respective data point at t = 0 h; k_d values are compatible with the expected saturation trend [5].

C. *Death rate model*

As shown in Fig. 3, the exponential model (4) is able to fit the k_d values estimated in the seven DOXO treatment experiments well. Model estimates suggest a maximum k_d value (i.e., parameter A) equal to 0.05 h^{-1}. The estimated parameter B is equal to 41.65 nM. Both parameters were estimated with good precision: CV(A) = 3.02%, CV(B) = 9.41%.

IV. CONCLUSION

In the present work, we aimed at modeling the effect of DOXO treatment in MM cells. Towards this end, a logistic growth and treatment response model was developed and identified on cell proliferation data of MM1r treated with seven different DOXO doses. This model proved to capture the observed dynamics well, both when the administered DOXO dose allows cell populations to regrow and when higher drug amounts lead to most of the cells dying. In particular, this was possible by accounting for a dose dependent drug induced death rate (k_d).

Some comments about the obtained results can be discussed. First, it is worth noting that the estimated k_d after administration of DOXO 50 nM resulted very close to the estimated proliferation rate (k_p). This would suggest that a cellular regrowth, even if not occurring in our experiment, may be observable for longer time periods. However, this is compatible with data coming from that of specific experiments in which some of the traces seemed to indicate cellular regrowth and some others did not. This could be also caused by instrumental errors leading to slightly different DOXO

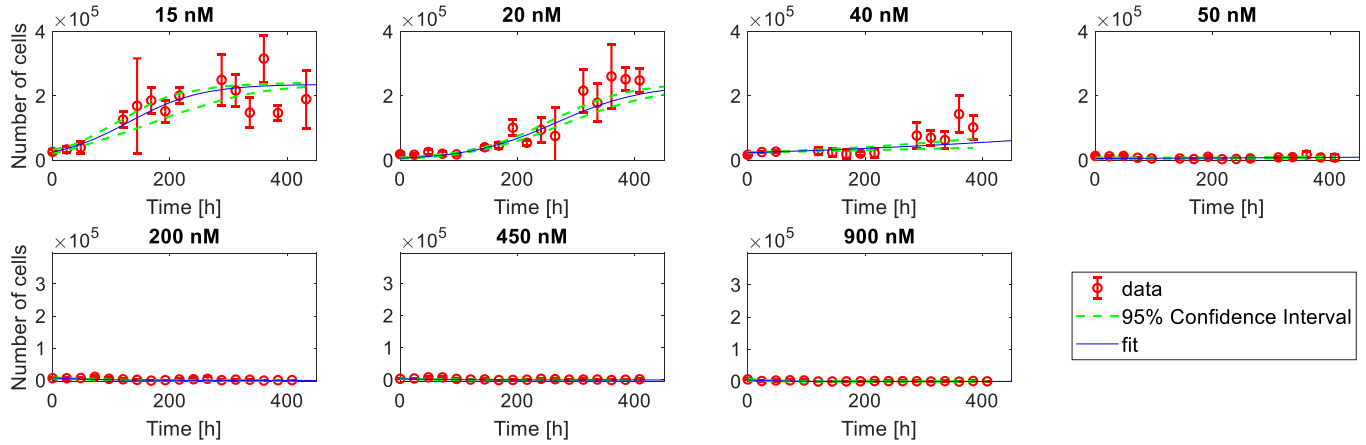

Fig. 2 Model fit on treatment experiment data obtained after administration of DOXO 15 nM, 20 nM, 40 nM, 50 nM, 200 nM, 450 nM, 900 nM. Cell count data are reported with red circles, with vertical bars representing the 95% confidence interval. Continuous blue line indicates model prediction, while green lines represent the 95% confidence intervals of the estimation, calculated with a bootstrap approach.

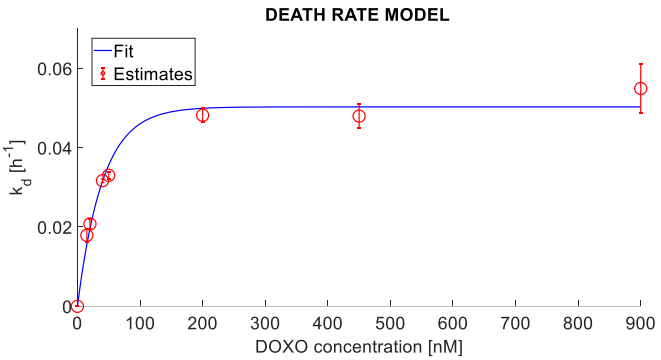

Fig. 3: Model fit describing relationship between DOXO amount and estimated cellular death rate (k_d). k_d values are plotted as red circles, with vertical bars indicating the estimated standard deviation. Continuous blue line indicates model prediction.

concentrations. In addition, we could model k_d as a function of the administered DOXO. Looking at the fitted death rate curve (Fig.3) can be enlightening; the curve around 50 nM is still steep, thus indicating that slight changes in the drug concentration may lead to sharp changes in the death rate value.

Given these considerations, longer experiments with DOXO doses around 50 nM will clarify this issue.

The k_d value estimated from experiment with DOXO 900 nM is the most uncertain and the highest among all the estimates. This is probably due to the fact that above a certain level of drug dose, cells rapidly die, and the resulting cell count remains constantly low for all the timepoints. This causes uncertainty in the death rate estimation, since, in principle, any value above saturation threshold ($A = 0.05$) grants a good fit. The same does not apply for the experiments with DOXO 200 nM and 450 nM, since cells start dying slightly later compared to what is observed during the experiment with DOXO 900 nM; higher k_d values would cause cell counts to decrease too sharply to properly fit these little delays.

It is important to underline that the present work is preliminary, and possible model refinements will be investigated in the future. In fact, the current version of the model does not account for any delay in the DOXO action, as k_d is assumed constant and always acting. This denies the ability to account for small initial fluctuations due to cellular growth followed by a gradual increase in the death rate, which causes the cell number to revert its trend and fall [5]. This behavior was noted in the experiments with the high administered DOXO, even if it was neglected since it involves low values of cell count (Fig. 2). Future works may include this feature to better describe small fluctuations.

DOXO effect fading should also be taken into consideration for future model refinements as it is likely that the drug loses its effect over time due to its half-life and dilution in the cells' nucleus after cellular replication.

These model improvements are currently under development.

In addition, in the current implementation, the maximum number of cells (θ) has been estimated from all data. However, to include the traces that remain flat at a low cell count is arguably useful, as these traces never approach the saturation values. Therefore, despite the precision of estimated θ was good, in future implementations it could be worth estimating this parameter only from saturating data and using this estimate as a fixed parameter on flat data.

It is also worth mentioning that the current experiments involved a single cell line, i.e., MM1r cells. Adding further cell lines would be greatly interesting and supportive as their pharmacodynamics could differ significantly, as already observed in other cancer types [5].

A final aspect to discuss is that cells had to be cultivated for unusual long times, requiring the administration of new culture media several times when needed, without a fixed refreshment protocol. As already mentioned, this caused fluctuations in the cell number that may or may not be synchronized among the single traces, possibly leading to refreshment-related patterns that are uninformative for the problem at hand (Fig. 1).

We chose to implement a simplified version of the model and we showed that it is nonetheless perfectly suitable to describe the evolution of cell populations for many different treatment conditions. It is to say however that our data had sensibly lower dose resolution due to the limited number of experiments if compared to other works [5].

In summary, here we proposed a simple yet effective model that summarizes the effect of DOXO with a single parameter, the drug-induced death rate (k_d) and we also propose a simple exponential law to characterize the relation between k_d and the applied DOXO dose.

***Abstract*—An open question in neuroscience regards the origin of the flexible and heterogeneous spatio-temporal patterns of neural correlations assessed with fMRI. Model-based approaches are commonly used to shed light on this problem with the aim to reproduce the same dynamical richness observed in the empirical recordings. In particular, dynamic causal models are generative top-down models commonly used in this field based on a state-space representation where the state refers to the hidden neural dynamic. The corresponding state matrix is the so-called effective connectivity that is interpreted as a representation of the causal interactions between each ordered brain region pair. By looking at the effective connectivity in the context of linear system theory, we can derive a rich characterization of the dynamics of the system. In this work we propose a method for studying how each brain region participate in defining the global stability of the system and its application to both mouse and human resting-state fMRI datasets. In detail, this analysis is based on a decomposition of the state matrix into two components: a dissipative symmetric gradient flow, and a solenoidal component which accounts for the asymmetric, i.e. directional, coupling. By acting on the solenoidal part, we can simulate the segregation of a single region and evaluate its effect on the eigenvalues of the state matrix, specifically those related to the slower dynamics.**

***Keywords*—Dynamic causal modelling, resting-state fMRI, asymmetric coupling, stability**

I. INTRODUCTION

In the last decades, network science has changed the way neuroscience looks at the brain. Much more attention has been paid to how brain units interact with each other rather than their isolated behavior. This has been possible due to technological advancements in the mapping and recording of large-scale neuronal system, on one side. And on the other, by the need of understanding two fundamental neuroscience principles: the brain functional integration and segregation. One way to pursue this goal is through a model-based (mechanistic) approach, and specifically top-down models are the most suitable for this type of studies at the macroscale level. They aim to solve the inverse problem, thus searching for the model parameters that better explain the empirical data. There are two main groups of top-down models: the brain network models (BNMs) and the dynamic causal models (DCMs). BNMs rely on the idea of placing local neural models on top of the structural connectivity (SC) which encodes (symmetric) anatomical information [1]. While DCMs are generative top-down models that characterize the dynamics of the system by fitting a state-space model: the state represents the hidden neural activity and the state matrix is the so-called effective connectivity (EC) [2]. Given a brain region, the related row of the EC matrix tells how the whole network participates in modelling its dynamics. In case of no a priori constraints, EC is an asymmetric matrix, thus it encodes directional information that are commonly interpreted as the causal interactions between each ordered brain region pair. Moreover, since DCM is defined as a state-space model, EC can be seen as its Jacobian matrix. This means that we can take advantage of the linear system theory to provide a detailed characterization of the temporal brain dynamics.

These motivated our choice to focus on DCMs for studying the dynamical richness that we observe in the empirical brain recordings. Recently, variants of DCM have been proposed to be applied on resting-state whole-brain fMRI data [3]–[5], showing the possibility of overcoming some limitations: the scalability to whole-brain data and the original task-based implementation that prevented its application to resting-state data. Here, we propose a method for studying how each brain region participates in defining the global stability of the system and show its application in both mouse and human resting-state fMRI datasets. Stability and closeness to instability boundary are topics that are supported by a rich literature in the field of neuroscience. In particular, it has been shown that a metastable regime is the optimal one to reproduce brain dynamics [6] and that the intrinsic brain timescales are mainly defined by the real and imaginary parts of the slower eigenmodes, i.e. the closer to the vertical axis, [7].

II. MATERIALS AND METHODS

We applied a recently developed method for estimating whole-brain effective connectivity (sparse DCM, [5]) to resting-state fMRI BOLD recorded from the following mouse and human datasets. Concerning mouse data, BOLD time series were acquired using functional echo-planar imaging (TR/TE=1000/15 ms, 2.3x2.3 cm, 1920 volumes) [8]. rs-fMRI preprocessing steps were carried out including motion correction, volume despiking, temporal filtering (0.01-0.1 Hz) and spatial registration to a common anatomical reference template (74 ROIs, 37+37). Concerning human data, resting-state fMRI scans (TR=1.400 ms, TE=39.4 ms, flip

angle=69°, FOV=202x202 mm, voxel size=2.3x2.3x.2.3 mm, volumes=657, MBAccFactor=4) of 107 healthy subjects (age range: 20-40 yo) were retrieved from the publicly available MPI-Leipzig Mind-Brain-Body dataset [9]. We extracted subject-level time series data from a 100-area parcellation scheme of the cortex provided by the Schaefer atlas [10], which maps to 7 resting-state functional networks. We also defined a set of 12 subcortical and cerebellar regions based on the AAL3 segmentation [11]: for each hemisphere, 6 regions consisting of thalamus, caudate, putamen, pallidum, hippocampus and cerebellum. The temporal traces were motion-corrected, volume-despiked and band-pass filtered in the same frequency range employed for murine data. In addition, a consensus clustering procedure was also applied to reduce the number of cortical parcels [12]. The resulting clustering procedure provided 62 cortical clusters, from which demeaned fMRI time courses were extracted and supplied as inputs to sparse DCM together with the BOLD signals from subcortical nodes. It follows that the application of DCM resulted in the estimation of the EC between 74 ROIs (referring to 62 cortical and 12 subcortical parcels) at the individual level.

Regarding sparse DCM, it incorporates a prior that induces sparsity in the EC estimation and a statistical linearization of the HRF model to address the high-dimensional solution space. In terms of dynamical systems, the EC matrix represents the state matrix of a linear state-space model, where the state component, solution of a linear differential equation, represents the neural response, whereas the output a transformation from the neural activity to the BOLD signal through the haemodynamic function. Importantly, EC can be decomposed such that:

$$EC = \left(-\frac{\sigma^2}{2}I + S\right)\Sigma^{-1} \tag{1}$$

where σ^2 is the variance of each brain endogenous fluctuation, assumed to be the same across regions, Σ is the covariance matrix of the state (i.e. the functional connectivity matrix), and $S = -S^\top$ is a skew-symmetric matrix. S embodies the asymmetric part of EC and allows the interpretation of its entries as directed causal interactions. Eq.1 parametrizes all EC matrices that give the same Σ, i.e. the covariance matrix of the state, for any S. Thanks to this parametrization, the symmetric and asymmetric parts of EC are disentangled, so we can separately intervene on them. For example, by deleting or enhancing some entries of S we can manipulate the pattern of causal interactions and then derive the related EC that ensures the same functional pattern. Following the terminology in [7], $\frac{-\sigma^2}{2}I\Sigma^{-1}$ is the (symmetric) dissipative gradient flow determined by the real eigenvalues of the system, while $S\Sigma^{-1}$ is the non-dissipative solenoidal flow defined by the complex eigenvalues which are responsible for the sinusoidal component.

III. RESULTS

On each mouse and human rs-fMRI data, we applied sparse DCM and decomposed the related EC in S and Σ. Fig.1a shows a scatter plot of the imaginary vs. real eigenvalues of each single-subject EC of the mouse dataset (the color identifies the subject). Each dot represents a mode of the system. All modes are stable by construction, meaning that the real part is negative. Concerning the imaginary part it can be either zero, i.e. real mode with exponential decay, or not, i.e. exponentially damped oscillatory mode. For each subject, the complex mode with the highest imaginary part and its conjugate are marked with a square, i.e. mode of the principal frequency. In general, these modes are not the dominant ones, i.e. the closest to the stability boundary, but they become so if we globally increase the contribution of S in Eq.1. Note that the frequencies of these oscillatory modes are very slow, about 0.03 Hz. These are the so-called ultra-slow frequencies, a key feature of the resting-state fMRI [13]. Fig.1b shows the modes for each subject computed by replacing S with αS in Eq.1 (α=100 in Fig.1b), thus α is a global scaling factor that tunes the strength of the asymmetric component. By increasing α, all modes tend to vertically align to a unique real value, except for the ones with highest imaginary parts which are the least sensitive to changes in α. For a representative mouse, Fig.2a shows the effect on the system stability of isolating each node by setting to 0 its column and row in S. In particular, it shows the real part of the complex eigenvalue with the maximum imaginary part. The horizontal straight line refers to the corresponding value in the original EC, i.e. with no intervention on S, and square markers highlight the regions that strongly affect the system stability by reducing the real part of the principal frequency mode, i.e. by making its decay faster. Similarly, in Fig.2b the regions that are most responsible for the stability regime of the system are shown for each mouse. Fig.2c shows the global results across mice, in particular it reports the frequency histogram for each brain region and it highlights those that have been selected in more than 50% of mice. Similarly, Fig.3 shows the rate of selection computed on the human dataset.

IV. DISCUSSION

In the present study, we have analyzed how the pattern of directed causal links exhibited by each brain region contributes to the global stability of the system. In particular, through the proposed factorization of the EC matrix, we can simulate the segregation of a given node from the rest, while preserving its own endogenous activity and its similarity, i.e. function connectivity, with the rest of the network. Across mice and coherently between hemispheres, the secondary motor area (MOs), the primary somatosensory area (SSp), the anterior cingulate area (ACA) and part of the retrosplenial area (RSP) have shown to play an important role in keeping the system closer to the stability boundary, i.e. a condition that can be associated with a metastable regime, thus the optimal regime to emulate the brain dynamics [14]. From their structural properties, they have all been characterized as hubs in [15]. Regarding human subjects, lower-order regions (i.e., visual and somatosensory-motor) seem to be the most involved in determining system metastability. Interestingly, these parcels include regions that are usually implicated in auditory and

motor-hand processing, which may be involved in the integration of information over different timescales performed by the dynamical core of the brain [14]. In addition, over-threshold visual ROIs are peripheral parcels in the visual system [16] that incorporate a fraction of the superior parietal lobule, which plays an important role in attention tasks [17]. On the other hand, attentive areas (referring to dorsal and salience ventral attention networks) and some right control ROIs are the highest-level cognitive nodes to unveil significant stability properties. These regions are mainly devoted to cognitive control and novel problem solving, whose high metastability was shown to be predictive of task-based reasoning [18]. Regarding subcortical nodes, cerebellar parcels play a key crucial role in the definition of network metastability. This is consistent with previous studies suggesting that cerebellum has an important synchronization effect across motor and cognitive tasks [19].

***Abstract*—The present work aims to reproduce and replicate the results of a prominent study in the computational neuroscience field. The objectives of this reproduction are verifying the original claims and results and assessing the research's degree of replicability. In the original study, the authors presented a detailed neural network model of the *striatum*, a nucleus in the subcortical basal ganglia of the forebrain. The methodology employed for the replication focuses on two scopes: the influence of network size and model complexity on the observed dynamics in the neural circuit. Different combinations of scale and complexity reduction have been performed and compared. The results show similar qualitative behavior, considering the limitations and simplifications adopted. Reducing the size primarily impacted the overall network mean activity and firing rates while simplifying the single-neuron models affected the network responses to cortico-thalamic inputs. Lastly, some recommendations are made for future works: improvements that can be implemented on the replicated models and evaluation and feedback on the documentation and accessibility of the original research.**

***Keywords*—Computational neuroscience, replicability, neural circuits, basal ganglia**

I. Introduction

One of the most important keystones in science is the idea of researchers being able to reproduce each other's experiments in order to assess the results and further study the same subjects. Based on this idea, the description of methodology in reports became extremely important, given that the level of detail and instructions should be enough so that other scientists could follow the published steps and obtain the same results as the original authors.

In this work, we have adopted the Association for Computing Machinery definitions of reproducibility and replicability: Reproducibility (different team, same experimental setup), for computational experiments, this means that an independent group can obtain the same results using the author's own artifacts; Replicability (different team, different experimental setup), this means that an independent group can obtain the same results using artifacts that they develop independently [1].

The computerization of scientific research brought new challenges to the ability to replicate and reproduce research findings. Other study formats, which have been established for a longer time, already have a good consensus about how the methodology should be shared in order to allow verification. However, it seems that the computational science fields are still working towards discovering how to publish a work's methodology to guarantee that it can be reproduced [2].

While publishing the related code is already a good starting point [3] to increase the research's transparency, it still does not guarantee that it is replicable. Over 70% of the researchers who participated in a survey [4] have tried and failed to reproduce a peer's work. From this same source, there's an even more striking result that over half of the surveyed scientists have already failed to reproduce their own research at some point.

The aim of the present work is to reproduce and replicate a prominent study of the computational neuroscience field. In this effort, the objective can be divided into two main parts: firstly, achieving the reproduction in itself - and therefore aiming to validate and increase the reliability and robustness of the original work. Secondly, assessing the replicability of the original research with a reductionist approach, testing to which degree network size and model complexity contribute to the model's behavior.

II. The original study

Hjorth and colleagues have reconstructed a full-scale model of the mouse *striatum* at a cellular level [5]. The population of the network matches the real-life physiological system and the level of detail is very high, giving each cell its fully complex behavioral model.

While the simulation results are already very interesting alone, another main appeal that made this work a good candidate for the replicability process presented here is the fact that the authors developed a tool to assist this task. Moreover, this software tool was designed in the format of an easy-to-use platform, which can then be adopted by other scientists in the community.

The methodology employed in the research can be structured into multiple steps that can be managed using software developed by the authors called *Snudda*, a tool that facilitates the modeling phase of neural networks. The user specifies the desired configurations of the network through a series of JSON files, which are read by the framework to result in the final model.

According to the network size specified, each cell is instantiated with its respective model. Analyzing the generated circuit, it is possible to attest that the overall neuron type distribution agrees with the data available in the literature. Spiny Projection Neurons (the direct and indirect pathways, dSPN and iSPN) make up about 95% of the *striatum* population, and this percentage is equally divided amongst them. The remaining

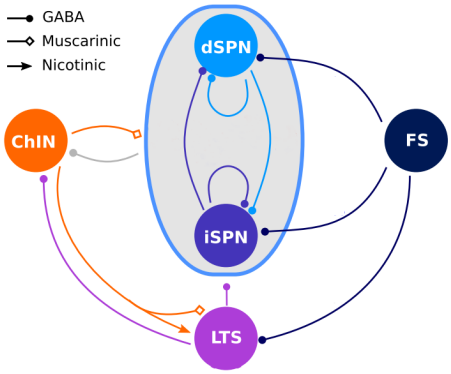

Fig. 1: Schematic connectivity within the dorsal *striatum* involving dSPN, iSPN, FS, LTS, and ChIN. Different arrows show the connectivity with GABAergic (inhibitory) connections and cholinergic ones (muscarinic and nicotinic). Adapted from [5]

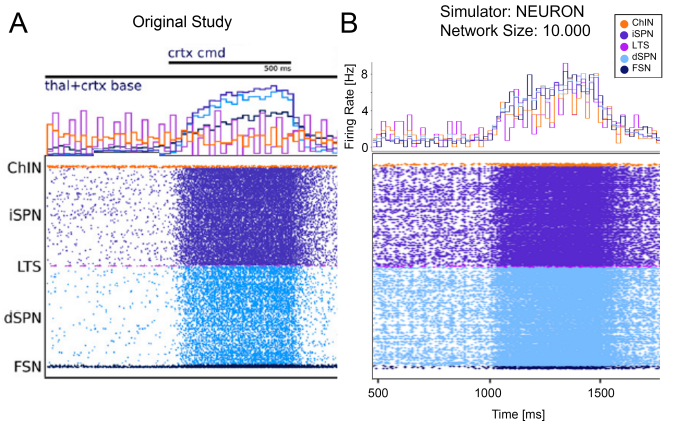

Fig. 2: Raster plots (lower panels) and firing rates (upper panels) from the original article [5] and the reproduction with our simulation (NEURON, 10'000 neurons network). *thal+crtx base* indicates the baseline thalamic and cortical input, while *crtx cmd* indicates the command signal from the cortex. The bin size of firing rates was set to 20 ms, as in [5]. Note that the vertical scale was not indicated for the firing rates of the original article.

5% are interneurons. The network only includes models of the three most frequent interneurons of the *striatum*: Low-Threshold Spiking (LTS), Cholinergic Interneurons (ChIN), and Fast Spiking Neurons (FSN). They represent, respectively, 1.3%, 1.1%, and 0.8% of the total neuronal population.

Each generated cell has a set of coordinates, indicating its position on the network. This information is fed into a touch-detection algorithm that signalizes any time there is enough proximity between two neurons. Combining the aforementioned values with the prescribed rules for synaptic connections, a realistic connection probability is set for each case, which can finally be used to obtain the connected network (Fig. 1).

Finally, with both the network model ready and the extrinsic input signals generated, the network is simulated with NEURON, a widely used simulator for biophysical neuron models [6].

III. Reproducibility and Replicability Studies

In this work, we not only attempted to reproduce the selected research but also to add insight and novelty by changing some aspects of it and analyzing the repercussions. Evidently, the original simulation involves many independent variables, which interact amongst themselves, contributing to the model, and assessing the impact of all of them would be infeasible.

Hence, two main scopes were chosen to be evaluated: the influence of network size and model complexity. Both of these aspects largely influence the computational power that a simulation demands, which in turn can determine whether it is feasible to replicate it. Consequently, the aforementioned dimensions were deemed interesting focuses for the framework.

Network size influence was assessed by generating three network structures of varying population numbers. In order to produce different enough structures, starting from the size of 10'000 neurons used in the original simulation, two reductions of one order of magnitude each were applied, resulting in additional neural networks of sizes 1'000 and 100 neurons.

The simplification of the model is implemented through a simulation tool change. While the *Snudda* software relies on the NEURON simulator, the simpler adaptation presented in this work was set on the NEST simulator for spiking neural networks that use point-neuron models such as leaky integrate-and-fire [7], [8].

The work can be therefore separated into three parts:

1) **Original study reproduction**. Using the 10'000 neuron network simulated with NEURON;
2) **Network size comparisons**. Studying how the network size (10'000 vs. 1'000 vs. 100 neurons) influences the output. All simulations were performed in NEURON.
3) **Model complexity comparison**. Studying how the simplification of neuron and synapse models, passing from biophysical multicompartmental (NEURON) to point-neuron (NEST) models, impacts the output. All simulations were performed with the 10'000 neurons network.

IV. Original Study Reproduction

With minor adaptations to the codes provided by the original paper's authors, we successfully generated and simulated through *Snudda* the 10'000 neuron network with NEURON. The network is driven by cortical and thalamic input. The two inputs represent 1) baseline activation of cortical and thalamic input from the beginning of the experiment and 2) a cortical command signal, starting at 1000 ms, during which the cortical activation is increased for 500 ms (given to all cells except the ChINs). We could therefore compare the simulation's output in terms of spikes patterns and the computation of firing rates for each population of neurons. Figure 2 shows that firing patterns and firing rates, divided per neuron type, are qualitatively similar to the original results.

There was a clear limitation due to the lack of information about the input that was used in the article's simulation.

Furthermore, the information shared about the inputs was primarily qualitative. Therefore, although it was clear that the sources of input spikes were the same as the ones provided in the example (Cortex and Thalamus), there was no confirmation that the frequencies of these spikes were the same as the ones observed in the original experiment. Furthermore, the authors deployed dopamine modulation for 300 ms in the original article. Unfortunately, this option was not available in the code provided to the public at the time of this project. Therefore, that part of the original results had no means of being reproduced. Another barrier that adds a challenge to the proper comparison of results is the absence of firing rate values. The original work features a figure with the firing rates for each cell type, but a scale is not present. For this reason, we focussed mainly on a visual analysis of the scatter plot and the qualitative aspects of the network's behavior.

Considering all these concerns, many relevant comparative results remain to be analyzed. Overall, the network's dynamic behavior is similar to the original simulation, most evidently in response to the addition of the cortex command. Even though the replication's projection neurons seem to have a higher basal activity level, the relative increase in the firing rates seems comparable to the one observed in Fig. 2A.

The opposite phenomenon can be detected in the FSNs' behavior. In the reproduction, this population has a lower basal activity rate. Nonetheless, the increase in firing with the cortical command is still present and considerably similar.

A notable distinction lies in the other interneurons' activity levels. In the original simulation, ChIN and LTS cells show a very constant and rhythmic firing rate pattern that suffers almost no alteration with the deployment of the cortical command. The replication results, on the other hand, exhibit different behavior. There is still a cyclic component to their dynamic, but the additional cortical input interferes with it, increasing the cells' activities.

A hypothesis for this discrepancy lies in one of the aforementioned limitations. Since the exact input configurations used on the original simulation are not available, it is speculated that it might be different from the one generated in the script made available for testing. One simple cause could be just that the frequency or weight of the inputs are not the same value. Another possibility is the existence of constant current injections in the original simulation, which might explain the interneurons' indifference toward the increase in input spikes. Unfortunately, we could not test this hypothesis because of the lack of data from the original paper and from the shared repository, too.

V. Network size comparisons

Having completed the first step, the reproduction of the original work, we continue our replication study by exploring variations in the striatal model. Using the same methodologies used for the 10'000 network, we have generated two smaller versions, with 1'000 and 100 neurons, respectively. It becomes evident in Fig. 3 that the reduction in network size interferes with the scale of the computed firing rates. Therefore, here we represent the firing rate plots both separately and together to allow better data visibility.

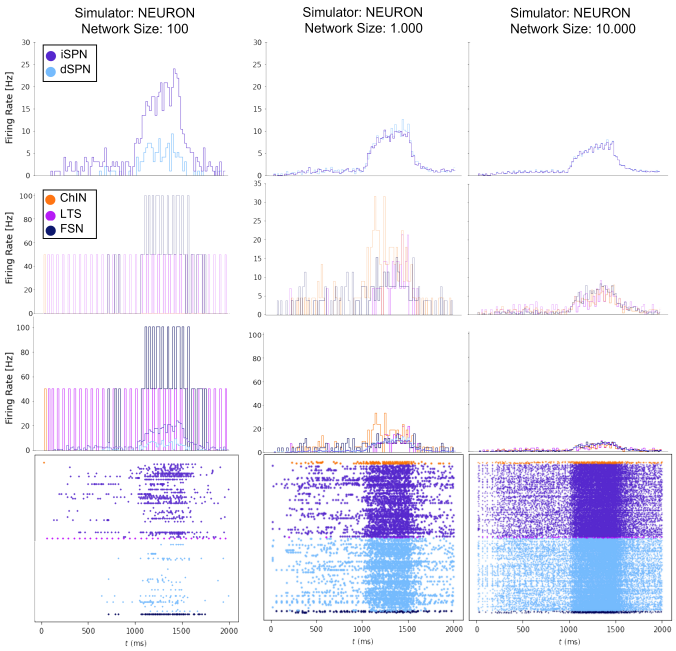

Fig. 3: Raster plots and firing rates of NEURON simulations with three network sizes: 100, 1'000, and 10'000 neurons. The first two rows show the firing rates of dSPN and iSPN (first row) and the other interneurons, i.e., ChIN, LTS, and FSN (second row), separately. The third row shows all the firing rates combined together.

The primary consideration to be made in this analysis regards the activity of the interneurons. The scale reduction of the network has a more significant effect on the interneurons since they represent a small percentage of striatal cells. This provokes a distortion in their behavior, which is most prominent in the firing rate values for the smaller network simulation. Furthermore, since the 100 neurons network has only one single interneuron of each type, the possible values of their firing rates are binary.

A phenomenon revealed by comparing neuronal firing rates is the consistency in the LTS firing rate. While the activity of the ChIN neuron is extinct in the 100 neurons network, and the FSN also suffers a reduction, the low threshold neuron continues to spike rhythmically.

Another interesting observation is the difference in the iSPN and dSPN behaviors under the cortical control signal. Observing the top row of Fig. 3, it is clear that the leftmost column has an increase in iSPN activity about 2 to 4 times higher than the dSPN. This discrepancy is only present on the smallest scale. In contrast, the middle and large-scale networks have a seemingly balanced response from the two projection neuron populations. This result suggests that the size reduction potentially caused too big of a change to the model, which in turn lost some of its dynamic properties.

On the other hand, the outline of the firing rate curves for the projection neurons on the 1'000 neuron network and the 10'000 neuron network are very similar. Both the rise and fall

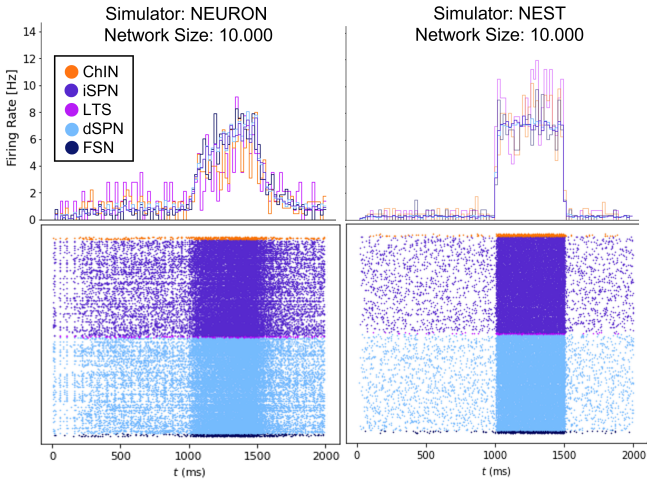

Fig. 4: Raster plots and firing rates of NEURON and NEST simulations of the 10'000 neurons network model.

patterns match really well, signaling that some fundamental characteristics were maintained with this change.

VI. Model complexity comparison

This section presents the results of the simulation obtained on NEST against the NEURON benchmark, using the 10'000 neurons network.

The results of the simulator change and model simplification have considerably good performance (Fig. 4), especially considering how simple the NEST model is. Furthermore, the observed range of firing rate values is almost the same as the NEURON benchmark, with peak values for the projection neurons reaching about 8 Hz.

One of the main divergences between the two simulations is the rise and decay behavior, which is much steeper in all cell types on NEST. This occurrence can be traced back to the fact that the neuronal models used on the simpler model, a leaky integrate-and-fire, have no active mechanisms. Therefore they purely respond to the input they are given, with no damping, attenuation, or other altering effects. Also, the synapse model is the same for every source and target combination, with only a change in the weight, but all with a fixed delay of 1 ms. Thus, all transmissions respond instantly to the input variations without any added gap in their transmissions. Both these factors can contribute to the almost immediate step-like change in the firing rates.

Lastly, there is a bigger contrast between the low firing rate values and the high ones. Simply put, the basal activity is somewhat lower for all the cell types, while the excited state is also slightly higher than the benchmark.

As previously discussed, the verification that a simpler model can generate consistent results is very compelling. The main advantage is that it allows for easier creation of similar work whenever the research objectives allow a more generalized overview of the results. Indeed, the simpler model cannot capture the dynamic nuances of each neuron, a task that is feasible with the complex biophysical model simulated in NEURON. But at the same time, this different approach admits more accessibility to the simulation by loosening the necessity of heavy computational power availability.

Another scenario where this framework can greatly benefit is on initial exploration steps of a research project. In hindsight, the work presented here actually used a similar tactic to allow faster testing. The learning process was facilitated by starting on a smaller scale since the temporal cost of trial-and-errors was minimized. The same logic can be applied when speaking of model complexity: before executing time-consuming and computational power-demanding simulations, it can be advantageous to perform simpler versions. Consequently, primary trials about configuration setting and parameter tuning are much quicker.

VII. Conclusion

In summary, there are two main conclusions about the work conducted in this project. The first one highlights the essential role in documenting and making available as much as possible the code, data, and software used in one's research. It becomes clear that this was, in different moments of this work, both the factor driving its feasibility and the one limiting and hindering the reproduction. Thus, it is fair to say that the thorough sharing of all that relates to a research's methodology is a decisive factor in its replicability and, by extension, its reliability. For this reason, we made publicly available all the codes and detailed descriptions of software versions and requirements to replicate our work at https://github.com/alberto-antonietti/BasalGanglia.

The second conclusion speaks of the intensive work and particular challenges that replication researches entail. Fully comprehending another author's work is extremely time-consuming, but at the same time, it fuels ideas for how to build on what was published and test new hypotheses. This is especially true in computational neuroscience, where models have endless applications and can be used to explore untested theories.

***Abstract*—Glucose-insulin interaction during an intravenous glucose tolerance test (IVGTT) has been widely investigated through the use of the glucose (GMM) and the insulin and C-peptide minimal model (IMM, CMM). The identification of these models usually employs a *forcing function* strategy (i.e., one measured profile is assumed to be an input of the system, known without error) to avoid compensation among model parameters. This approach may lead to the underestimation of concentration peaks and to an incorrect propagation of the measurement error, which in turn, may provide biased estimates of model parameters. Moreover, the separate identification of the system sub-models precludes a robust estimation of correlations among model parameters, which may rather be physiologically relevant. To overcome these limitations, here we aimed to build a comprehensive glucose – insulin – C-peptide MM, using nonlinear mixed effects (NLME) modeling, able to simultaneously describe glucose, insulin, and C-peptide concentrations during an IVGTT, and their inter-subject variability in a healthy population.**

Results showed that assuming a two-compartment model for both glucose, insulin, and C-peptide kinetics and log-normally distributed parameters best fitted the data and provided precise estimates of model parameters. Intriguingly, with the NLME approach, we highlighted significant positive correlations between parameters of the IMM and CMM and a significant negative correlation between insulin sensitivity and beta-cell function. In conclusion, with this study, we proved that is possible and worth applying the NLME approach to the simultaneous identification of a glucose, insulin, and C-peptide MM during IVGTT.

***Keywords*—Diabetes, NONMEM, parameter estimation, population modeling**

I. Introduction

The intravenous glucose tolerance test (IVGTT) is a clinical experiment used to assess insulin sensitivity, glucose effectiveness, and pancreatic beta-cell function, three clinical indices useful to summarize the metabolic portrait of a subject, possibly predicting the development of pre-diabetes and diabetes. This test consists of a rapid intravenous injection of glucose, sometimes followed by a rapid injection of insulin (insulin-modified IVGTT, IM-IVGTT), and the frequent collection of plasma samples for measuring glucose and insulin concentrations. When possible, also C-peptide concentration is measured, since C-peptide is a better marker of insulin secretion than insulin itself, given that insulin and C-peptide are secreted in a 1:1 ratio but, while insulin is partially extracted by the liver, C-peptide is not. Data collected during an IVGTT can be interpreted with the so-called minimal models (MMs) [1], [2], whose identification provides estimates of the aforementioned indices. The identification of these models usually employs a *forcing function* strategy to avoid compensation among model parameters, i.e., one measured profile is assumed to be an input of the system, ignoring that those measurements are affected by noise. For instance, when identifying the glucose MM [1], plasma glucose is considered the measured output while the interpolated insulin profile is used as known input. Vice-versa, when identifying insulin and C-peptide MMs (IMM and CMM) [2], the glucose profile is the one assumed as known. The most used method for identifying these models is the weighted nonlinear least squares approach [1]–[3], but examples exist of using more sophisticated Bayesian methods [4], [5]. In both cases, the identification problem was tackled at a single individual level. Therefore, any statistical moment or covariate analysis was performed *a posteriori* on the estimated parameters without considering the uncertainty that affects estimates, thus, leading to upwardly biased results [6].

Alternative approaches have been developed over the years trying to overcome such limitations. Among them, the nonlinear mixed effects (NLME) modeling has been shown to bring interesting advantages [6]. This technique consists in the simultaneous fitting of the model to the data of all individuals while allowing a hierarchical description of the variability present in the system. This is of particular importance, especially when modeling biological systems where a typical behavior is shared between individuals, but several factors (from demographic characteristics to seasonal fluctuations) contribute to the between-subject (BSV) and between-occasion variability. Hence, parameters describing the variability are estimated together with all other model parameters, allowing propagating measurement uncertainty, and avoiding biased results. In addition, covariates of the subjects can potentially be incorporated into the model leading to a better description of the BSV. The list of advantages of NLME propagates further with the possibility to employ measures fallen below or above the limits of detectability (often discarded from the analysis), the usability of the model in the case of sparse data, and the possibility to simultaneously identify the model on datasets

coming from different studies. NLME has already shown its potential when applied to the MMs [7]–[10]. However, to the best of our knowledge, the simultaneous identification of GMM, IMM, and CMM has never been attempted on glucose, insulin, and C-peptide data. In this study, we filled this gap and developed a comprehensive NLME model of glucose, insulin, and C-peptide interaction during IVGTT, able to describe the parameter distribution of a healthy population.

II. Methods

A. Database

An IM-IVGTT was performed on 204 non-diabetic subjects (118 males and 86 females, age = 55.5 $\pm$ 21.7 years, weight = 77.9 $\pm$ 13.3 kg) at the Mayo General Clinical Research Center (Mayo Clinic, Rochester, MN, USA). The protocol consisted of a constant intravenous injection of glucose (0.330 g per kg of body weight) for 2 minutes starting at time 0 followed by a constant insulin infusion (0.02 U per kg of body weight) for 5 minutes starting at time 20 min. Blood samples were collected at 0, 2, 4, 6, 8, 10, 15, 20, 22, 25, 26, 28, 31, 35, 45, 60, 75, 90, 120, 180, and 240 min for measurement of plasma glucose, insulin, and C-peptide concentrations. Median, 5th, and 95th percentiles of the data are visible later in this manuscript, in Fig. 2 in the *Results* section (continuous black lines). A complete description of the protocol is available in [11].

B. Nonlinear Mixed Effects Model

A series of models of increasing complexity were tested: one- vs two-compartment structures, including or not correlations between model parameters. All were made of three components: i) a structural model describing kinetics and interactions of glucose, insulin, and C-peptide, ii) a model describing the BSV of the structural model parameters, and iii) an error model for the residual unexplained variability.

1) Structural model: The tested structural models integrated and possibly expanded, the GMM [1], the IMM, and the CMM [2]. The main difference with respect to the original ones was that model equations were re-parameterized so that state variables represented amounts, instead of concentrations, and clearances (CL and BCL) were estimated instead of rate constants (k). Moreover, as already anticipated, at variance with the original works, here we assessed the performance of both a one- and a two-compartment description for glucose and insulin kinetics, to test if the NLME framework favored the identification of the peripheral compartments, which were difficult to identify in [1] and [2]. Below, the differential equations of the model are reported separately for each submodel, where two-compartment kinetics were assumed for the GMM and IMM. Equations for GMM are

$$\begin{cases} \dot{G}_1(t) = -[S_G + k_{G1} + A(t)]G_1(t) + S_G G_b V_{G1} \\ \qquad\qquad +k_{G2}G_2(t) + u_G(t) \\ \dot{G}_2(t) = -k_{G2}G_2(t) + k_{G1}G_1(t) \\ \dot{A}(t) = p_2 S_I[I(t)/V_{I1} - I_b] - p_2 A(t) \end{cases} \tag{1}$$

for the IMM

$$\begin{cases} \dot{I}_1(t) = -(k_{I0} + k_{I1})I_1(t) + k_{I2}I_2(t) + \\ \qquad\qquad m_I X_I(t) + u_I(t) \\ \dot{I}_2(t) = -k_{I2}I_2(t) + k_{I1}(t) \\ \dot{X}_I(t) = -m_I X_I(t) + Y_I(t) \\ \dot{Y}_I(t) = -\alpha_I Y_I(t) + \alpha_I\{\beta_I[G_1(t)/V_{G1} - G_b] \\ \qquad\qquad +k_{0I}I_b\}V_{I1} \end{cases} \tag{2}$$

and for the CMM

$$\begin{cases} \dot{C}_1(t) = -(k_{C0} + k_{C1})C_1(t) + k_{C2}C_2(t) + \\ \qquad\qquad m_C X_C(t) \\ \dot{C}_2(t) = -k_{C2}C_2(t) + k_{C1}(t) \\ \dot{X}_C(t) = -m_C X_C(t) + Y_C(t) \\ \dot{Y}_C(t) = -\alpha_C Y_C(t) + \alpha_C\{\beta_C[G_1(t)/V_{G1} - G_b] \\ \qquad\qquad +k_{0C}I_b\}V_{C1} \end{cases} \tag{3}$$

where $G(t)$, $I(t)$, and $C(t)$ are amounts of glucose, insulin, and C-peptide, respectively. Subscripts G, I, and C stand for glucose, insulin, and C-peptide sub-model, respectively; subscripts 1 and 2 for plasma and peripheral compartments, respectively, and subscript b for basal concentration. Exogenous infusions are represented by $u(t)$. V represents the volume of distribution. S_G is the glucose effectiveness, S_I the insulin sensitivity and p_2 is the rate constant describing the insulin action, $A(t)$. $X(t)$ is the amount of insulin or C-peptide (depending on the subscript) ready to be delivered in the circulation after the hepatic extraction or to be secreted by the beta-cells, respectively. $Y(t)$ is the insulin or C-peptide provision. α, β, and m are the parameters describing post-hepatic insulin delivery and C-peptide secretion. The model is assumed at steady state at time 0, except for $X_I(0) = X_{I0}$ and $X_C(0) = X_{C0}$ that represents insulin and C-peptide delivered right after the glucose injection (the so-called "first-phase insulin secretion"). For a detailed description of the model, we refer to the original works of [1] and [2].

Re-parametrization of transfer rates k was done according to

$$CL_l = k_{l,0} \cdot V_{l,1} \quad \text{and} \quad BCL_l = k_{l,n} \cdot V_{l,n} \tag{4}$$

where CL is the elimination clearance from the central compartment and BCL is the between-compartment clearance. Subscript l indicates the sub-model of glucose (G), insulin (I) or C-peptide (C), and n indicates central (1) or peripheral (2) compartments.

2) Model of the between-subject variability: The stochastic model assumes a log-normal distribution for all model parameters

$$\boldsymbol{\psi}_j = \boldsymbol{\theta}\exp(\boldsymbol{\eta}_j) \tag{5}$$

where $\boldsymbol{\psi}$ is the vector of model parameters for the jth subject, $\boldsymbol{\theta}$ is the vector of population parameters (fixed effects), and $\boldsymbol{\eta}$ is a vector of Gaussian random variables (random effects) with zero mean and covariance matrix Ω, which can be full or not, depending on whether the model does or does not account for correlation among parameters. This description of parameter

RSE = Relative Standard Error.

variability is the most used since it allows a flexible description of parameter distribution with only two degrees of freedom, and it assumes non-negativity of physiological parameters.

3) Residual error model: Residual variability was assumed to be normally distributed with zero mean and standard deviation which is a combination of a constant component and a component proportional to the measured concentrations. The resulting six parameters of the error model (two for each measured concentration) were collected in the vector $\boldsymbol{\epsilon}$ and estimated along with the other model parameters.

C. Model Identification and Validation

During the identification of each model, the vector of population parameters $\boldsymbol{\theta} = [S_G, V_{G1}, V_{G2}, BCL_G, G_b, p_2, S_I, CL_I, V_{I1}, V_{I2}, BCL_I, I_b, m_I, \alpha_I, \beta_I, X_{I0}, CL_C, V_{C1}, V_{C2}, BCL_C, C_b, m_C, \alpha_C, \beta_C, X_{C0}]$, the covariance matrix of the random effects, Ω, and the vector of error parameters $\boldsymbol{\epsilon}$ were all estimated in a one-step procedure.

Model identification was performed in NONMEM [12] using the stochastic approximation of expectation maximization algorithm for parameter estimation, and an importance sampling algorithm to compute the exact maximum likelihood (ML). The best model was selected based on its ability to fit individual profiles, the physiological plausibility of its parameter estimates, and their precision. In particular, the objective function to be minimized was $\text{OF} = -2\ln(\text{ML})$, where a reduction in the OF greater than 3.84 units for each degree of freedom added to the model was considered statistically significant (p-value < 0.05), and therefore worth including in the model. Finally, a visual predictive check (VPC) plot was used to assess the predictive capability of the model visually.

III. RESULTS

The best model assumed that both glucose and insulin kinetics was described by a two-compartment model. Parameters of the structural model were estimated with good precision and lay within physiological ranges, as reported in Table I. Elements of ϵ and Ω were estimated with good precision as well (not reported). Relevant correlations among parameters were $\rho_{I_b,C_b} = 0.74$, $\rho_{m_I,m_C} = 0.65$, $\rho_{\alpha_I,\alpha_C} = 0.95$, $\rho_{\beta_I,\beta_C} = 0.51$, $\rho_{X_{0,I},X_{0,C}} = 0.91$, all related to insulin and C-peptide provision and secretion (as expected, since the two processes are physiologically and strongly related to each other), $\rho_{\beta_I,I_b} = 0.74$, as previously found in [10], and $\rho_{\beta_I,S_I} = -0.59$ as in [13]. The model was able to well fit individual profiles, as shown in Fig. 1, where observations are compared with individual predictions. Finally, the VPC (Fig. 2) showed that the model was able to reproduce both the average trend (95% prediction interval of the 50th percentile, red areas) and the variability (95% prediction interval of the 5th and 95th percentiles, blue areas) of the observed data well.

IV. CONCLUSIONS

In this work, we integrated the widely used GMM, IMM, and CMM in an NLME framework. The resulting model was able to simultaneously fit glucose, insulin, and C-peptide measured in 204 healthy subjects during an IM-IVGTT and provided precise and reliable estimates of insulin sensitivity, glucose effectiveness, and beta-cell function. This was done without resorting to the *forcing function* strategy, avoiding the risk of missing concentration peaks, and likely correctly propagating the uncertainty of measurements on model parameters. It is worth noting that the selected model included peripheral compartments for both glucose and insulin kinetics, which were not easily identifiable in a single-individual identification framework. The model also allowed estimating the kinetics parameters of C-peptide, which are usually fixed to population values [2], [14]. The integrated model provided a complete characterization of the joint parameter distribution of a healthy population. Further studies are needed to assess the possible covariate effects on model parameters and the usability of the model in prediabetic and diabetic populations.

***Abstract*—Multiple myeloma (MM) is a plasma cell neoplasm that is usually treated with chemotherapeutic drugs such as doxorubicin (DOXO). During treatment, drug administration must be optimized according to the patient's needs to reduce the side effects of therapy and increase its efficacy. To support the study of DOXO and treatment optimization, we have recently developed a pharmacokinetics (PK) model of DOXO in MM cells. Here we aim to evaluate the robustness of the PK model by assessing its performance in the context of a population-based approach.**

A series of *in vitro* experiments in MM1R cells treated with DOXO at 200 nM and 450 nM was performed. The measured intracellular DOXO concentrations have been organized to generate three different population datasets: a naive average dataset (NAD), obtained by averaging all cell readings and two datasets obtained by averaging the cell readings within the same experiment well or the same image field, respectively. The PK model has been identified on each population dataset, and the resulting model predictions and estimated parameters were compared across populations.

Model fit was satisfactory in all combinations, and the estimated model parameters were precise and comparable across population datasets. Although slight differences were found between results obtained with NAD and field-population dataset, they were mainly attributable to the expected different intrinsic dataset variability. On the other hand, the population approach based on the within-well cellular data provided almost superimposable results to those obtained with NAD, proving the model's ability to reliably describe DOXO PK in MM cells.

I. INTRODUCTION

Multiple Myeloma (MM) is a malignancy of monoclonal plasma cells in the bone marrow. It has a 126% global incidence increase from 1990 to 2016 and can target several areas of the body. Its risk factors include chronic inflammation, inherited genetic variants, and exposure to radiation or chemicals [1].

MM does not show any evident symptoms in the early stages, which produces a process of diagnosis that is long, complicated, and discouraging for the patients. The most common treatment adopts chemotherapy drugs, with doxorubicin (DOXO) as a well-established treatment in MM, as well as breast cancer. [2], though it has serious side effects. Therefore, treatment with DOXO has to be optimized in terms of dose regimen to maximize drug efficacy and reduce side effects.

In this regard, mathematical modeling of pharmacokinetic (PK) and pharmacodynamic (PD) represents a valid approach to investigating the cellular response to the drug. A preliminary study explored which model could be more suitable to describe DOXO PK in MM cells. Here we aim to assess the robustness of the most promising model by evaluating its performance with a cell population approach that increases the variability in the available data. In particular, we will consider three different possible assumptions that could be made regarding the measurement error of the MM1R cell line data collection.

The paper is structured as follows: Section II describes the data collection, cell population setup, and the compartmental PK model, Section III outlines the model identification setup, Section IV reports the results and Section V provides a discussion about the closing remarks and future research development.

II. METHODS

A. Data collection

The dataset consists of *in vitro* experiments performed on MM1R human cell line (American Type Culture Collection (ATCC), http://www.atcc.org). Cells were cultured with a density of 5 x 10^5 cells/mL in Roswell Park Memorial Institute (RPMI) 1641 medium supplemented with 1% penicillin/streptomycin and 10% fetal bovine serum (FBS). The MM1R cell line is used to study DOXO cellular uptake and release by exploiting its autofluorescence property (i.e., it excites at 470 nm and emits light at 570 nm of wavelength [3]), measured using a fluorescence microscope (Nikon® Eclipse T1-U). The experiment is designed in two different phases. During the first phase (uptake), the cell line is treated with DOXO for 3 hrs at two concentrations, 200 nM or 450 nM. Immediately after DOXO administration at $t = 0$, hr 200 μL containing 10^5 cells are drawn and seeded in duplicate (i.e., 100 μL with 5 x 10^4 cells each) within two μ-Slide VI$^{0.4}$ wells (ibidi GmbH, Gräfelfing). For each well 4/5 images (fields) are then acquired every 20 minutes for 3 hrs at 40x magnitude for both bright-field and fluorescence. At $t = 3$ hrs, coinciding with the uptake end, the remaining cells are centrifuged for extracellular DOXO removal and resuspended in 300 μL of PBS, 20% FBS obtaining a density of 5 x 10^4 cells/100 μL. During this second phase (release), the cells are drawn and seeded in triplicate (i.e., 100 μL with 5 x 10^4 cells each) within three μ-Slide VI$^{0.4}$ wells. Analogously to the uptake phase, 4/5 images/well are then acquired at $t = [3.5, 4, 4.5, 5, 5.5, 6, 7, 8]$ hrs at 40x. Each acquired image is processed by ImageJ software and is related to a different frame of the well. Within every frame, it could be detected

a different amount of independent cells, which are measured to obtain their intracellular fluorescence intensity (*Int*). The latter is then removed of the background signal and mapped to DOXO concentration (*C*) values in nM. The mapping function is estimated empirically by a linear regression model fit to *C-Int* data, produced by serially administering known DOXO concentrations to a μ-Slide VI$^{0.4}$ well.

$$Int = 15.26 \cdot C + 508.66 \tag{1}$$

B. Data preprocessing

In order to remove possible outliers, for each time sample, only 95% of data measurements were maintained, while the remaining 5% was uniformly removed from both tails of data distributions. Moreover, an inconsistent increase in raw intracellular concentration after the end of the uptake phase was observed, likely due to the rewashing of the extracellular environment. Thus, data normalization was proposed to correct all the observations acquired in the release phase:

$$f = \frac{0.5 \cdot \left(\bar{C}_{1,\ t=3} + \bar{C}_{2,\ t=3}\right)}{max\left(\bar{C}_{1,\ t=3.5}, \bar{C}_{2,\ t=3.5}, \bar{C}_{3,\ t=3.5}\right)} \tag{2}$$

$$C_{j,t=i} = f \cdot C_{j,t=i} \tag{3}$$

where $j = 1, \ldots, 3$ and $i = 3, 3.5, \ldots, 8$ represent the well and time sample (hrs), respectively.

C. Datasets design

The data collection opens for considering different datasets containing distinct aggregated data. This feature is exploited for a population approach, i.e., by considering three possible datasets: 1) a naive average dataset (NAD), 2) a second dataset consisting of three well-dependent average data, and 3) a third one consisting of up to fifteen field-dependent average data.

Dataset 1: The first dataset, corresponding to a naive average data (NAD) approach, considers the average C across all detected cells at each time instant t (18 x 1) by considering all wells.

Dataset 2: The second dataset considers each experimental series as independent from the other ones and averages all detected cells at each time instant t within the same experiment. As such, this configuration implies that each time sample accounts for two or three data points, for uptake or release phase, respectively. Each experimental series is related to a different μ-Slide VI$^{0.4}$ well.

Dataset 3: The third dataset considers each acquired field, sorted by order of acquisition, as independent from the other ones and averages all detected cells at each time instant t within the same field.

D. Modeling Doxorubicin PK

Administering DOXO to a cell culture causes cells to absorb it and increase their intracellular concentration following certain kinetics. On the other hand, by removing the DOXO, the cells release the drug if it is not bound to DNA. Such a description has been modeled in breast cancer [4] and very recently in MM [5]. In the latter study, three different models were compared, and the following one resulted in the most suitable to describe DOXO PK in MM1R cells.

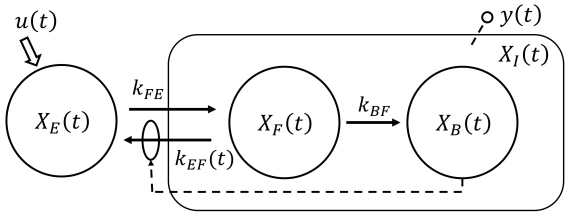

Fig. 1: DOXO PK model scheme

The model, schematized in Fig. 1, is described by three compartmental equations representing DOXO concentration in the extracellular space (X_E), in the cell cytoplasm (X_F) and bound to DNA (X_B):

$$\begin{cases} \dot{X}_E(t) = k_{EF}\frac{V_I}{V_E}X_F(t) - k_{FE}X_E(t) + u(t) \\ \dot{X}_F(t) = k_{FE}\frac{V_E}{V_I}X_E(t) - k_{EF}X_F(t) - k_{BF}X_F(t) \\ \dot{X}_B(t) = k_{BF}X_F(t) \end{cases} \tag{4}$$

where k_{FE}, k_{BF}, k_{EF} (hr^{-1}) are rate parameters describing transit from extracellular space to free intracellular, from free intracellular to bound to DNA, and from free intracellular back to extracellular space. In particular, k_{FE} and k_{BF} are constant and assumed being independent form drug dosage and exposure time, while k_{EF} is modeled with a Hill-like equation of order $q = 2$ dependent on the bounded DOXO concentration:

$$k_{EF} = V_{max}\frac{X_B^{q-1}(t)}{K_{th}^q + X_B^q(t)} \tag{5}$$

where K_{th} (nM) denote the X_B concentration at which $k_{EF}(t)$ is equal to its maximum value $V_{max}/2K_{th}$ and where V_{max} has units (nM/hr). This formula is aimed at implementing a cellular drug resistance mechanism that might be a consequence of DOXO binding to DNA in the cell nucleus, causing an increment in the outflow from the free intracellular towards the extracellular compartment.

Model input $u(t)$ is defined as:

$$u(t) = \begin{cases} D \cdot \delta(t) & if\ t = 0 \\ 0 & otherwise \end{cases} \tag{6}$$

where D denotes the amount of DOXO administered at $t = 0$. The accessible measurement site is represented by the intracellular concentration $X_I(t)$, which is given by the sum of free and bound DOXO concentration:

$$X_I(t) = X_F(t) + X_B(t) \tag{7}$$

III. MODEL IDENTIFICATION

A. A priori identifiability

In the present work, the a priori identifiability of model eq. (4-7) has been assessed by the Differential Algebra for Identifiability of Systems (DAISY) software, a tool developed to check for global identifiability of biological and physiological

systems [6]. It is assumed that the volumes $\{V_E, V_I\}$ are equal to 100 μL and 0.0703 μL.

B. System identification

Model identification is designed to estimate a unique set of model parameters based on the available observations of each one of the aggregated datasets described in section II-C. In our problem, the model of equations (4-7) has been identified on intracellular DOXO concentration X_I. In order to generalize the optimization problem to the dataset dimensions, the available observations are reshaped to be in the form of a column vector and maintaining the temporal order:

$$X_I(t) \qquad X_I(t) = \begin{bmatrix} X_{I,1}(t) \\ X_{I,2}(t) \\ X_{I,ne}(t) \end{bmatrix} \quad X_I(t) = \begin{bmatrix} X_{I,1}(t) \\ \vdots \\ X_{I,nf}(t) \end{bmatrix},$$

where X_I relates to datasets 1,2, and 3, from left to right, respectively, and ne, nf are the total number of experimental series and image fields.

Furthermore, both the observations acquired in 200 nM and 450 nM administered DOXO are merged together in one single vector *y(t)* in order to make the identification dosage-independent:

$$y(t) = X_I(t) = \begin{bmatrix} X_I^{200}(t) \\ X_I^{450}(t) \end{bmatrix} \tag{8}$$

Then, the measurement model is defined as:

$$\hat{y}(t) = \hat{X}_I(t, \theta) + v(t) \tag{9}$$

where $\hat{X}_I(t, \theta)$ represents the model prediction of the total intracellular concentration, function of the parameter vector $\theta = [k_{FE}, V_{max}, K_{th}, k_{BF}]$, and $v(t)$ is the DOXO measurement error, assumed as known and described by sampled standard deviation calculated from each population dataset. The model forcing-function is the DOXO amount (200 nM or 450 nM) administered at $t = 0$ hrs. At $t = 3$ hrs, X_E was forced to zero, in order to simulate DOXO removal and medium replacement occurring at the end of the uptake phase.

Model identification was done by using a Bayesian Maximum a Posteriori (MAP) estimator implemented in MATLAB 2022b (Natick, MA) [7] and solved by using the $lsqnonlin$ function. Specifically, for each population dataset, the optimal set of model parameters is obtained by solving the following problem,

$$\hat{\theta} = \underset{\theta}{argmin} \left[||y - \hat{X}_I(t, \theta)||^2_{\Sigma_v} + (\theta - \mu_\theta)' \Sigma_\theta^{-1} (\theta - \mu_\theta) \right] \tag{10}$$

where $\hat{X}_I$ is repeated according to the dimension of y.

Equation (10) accounts for both the weighted residual sum of squares (WRSS) and the distance from the estimated parameters and their joint prior distribution, i.e., the parameter average vector μ_θ and the covariance matrix Σ_θ. In particular, *a priori* information was considered for V_{max} and K_{th}, based on a previous study [8].

C. Model assessment

Model performance was assessed both graphically, by evaluating model's ability to predict the data, and numerically, in terms of plausibility of estimated model parameters and their precision described by percent coefficient of variation (CV).

The robustness of the model across the datasets was then evaluated by comparing the predicted cellular model compartments (X_I, X_F and X_B) and calculating the percent difference (Δ) between the same *i*-th model parameter estimated from dataset 2 ($p_{i,2}$) or 3 ($p_{i,3}$) and the corresponding one obtained from dataset 1 ($p_{i,1}$):

$$\Delta(p_i) = \frac{p_{i,n} - p_{i,1}}{p_{i,1}} \cdot 100 \ , \quad n = \{2, 3\}. \tag{11}$$

IV. RESULTS

A. Model performance

Figure 2 shows the model fit on MM1R intracellular DOXO concentration data. It is shown that the model predicts DOXO data by distinguishing between free DOXO in the cytoplasm and DNA-bound DOXO (Figure 3). In particular, the model well describes data measured during the experiment with DOXO 200 nM, while it underestimates three data points collected between 40 and 80 min after DOXO 450 nM administration. In this regard, dose dependent model identification was already conducted and not showing any significant improvement (results are not shown) [5].

Table I reports the model parameter estimated from each dataset. For all model identifications, all the model parameters have comparable values across the population datasets and are estimated with good precision, as proved by the low CV. Overall, the identification shows consistency and good reliability between all parameters and population datasets.

	k_{FE} (10^{-4} hr^{-1})	V_{max} (10^5 nM/hr)	K_{th} (10^3 nM)	k_{BF} (hr^{-1})
NAD	7.72 (2.63%)	2.10 (10.5%)	1.44 (4.91%)	1.48 (4.36%)
wells	9.45 (12.3%)	2.30 (12.7%)	1.40 (5.55%)	1.43 (8.63%)
fields	8.54 (14.0%)	2.38 (13.2%)	1.38 (5.86%)	1.33 (12.4%)

TABLE I: Model parameter estimates and their precision (described by coefficient of variation CV between parenthesis) for datasets 1 (NAD), 2 (wells) and 3 (fields).

B. Model robustness

Figure 3 shows the comparison between the model prediction of X_I, X_F and X_B for each population dataset. It can be observed how all the cell model states resulting from model identification on datasets 1 (NAD) and 2 (well population) are almost superimposable, while a different X_I predicted from dataset 3 (field population) is more evident, and mainly attributable to a different X_B. This is reflected by the numerical comparison of estimated model parameters (Table II), which shows that k_{BF} estimated from the field population data is about 10% slower than the respective counterpart

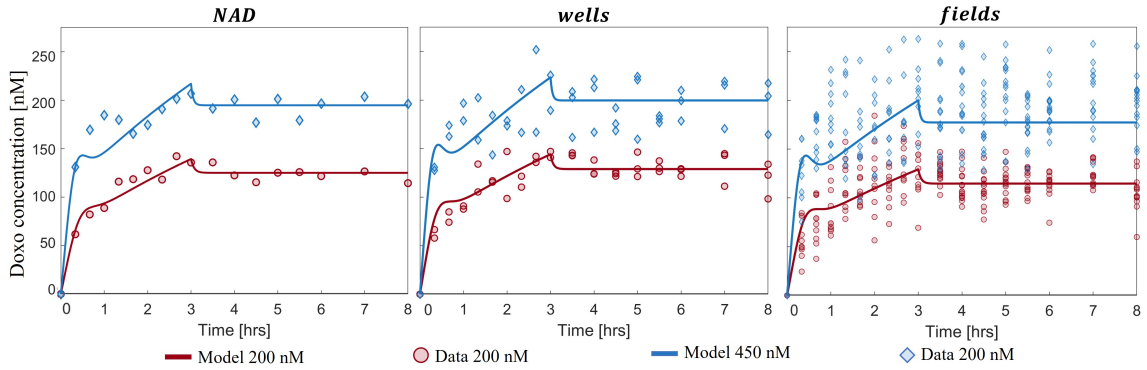

Fig. 2: Model fit on DOXO 200 nM and 450 nM intracellular data for each population dataset: NAD (left), wells (middle), fields (right).

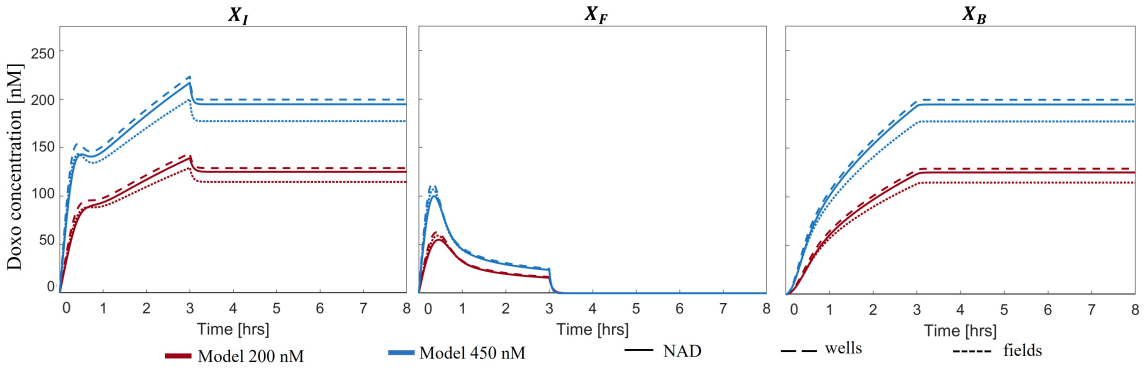

Fig. 3: Predicted model states across population datasets: total intracellular (X_I, left), free (X_F, middle) and DNA-bound (X_B, right).

obtained from NAD. Similarly, about 22% difference results by comparing k_{FE} estimated datasets 1 vs. 2. This translates into a slightly higher peak in X_F around 30 min.

%	$\Delta(k_{FE})$	$\Delta(V_{max})$	$\Delta(K_{th})$	$\Delta(k_{BF})$
wells	22.3	9.52	-2.37	-3.78
fields	10.6	13.1	-3.92	-10.4

TABLE II: Parameters percent difference between population datasets 2 (wells) or 3 (fields) vs. 1 (NAD).

V. CONCLUSION

The DOXO PK model is able to satisfactorily predict drug concentration data, irrespective of the population dataset subject of the analysis, thus strengthening the reliability of its identification in the case of the NAD approach. Some differences between estimated model parameters across population datasets have been found. However, they were expected since the population datasets show different shapes compared to the NAD approach, which substantially averages possible differences. It is worth mentioning that the proposed population approach yields promising results, particularly in the case of the well's population dataset, which intuitively might better represent independent experiments.

Future works will include the analysis of a second set of experiments administering DOXO in a different MM cell line in order to further strengthen the model assessment. In addition, since the estimated Hill function describing the DOXO efflux rate (k_{EF}) is only partially explored by the range of the current DOXO concentrations, it would be interesting to study DOXO PK with higher dosages. Alternatively, further possible models of the DOXO efflux rate could be evaluated.

Numerical simulations of the cerebrospinal flow through the Sylvius aqueduct modeled as a diffuser/nozzle pump

P. Peruzzo[1] and F.M. Susin[1]
[1] *HER Lab, Department of Civil, Environmental and Architectural Engineering, University of Padova, Italy*

***Abstract*—The circulation of the cerebrospinal fluid is rhythmic with a preferential flow direction. In the present study, we performed a series of numerical simulations demonstrating that the shape of the Sylvius aqueduct is functional to this characteristic circulation acting as a diffuser/nozzle pump.**

***Keywords*—Cerebrospinal fluid, Diffuser/nozzle pump, CFD.**

I. Introduction

The cerebrospinal fluid (CSF) is a clear, colorless fluid that is part of the central nervous system (CNS). It belongs to the cerebral extracellular matrix and contains both inorganic and organic substances, including glucose, lactic acid, proteins, urea, sodium, potassium, magnesium, calcium, and lymphocytes [1]. CSF preserves brain functionalities since it damps mechanical stress, compensates for blood volume variations during the heartbeat, guarantees the transport of nutrients, and removes the toxins produced [2].

Precisely, the CSF is actively produced by both plexuses and brain parenchyma. It circulates through the ventricles of the brain (lateral ventricles of each hemisphere, third and fourth ventricles), the subarachnoid space, and the central canal of the spine. Finally, it is reabsorbed into the venous system, with a net volume daily exchanged of about 500 mL. The observed transport of species by the CSF is owing to a rhythmic oscillation of the fluid within the CNS promoted by the pressure variation in the surrounding cerebral cardiovascular circulation [3]. Therefore the resulting flow dynamics are rather complex, and not all the mechanisms that determine the observed net flux are fully understood yet.

Longatti et al. [4] recently argued that the trumpet shape of the Sylvius aqueduct connecting the third and fourth ventricles acts as a diffuser/nozzle pump, promoting a pulsatile flow with a net flow toward the craniocaudal direction. A 1D hydrodynamic model was applied to a simplified geometry of the anatomical district of interest obtained by magnetic resonance images (MRI) of a cohort of 10 volunteers. The analysis showed that the expected flow rate by the modeled diffuser/nozzle pump compared favorably with the flow rate measured within the aqueduct. Nevertheless, the theoretical model proposed by Longatti et al. was based on the mechanical energy conservation principle applied to a quasi-stationary flow through a standard conical diffuser/nozzle, i.e., a geometry fitting not perfectly to the aqueduct. Accordingly, the model was able to capture only the essential interactions among the geometric shape of the complex, the forcing pressure, and the CSF net flow.

In the present work, to have a more reliable picture of the relevance of the anatomy of the Sylvius aqueduct, we analyze numerically the hydrodynamics in the third ventricle-Sylvius aqueduct-fourth ventricle for the cohort of patients schematized in [4].

II. Materials and Methods

A. Numerical model

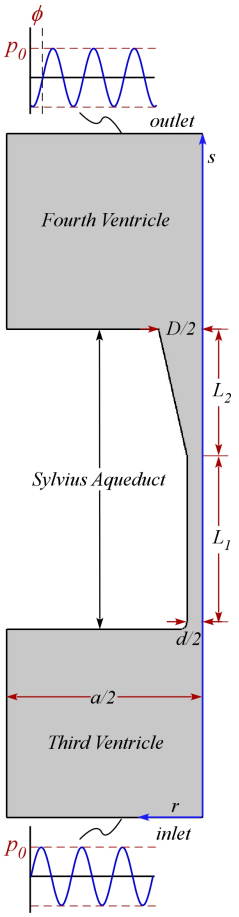

Fig. 1: Sketch of the geometry and boundary conditions of the simulations. s and r are the axial and radial directions, respectively.

TABLE I: The geometrical configurations of the third ventricle-Sylvius aqueduct- fourth ventricle system of the cohort of volunteers in [4]. RC is the reference case of the sample.

Case	d [mm]	D [mm]	L_1 [mm]	L_2 [mm]
1	2.49	5.29	14.86	14.10
2	1.55	4.06	16.53	13.67
3	1.94	5.33	14.89	17.78
4	2.12	5.04	16.88	13.56
5	1.40	4.73	16.37	13.64
6	1.65	3.27	19.20	10.48
7	2.07	3.97	16.83	12.39
8	1.78	4.65	17.85	11.56
9	1.77	3.85	10.50	10.36
10	2.40	6.77	8.22	14.90
RC	1.60	4.50	17.00	13.00

The flow through the Sylvius aqueduct has been computed numerically. The hydrodynamics has been solved in a parametrized 2D axisymmetric domain where two oscillating pressures act on both the inlet and outlet. The numerical model has been built in the CFD module of COMSOL Multiphysics 5.3 (Comsol Inc., Stockholm), which solves the Navier-Stokes equations for an uncompressible Newtonian as the CSF, and assumes laminar flow conditions in the entire domain since the physiological Reynolds number is not larger than some hundreds.

Fig. 1 shows the computational domain consisting of a cylindrical pipe and a conical diffuser in series (both schematizing the Sylvius aqueduct) that connect two cylindrical chambers of diameter a (the ventricles). The cylindrical stretch has a length L_1 and diameter d, whereas the conical portion has a length L_2 and a minimum and maximum diameter equal to d and D, respectively. In both chambers, the diameter was set $a = 10\,D$. The inlet between the third ventricle and the aqueduct was tapered with a fillet, whereas the connection with the outlet chamber (the fourth ventricle) was sharp. Such inlet/outlet geometry should have favored the asymmetrical behavior of the flow in the diffuser/nozzle phases [5].

The domain is discretized with indicatively 30,000 elements and consisted of an unstructured triangular grid in the bulk region and a structured quadrangular grid near the rigid wall.

B. Simulations

Two sinusoidal pressure waves of amplitude $p_0 = 1.0$ mm_{Hg} ($\approx$ 133 Pa) and frequency $f = 1$ Hz phased by ϕ were imposed at the inlet and outlet. The phase between the two pressures results from the delay of the pressure wave propagation along the aqueduct and is equal to $\phi = 2\pi\, f\,(L_1 + L_2)/c$, with $c = 5.0$ m/s the speed of the pressure perturbation [6]. Initially, the system was at rest and reached a steady periodic state in about ten cycles. The results of the last cycle were used in the analysis.

We performed a series of numerical experiments to evaluate the effectiveness of the theoretical solution using the configurations of the Sylvius aqueduct gathered from the magnetic resonance images of the volunteers population in Longatti et al. [4]. The total runs analyzed counts 11 experiments (10 volunteers and one configuration inferred as reference case of the cohort). The geometry details of the studied configurations are summarized in Table I. Fluid properties were constant, and in all tests, we prescribed for the CSF the density and kinematic viscosity equal to ρ=1000 kg/m^3 and ν=1.0$\times$10^{-6} m^2/s, respectively.

III. Results and Discussion

Fig. 2 shows some examples of the flow rate computed during the last cycle of the simulations. The flow rate in Reference Case (RC) shown in Panel a varies from 12.18 (toward the fourth ventricle) to -11.59 mL/min (toward the third ventricle), i.e., within the values of 10÷20 mL/min estimated in other studies [7], [8]. The computed net flow results in $Q_{net} \approx 0.34$ mL/min, equivalent to a daily volume of 483 mL. These results are thus in agreement with the physiological flows and confirm that the shape of the Sylvius aqueduct can facilitate CNS circulation.

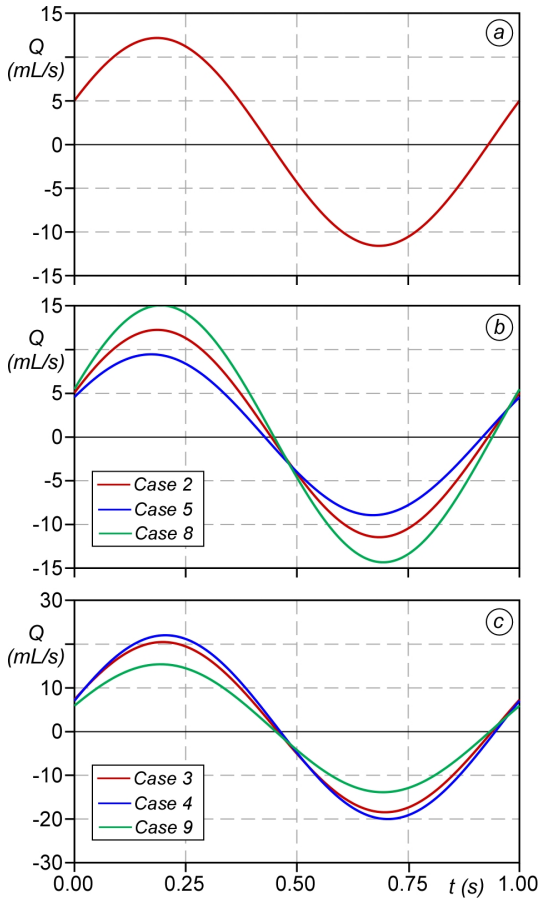

Fig. 2: Time-varying flow rate computed in the Sylvius aqueduct. a) Solution of RC; b) solutions for Cases 2, 5, and 8; and c) solutions for Cases 3, 4, and 9.

The variation of the Aqueduct shape inherently affects the hydrodynamics and the capability of the conduit to convey the CSF, as shown in Panels b and c, where we reported some of the simulations based on aqueduct geometries directly

measured by MRIs. Most cases have the peak flow in the physiological range (9.38÷21.87 mL/min), and, albeit the daily volume turns out to be in some runs overestimated (303÷1322 mL), the results seem coherent with RC. In contrast, two configurations (Cases 1 and 10) exhibit anomalous values of peak flow (31.62 and 36.00 mL/min) and significantly large exchanged volumes (2383 and 3267 mL). However, the presence of these outliers, rather than questioning the role of the Sylvius aqueduct as a pump, highlights the limits of the simplified anatomy used to model the CSF circulation accurately.

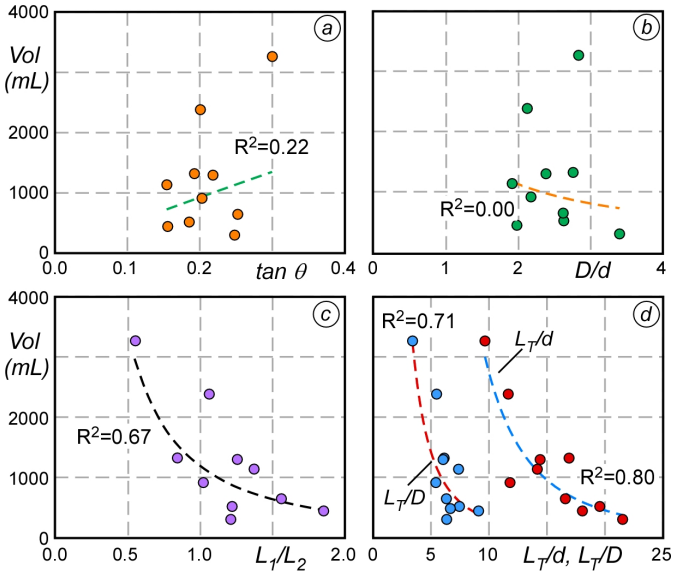

Fig. 3: Dependency of the daily net volume on $a)$ θ, $b)$ D/d, $c)$ L_1/L_2, and $d)$ L_T/d and L_T/D. Dashed lines are the best-fit power law regression of the experiments, and R^2 is the determination coefficient associated.

To get an insight into the relevance of the parameters and hence identify the potential drivers of the flow rate through the Sylvius aqueduct in the investigated population, we analyzed the total daily volume flowing through the system as a function of some non-dimensional quantities. Fig. 3 shows the model response considering the diffuser cone angle, θ, which is defined as $\theta = 2\arctan(D-d)/L_2$, the diameters ratio D/d, the length ratio L_1/L_2, and the tube slenderness L_T/d (or L_T/D), with $L_T = L_1 + L_2$.

Although the standard diffuser/nozzle pump varies its efficiency with θ [9], in the present configuration, the increase of the opening of the diffuser shows only a weak positive effect on the performance ($R^2 = 0.22$, Panel a), whereas is substantially unaffected by D/d ($R^2 = 0.00$, Panel b). This indicates that the diffuser/nozzle element is not *di per se* sufficient to explain the flow in the proposed Sylvius aqueduct schematization. The results reported in Panel c and d confirm this conclusion. Indeed, the cylindrical portion strongly limits the asymmetry of the pumping action, as evidenced by the inverse correlation between the volume and L_1/L_2 ($R^2 = 0.67$, Panel c). A similar trend is also observed in Panel d for the total slenderness of the aqueduct ($R^2 = 0.71$ for L/D and $R^2 = 0.80$ for L/d).

Further analyses, here not reported for brevity, aimed at investigating the role of the phased, ϕ, show that the present results are independent on this parameter (R^2 =0.12).

We can conclude that, in the cohort of investigated patients, the channel length is the primary factor influencing the flow rate since it is directly related to the flow dissipation. In addition, a relatively short straight channel portion facilitates the flow asymmetry that the diffuser/nozzle element promotes. However, the essential geometric modeling of the third ventricle-Sylvius aqueduct-fourth ventricle system adopted in the analysis suggests some caution in the generalization of these results and their direct application to the clinical setting.

IV. Conclusions

In the present work, we proposed a series of numerical simulations of the hydrodynamics through a channel consisting of a cylindrical pipe and a conical diffuser/nozzle element, which mimics the Sylvius aqueduct.

The results showed that $i)$ the trumpet shape of the aqueduct is functional to promote a preferential flow direction from the third ventricle toward the fourth ventricle of the central nervous system, and $ii)$ the key parameters influencing such net flow rate are the channel slenderness and the ratio between the straight and the diffuser/nozzle elements.

An exhaustive frame of the complex flow dynamics in the CSF circulation deserves further analyses based on more realistic models of the apparatus and possibly comparing the results model not only to population- but also to patient-specific flow data. A detailed sensitivity analysis of the model with respect to any single parameter is also required to further corroborate the presented results. This work represents the first step toward the realization of this numerical tool.

Abstract*—Glucagon is a hormone secreted by the pancreatic alpha cells and plays a key role in glucose homeostasis and in the pathophysiology of type 2 diabetes (T2D). Different mechanisms are involved in its regulation, but exact mechanisms are still largely unknown. This study aimed to propose a model describing glucagon inhibition during an oral glucose tolerance test (OGTT), accounting for a double regulation mechanism. The model has been developed starting from a model previously proposed by our group that includes two differential equations, one for plasma glucagon and one for C-peptide (marker of insulin at pancreatic level). In the new model, in addition to plasma C-peptide, plasma glucose is included as model input. The model provides two parameters of possible clinical relevance, namely S_{GLUCA} and k_G (alpha-cell insulin and glucose sensitivity, respectively) and has been validated on mean literature data of healthy subjects and subjects affected by T2D (CNT and T2D, respectively). Model analysis yielded S_{GLUCA} estimates ranging from -0.1515 to 0.7629 and from -5.5602 to 1.1067 (ng of glucagon·nmol of C-peptide^{-1}) in CNT and T2D groups, respectively; according to the 95% confidence intervals (CIs), S_{GLUCA} was significantly different from zero in 4 and in 0 out of 8 time points, in CNT and T2D. Estimates for k_G were equal to 2.8302 (95% CIs: 1.1973 – 4.4632) and 0.9913 (95% CIs: -0.5559 – 2.5386) ng of glucagon·mmol of glucose^{-1}. Thus, results suggest both insulin (represented by C-peptide) and glucose significantly contributes to glucagon inhibition in healthy subjects, but not in T2D. In conclusion, the proposed model may help to describe different mechanisms acting on glucagon inhibition in the single individuals.

I. Introduction

GLUCAGON is a hormone secreted by the alpha cells of the pancreas and it has the effect of elevating blood glucose level when it drops under normal values. Thus, in maintaining the glucose homeostasis glucagon appears to have an opposite action with respect to that of insulin (secreted instead by the beta cells of the pancreas). However, in recent years a more complex role has been ascribed for it beyond simple counterregulation of insulin especially in postprandial conditions [1]. Glucagon has also been given a role in pathophysiology of type 2 diabetes (T2D), but this is still controversial [2]. Indeed, in people with T2D, secretory defects of glucagon exist, resulting in inappropriately high glucagon levels in both fasting and postprandial states; however, also beneficial effects have been observed [3].

Remarkable evidence suggested that the regulation of glucagon secretion is achieved mainly through alpha-cell paracrine control by insulin (the so-called "intra-islet interaction"), but the role of other determinants of glucagon secretion or inhibition is not fully elucidated yet [4]. Especially, glucose may play a not-negligible role. Indeed, previous studies performed considering different macronutrients ingestion in healthy and in T2D subjects demonstrated that glucagon time patterns are highly heterogeneous, and the relationship with glucose and insulin strongly depends on the class of nutrients ingested [5].

Mathematical models may help to gain a deeper knowledge on the mechanisms relating glucagon kinetics to insulin and glucose. To date, a significant number of mathematical models accounting for glucagon contribution have been proposed, but just a few of them was designed to have potential applications to the clinical practice [6]–[12]. Among these models, those referring to glucose challenge tests are particularly suitable for this purpose [6], [7], [12]. In particular, the models by Kelly et al. [6] and Subramanian et al [7] were based on intravenous tests, which however are more difficult to perform compared to an oral glucose tolerance test (OGTT). In fact, our group proposed a mathematical model for the description of glucagon kinetics during an OGTT, providing the opportunity to individually estimate alpha-cell insulin sensitivity [12]. The aim of this study was to formulate an improved version of the previously proposed mathematical model to describe glucagon kinetics (especially, its inhibition) during an OGTT, by accounting for both mechanisms.

II. Materials and methods

A. Model formulation

The proposed model has been designed starting from the formulation previously proposed by our group [12] and considering inhibition of glucagon secretion during an OGTT as controlled by both insulin (C-peptide) and glucose-based mechanisms.

The latter, being the novelty of the present study, accounted for glucokinase activity [13], and were modelled considering glucagon inhibition controlled by the rate of change in plasma glucose. The former, as already done in the previous formulation [12], exploited plasma C-peptide as a marker of insulin secreted by the pancreatic beta cells (being C-peptide secreted equimolarly to insulin but not affected by clearance carried out by the liver).

The compartmental description of the model is depicted in Figure 1.

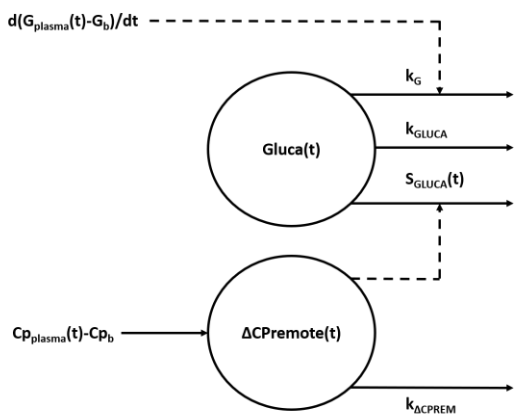

Fig. 1: Schematic representation of the compartmental model. The two compartments of the model are the plasma glucagon compartment, Gluca(t), and a delayed version of remote (from plasma) C-peptide, $\Delta CP_{remote}(t)$; the suprabasal C-peptide concentration in the remote compartment ($Cp_{plasma}(t)$-Cp_b) and the rate of change of suprabasal plasma glucose concentration ($G_{plasma}(t)$-G_b) exert a control action on Gluca(t) through the parameters $S_{GLUCA}(t)$ and k_G, respectively. k_{GLUCA} denotes glucagon elimination rate from plasma and $k_{\Delta CPREM}$ is the C-peptide elimination rate from the remote compartment.

The model is represented by two compartments, one for plasma glucagon and one for remote (from plasma) C-peptide, described by the following two differential equations:

$$\frac{dGluca(t)}{dt} = -k_{GLUCA}(t) \cdot Gluca(t) - k_G \cdot \frac{dG_{plasma}(t)}{dt} - S_{GLUCA}(t) \cdot \frac{d\Delta CP_{remote}(t)}{dt} \qquad Gluca(t) = Gluca_b \tag{1}$$

$$\frac{d\Delta CP_{remote}(t)}{dt} = -k_{\Delta CPREM} \cdot \Delta CP_{remote}(t) + \left(CP_{plasma}(t) - CP_b\right) \qquad \Delta CP_{remote}(0) = 0 \tag{2}$$

where Gluca(t) ($ng \cdot L^{-1}$) and $\Delta CP_{remote}(t)$ ($nmol \cdot L^{-1}$) represents the glucagon concentration in the plasma compartment and the suprabasal C-peptide concentration in a compartment remote from plasma, respectively. The first term on the right-hand side of Eq. (1) accounts for glucagon elimination from plasma due to clearance, through the clearance-rate parameter k_{GLUCA} (min^{-1}); the second term accounts for glucagon inhibition due to mechanisms controlled by the rate of change in plasma glucose (G_{plasma}, $mmol \cdot L^{-1}$) through the parameter k_G, representing the glucagon-inhibition sensitivity to glucose (*i.e.*, alpha-cell glucose sensitivity); eventually the third term accounts for glucagon inhibition due to paracrine mechanisms controlled by suprabasal C-peptide in a compartment remote from plasma through the time-varying parameter $S_{GLUCA}(t)$ (ng of glucagon·nmol of C-$peptide^{-1}$) representing glucagon-inhibition sensitivity to glucose-induced insulin secretion (*i.e.*, alpha-cell insulin sensitivity). Parameter $k_{\Delta CPREM}$ (min^{-1}) in Eq. (2) represents the C-peptide elimination rate from the remote compartment; CP_{plasma} represents plasma C-peptide concentration (CP_b being its basal value). G_{plasma} e CP_{plasma} are the model inputs.

B. Model implementation

The model has been implemented using Simulink and the parameter estimation procedure was set up on Matlab® R2022b. Values for the unknown model parameter vector $p=[k_{GLUCA}, k_{\Delta CPREM}, k_G, S_{GLUCA}(t)]$ have been estimated using the lsqnonlin function, providing a solution for the following nonlinear least-squares curve fitting problem:

$$\min_p \|f(p)\|_2^2 = \min_p \left[\text{RSS} + k_{GLUCA} + \frac{1}{k_G} + w1 \cdot S''_{GLUCA}(t) + w2 \cdot \text{count}(S_{GLUCA}(t) < 0)\right] \tag{3}$$

where RSS is the residual sum of squares, with residuals being the differences between model response and glucagon experimental measurements, and the other terms are added constraints that have been used to introduce further information to the problem. k_{GLUCA} denotes glucagon clearance and it should be small during an OGTT, during which the main contribution to glucagon suppression is given by insulin and glucose-based mechanisms. The term $1/k_G$ is included in equation (3) to prevent excessively small parameter values. $S_{GLUCA}''(t)$ is the second derivative of the parameter $S_{GLUCA}(t)$, and it is used to discourage abrupt changes of the parameter during the test. Similarly, including count($S_{GLUCA}(t)<0$) term allows limiting the number of samples where the parameter assumes negative values. Value for w1 and w2 weights has been manually adjusted. Using the lsqnonlin function, the trust-region-reflective algorithm has been selected, and the function and step-size tolerances have been set to 10^{-6}. Lower and upper bounds of parameter ranges have been set as follows: (0,1) for k_{GLUCA} and $k_{\Delta CPREM}$; ($-\infty$, $+\infty$) for k_G and $S_{GLUCA}(t)$; 95% confidence intervals (CIs) for all the model parameter estimates have been computed by using the nlparci function.

C. Model validation on reported mean experimental data

Mean experimental data used to validate the model are those reported in a recent study by Sonne et al. [14] involving 15 subjects having T2D and 15 healthy control subjects (CNT). All subjects underwent a 75 g OGTT, and blood samples were drawn 20, 10 and 0 min before and 15, 30, 45, 60, 90, 120, 180 and 240 min after glucose ingestion. The glucagon assay was directed against the C-terminal of the glucagon molecule and, thus, measures glucagon of pancreatic origin. In the present study, mean plasma glucose, C-peptide and glucagon concentrations in the two groups of the study by Sonne et al. [14] have been considered. Results are expressed as means±S.D. unless otherwise stated.

III. RESULTS

The best fit on mean experimental data reported by Sonne et al. [14] for CNT and T2D groups are shown in Figure 2, and the parameter estimates with related confidence intervals are reported in Table I. Trends of $S_{GLUCA}(t)$ for CNT and T2D during the whole OGTT is reported in Figure 3. According to the 95% CIs, estimates of $S_{GLUCA}(t)$ was significantly different from zero in 4 out of 8 time points in the CNT group, whereas in the T2D group $S_{GLUCA}(t)$ did not showed values significantly different from 0 throughout the whole OGTT. As regards k_G, lower values were found in T2D with respect to CNT; in the former value was not significantly different from 0, whereas in the latter a significant difference from 0 was found.

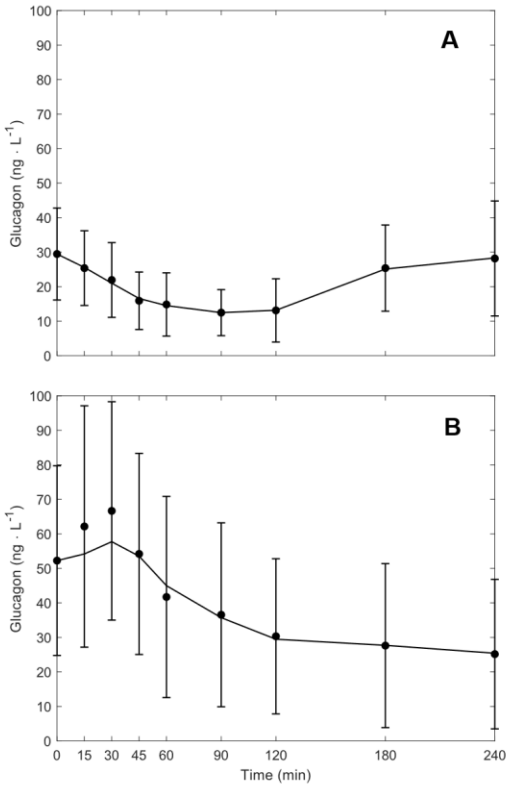

Fig. 2: Best fit of the model validated on mean experimental data by Sonne et al for the control group (panel A) and for the T2D group (panel B). Closed circles are the reference experimental values (mean ± SD); the continuous line is the model prediction.

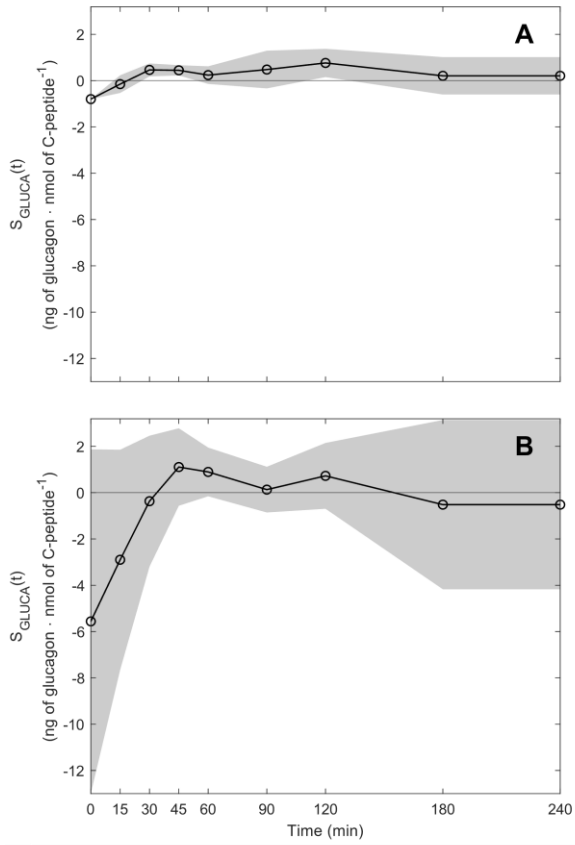

Fig. 3: $S_{GLUCA}(t)$ temporal estimates on reference mean experimental data for the control group (panel A) and for the T2D group (panel B) are shown with open circles and continuous line. Dashed lines represent related 95% CIs.

IV. DISCUSSION

This study proposed a mathematical model able to describe sensitivity of the alpha cell to insulin and glucose in the single individual during an OGTT. The new model has been derived from a former formulation proposed by our group [12]. Such former model was designed to account for paracrine mechanisms that lead to glucagon secretion/inhibition, and in particular it accounts for the control exerted by neighbouring beta cells secreting insulin according to the hypothesis called "intra-islet interaction". Thus, the main improvement of this new model formulation, was to include the contribution of mechanisms related to alpha-cell glucose sensing, under the consideration that the relationship linking glucagon to glucose and insulin is highly heterogenous and a model including different contributors of glucagon secretion may be important in capturing and elucidating such a high heterogeneity. Moreover, this may be of impact in understanding how

mechanisms and postprandial response change in relation to T2D state and/or to different macronutrients ingestion. Indeed, paracrine control of glucagon secretion is compromised in T2D state [15], resulting in a V-shaped non-physiological dose response to glucose with maximal exocytosis at hyperglycaemia.

Results of model validation on mean data of healthy and T2D subjects demonstrated that the proposed model provides results that are consistent with physiological and clinical observations. Indeed, both insulin and glucose-based mechanisms may play a remarkable role in determining glucagon secretion or inhibition (and thus, glucagon time course), as demonstrated by k_G and $S_{GLUCA}(t)$ values significantly different from zero in the healthy group. In contrast, in the T2D group, both glucagon regulation controls are impaired (S_{GLUCA} (t) and k_G not significantly different from zero), resulting in a defective glucagon inhibition.

Similarly to the previous model formulation, the new one was conceived to allow individual estimation of all model parameters and thus, it was maintained as simple as possible. No additional compartment was added to account for glucose contribution, which was represented as an input to the model. In more detail, the glucose regulation mechanism was modelled as dependent on glucose-concentration rate of change rather than the absolute value, consistently with results of studies on animal models showing that in the alpha cell the regulation of glucose sensing is operated by glucokinase [13], whose activity is driven by changes in plasma glucose [16].

Considering the postulated model structure, the addition of penalties in the form of constraints in the parameter estimation procedure was necessary to overcome the problem of ill-posedness and prevent overfitting. In particular, constraints on $S_{GLUCA}(t)$ were already included in the former model formulation with the aim of preventing excessively rapid variations and favouring the occurrence of positive rather than negative values (considering that suppression during OGTT is more likely than stimulation). In this new study, one further constraint has been added, related to k_G, to avoid the contribution of the glucose-based mechanism being excessively small, and possibly collapsing into other parameters. In addition, k_G was allowed to assume positive and negative values, indicating that, in principle, glucose may either inhibit or stimulate glucagon secretion.

Several others factors have been shown to possibly modulate glucagon secretion from alpha cells, including nutritional as well as chemical and ambient factors [17], [18]. As a fact, there are aspects of glucagon contribution to glucose homeostasis that still need clarification. Future models may consider the role of these other factors that, as for its intended purpose, the present model has disregarded.

V. Conclusion

In conclusion, the proposed model allows estimation of alpha-cell sensitivity to insulin and glucose in the single individual, and thus it may help to characterize distinct mechanisms acting on glucagon inhibition on different individuals and conditions.

***Abstract*—Aggressive forms of dementia like Alzheimer's disease (AD) are known to cause deep structural alterations in the brain of affected subjects. The state of these alterations is nowadays deduced from invasive and/or expensive imaging techniques such as Magnetic Resonance Imaging and Positron Emission Tomography. Herein, we present a novel biophysically-inspired multi-scale cortical network model of disease progression enabling the reconstruction of AD-related structural alterations from resting state electroencephalography (EEG). The model, based on the The Virtual Brain platform, reproduced EEG features (power spectral alterations and changes in functional connectivity) of subjects in prodromic states of AD, i.e., subjective cognitive decline (SCD) and mild cognitive impairment (MCI). In particular, the model accounts for the counter-intuitive finding that subjects with SCD display a stronger functional connectivity than both MCI subjects and healthy controls. This model paves the way for an EEG-based reconstruction of patient-specific structural alterations.**

I. INTRODUCTION

The diagnosis of Alzheimer's disease is an extremely difficult task. The only certain diagnostic method nowadays known is the autoptic exam [1], nonetheless, there are many imaging techniques that can determine the presence and even the severity of the disease in the human brain such as MRI, PET, and extraction of cerebrospinal fluid (CSF). However, these techniques are either very demanding for the dispensing facility, or stressful for the patient receiving it, or both. The evident drawbacks of such imaging techniques cause the clinicians to usually prescribe these tests when there are already evident signs of the disease. Moreover, in the last years, great attention has been paid to pre-AD states such as mild cognitive impairment [2] (MCI), and in cognitive complaints in people without evident symptoms of dementia, a condition called subjective cognitive decline [3] (SCD). People falling in these categories show a high probability of transition to AD [3], and would benefit the most from an early diagnosis of the disease, but are often excluded from imaging techniques with high discriminating power, for the reasons beforehand stated. On the other hand, EEG is a fast and cheap screening exam, that has been used reliably as a diagnostic tools for diseases such as epilepsy and stroke. EEG recordings in the resting state have also been used to discriminate AD patients from healthy subjects [4], and there are known EEG biomarkers of AD, mostly related to the spectral content and the functional connectivity (FC) computed from the recorded signals. However, when it comes to AD diagnosis, EEG is a far inferior tool when compared to more invasive and demanding tests such as MRI [5]. In the past years, along with standard imaging techniques, several computational tools have seen widespread use in modelling both physiological and pathological conditions. Many computational models have been able to capture salient features of AD such as the spreading of the disease in the human cortex and the alteration of brain waves [6], but there is no model nowadays able to describe local and global alterations of Alzheimer's in a biophysically realistic fashion. We here propose a hybrid clinical and computational pipeline, in which a multi-scale network model of disease progression - implemented in the The Virtual Brain software [7] - is used alongside experimentally recorded resting state EEG signals to determine the state of AD-related structural alterations. This constitutes the first example of a personalized, computational model of disease progression that doesn't rely on structural data (e.g. MRI or PET scans) to obtain a high fidelity to experimental recordings while also providing viable explanations for the experimentally observed alterations.

II. METHODS

A. Subjects recruiting and diagnosis

We collected EEG signals from 30 subjects sitting in a chair with eyes closed in a comfortable position for 30 minutes. The recorded signals were preprocessed according to the PREP pipeline [8] with subsequent ICA analysis in order to remove artifacts from the signals. The subjects were divided into three groups, healthy control group (HC, n = 9), SCD (n = 9) and MCI (n = 12) subjects. The assignment of subjects to these groups was based on extensive neurophysiological

assessments of cognitive performance and complaints of the subjects, along with an analysis of peripheral blood samples, to determine the presence of molecular hallmarks of the disease such Apolipoptrotein E and BDNF gentoypes.

B. EEG features

We then performed a quantitative analysis on the recorded signals, to assess the presence of significant difference between the EEG recordings of the three groups. We analyzed power spectral density (PSD) and functional connectivity between electrodes. We computed the average PSD for each group, comparing the results to assess the presence of significant differences between groups. PSD was computed with Welch method with Hanning windowing. We analyzed FC by computing the average FC matrices for each group, that we then thresholded and binarized to assess the differences in the number of significant functional connections between groups. FC was computed in all frequency bands except for gamma, whose values are too small to be used to deduce functional connections between electrodes. We also computed the time-domain FC, as envelope correlation between electrodes. We used one-way ANOVA f-test as statistical test to assess differences between groups.

C. Personalized network model of dementia progression

We developed a multi-scale cortical network model by using the TVB platform. This model is able to describe the electrophysiological activity of n=76 cortical regions by means of a network of neural masses. Connections between these masses are determined by a structural connectivity matrix that assigns to each pair of regions i and j a connective weight $C_{i,j}$; this matrix is a mathematical representation of the human connectome [9]. The masses capture in a mean-filed approximation the extracellular voltage fluctuations due to neuronal activity. We utilized the Jansen-Rit model [10] to describe the activity of each mass. The Jansen-Rit is a neural mass model that depicts every cortical region as a sum of three neuronal subpopulations (pyramidal and stellate cells along with inhibitory interneurons); we chose this model because it produces waves with the same spectral and dynamical features of the resting state EEG [10]. Parameters of the model are reported in Table 1. We then implemented AD-related circuital anomalies by changing the parameters of our model in both the meso (neural mass model) and macro (structural connectivity) scale. We altered the characteristic times of inhibitory and excitatory synapses [11] in the neural mass model, and the connective weights in the structural connectivity matrix, to introduce known AD-related alterations such as excitatory/inhibitory imbalance [11], hyperexcitation [12], white matter atrophy [13]. We also considered neuroplasticity [14] when altering the $C_{i,j}$ of the structural connectivity matrix. These alterations were introduced in the regions that are usually initially affected by the disease, according to the well-known Braak staging [15]. We condensed the meso-scale alterations of the neural mass models in a single local parameter lp, and the structural macro-scale alterations of the connectome in a connectivity parameter cp. Both parameters range from 0 to 1, with their value increasing with the severity of the condition.

TABLE I: Model Parameters

Parameter	*Description*	*Value*
A	Maximum Excitatory post-synaptic potential	3.25 mV
B	Maximum Inhibitory post-synaptic potential	22.0 mV
τ_e	**Excitatory time constant**	10 ms
τ_i	**Inhibitory time constant**	20 ms
v_0	Voltage threshold for which a 50 % firing rate is achieved	6.0 mV
ν_{max}	Maximum firing rate of neural population	0.0025 s^{-1}
r	Steepness of sigmoidal transfer function	0.56 mV^{-1}
C_1	Average probability of synaptic contacts in the feedback excitatory loop	1.0
C_2	Average probability of synaptic contacts in the slow feedback excitatory loop	0.8
C_3	Average probability of synaptic contacts in the feedback inhibitory loop	0.25
C_4	Average probability of synaptic contacts in the slow feedback inhibitory loop	0.25
η	Mean input noise	0.22 s^{-1}

We simulated brain waves with this model for various combinations of the parameters describing the disease progression, and we computed PSD and FC from these simulated signals with the same methods discussed in the previous subsection. We then compared the PSD and FC obtained from simulated signals with those computed from experimental EEG recordings, looking for the combination of lp and cp that best fitted the value of both quantities. We thus obtained three combinations of parameters that describe the structural alterations operated by the disease, one per group. These combinations should describe the average level of synaptic and connectomic degeneration for each group.

III. RESULTS

The PSD displayed significant differences between groups in the alpha (f = 6.87, p = 0.011) and theta (p = 4.88, p = 0.37) bands. In both delta and theta bands, average spectral power was higher for MCI subjects than for SCD, and for SCD than HC. A precise ordering is also present in the alpha band, where power is higher in HC than in SCD subjects, and in SCD than in MCI ones, see Figure 1a.

A non-linearity in the number of significant connections emerged from FC analysis (Figure 1b-c). In particular, we found that the HC group had an average of 26.4 % of significant connections, while the SCD group had 28.3 % and the MCI had 23.5 %. Overall, these findings are coherent with the known literature on AD biomarkers in EEG [4]

The quantitative analysis of EEG allowed us to fit the model parameters to describe both the spectral and FC features computed from experimental signals. We found three combinations of parameters, one per group, whose ordering is consistent with the severity of the diagnosed condition. In particular, we

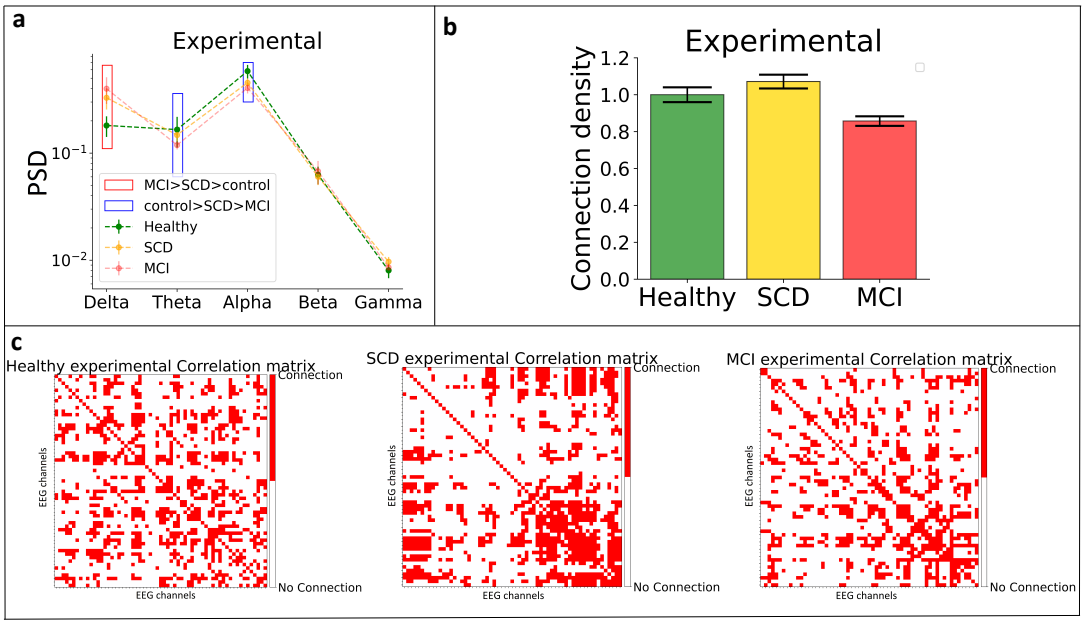

Fig. 1: FC and PSD features computed from experimental recordings: **a**: Band-wise PSD for each group. (* = p < 0.05) **b**: Barplot of the average FC density for each group **c**: Average thresholded FC matrix for each group

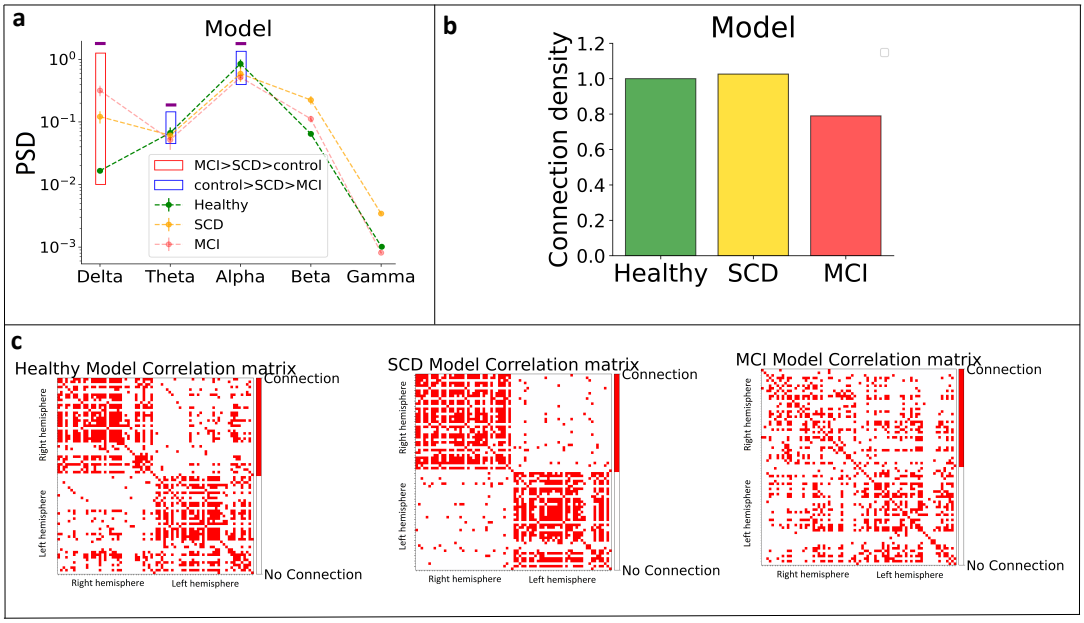

Fig. 2: FC and PSD features computed from simulated signals: **a**: Band-wise PSD for each group. (* = p < 0.05) **b**: Barplot of the average FC density for each group **c**: Average thresholded FC matrix for each group

found, for HC: lp = 0.52, cp = 0.24; for SCD: lp = 0.64, cp = 0.46; for MCI: lp = 0.74, cp = 0.90.

These combinations of model parameters were able to reproduce the ordering of PSD observed in experimental recordings in delta, theta and alpha bands, although difference were significant in the theta band only (f = 3.82, p = 0.04 in the theta band, f = 3.38, p = 0.063 in delta and f = 1.69, p = 0.22 in alpha, see Figure 2a). We reproduced also the non-linearity of FC values (24.0 % relevant functional connections in the modeled HC network, 24.8 % in the SCD, and 19.1 %

in the MCI one, Figure 2b-c). Furthermore, the model allows us to propose an explanation for the non-linearity observed in the FC. In fact, we found a quantity of the network, computed from the structural connectivity matrix, to also display a non-linear evolution during disease progression (Figure 3a) highly similar to that of FC connections. This quantity, called the Randic index [16] that is linked with network assortativity and the rich-club phenomenon [9], by bridging between the state of structural and functional connections, could explain why we observed a transient FC increase. Interestingly, in fact, when we computed the evolution of the Randic index in a network where all the dementia-related structural alterations were present, but with no neuroplastic effects, we found the Randic to evolve monotonously (Figure 3b). This would suggest that neuroplastic adjustments could explain the experimentally observed FC-nonlinearity.

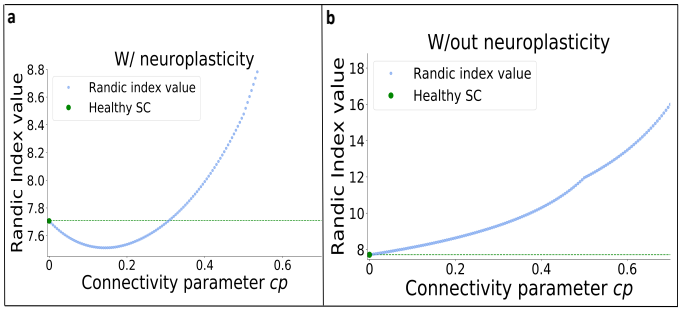

Fig. 3: **a**: Randic index evolution according to *cp* in the model with neuroplastic adjustments **b**:Randic index evolution according to *cp* in the model with no neuroplastic adjustments

IV. CONCLUSIONS

We presented a novel model of local synaptic degradation and global connectivity alterations due to the progression of cognitive decline. The model was validated comparing simulated neurophysiological features to EEG recorded in patients in healthy, SCD and MCI condition, and highlighted the mechanisms underlying non-monotonous evolution of functional connectivity. We plan to apply this approach to develop a personalized model of structural alterations underlying cognitive decline.

Noise-Induced Dynamics and Stochastic Slow Manifolds in the Bistable Xiong-Ferrell Model

M. Martin[1] and M.G. Pedersen[1]
[1] *University of Padova, Department of Information Engineering*

***Abstract* — In biology many phenomena involve noise and multiple time scales. Noise may be constructive and induce dynamics not seen in the deterministic version of the system of interest. The aim of this work is to give an explanation to the noise-induce dynamics observed in a polynomial simplification of the Xiong-Ferrell model as the noise variance (γ) and stimulation intensity (S) are changed. To understand this behaviour, the Stochastic Differential Equation (SDE) system is analysed with the use of a slow manifold statistical description and converted into an Ordinary Differential Equation (ODE) system via the G method, to investigate the location of saddle-node bifurcations in the (S, γ) plane. Our results explain why, due to and depending on the delocalization of these latter bifurcations, the system might present fluctuations around a stable equilibrium or exhibit noise-induced transitions and oscillations.**

***Keywords* — Modelling, Stochastic Dynamics, Bistability, Slow-fast dynamics, Bifurcation**

I. Introduction

Noise influences biological processes at all scales. In cellular systems, noise reduces the duration of beta cell's burst [8] and alters the behaviour of single neurons and neuronal network [3], [4] and [9]. In genetics, noise is an intrinsic property of the system due to the low copy number in genetic networks [10], [11]. Noise-induced phenomena that cannot be explained with the features of the corresponding deterministic model are known as noise-induced effects [6].

In dynamical systems theory, qualitative changes of the model's behaviour when varying parameters are known as bifurcations. For deterministic models, bifurcations occur in general for discrete values of some parameter. On the other hand, in stochastic models, bifurcations can occur smoothly in a parameter range, and moreover may be classified as phenomenological or dynamical [7], where the former are linked to changes in the stationary probability distribution.

The main aim of this work consists in analysing a simplified formulation of the Xiong-Ferrell model [1] under the perturbation by coloured noise. This model was developed to explain how positive feedback loops in complex gene networks may irreversibly alter biological functions, as experimentally observed in the p42 MAPK/Cdc2 system during Xenopus oocytes maturation. The analysis will be done via the extended Rodriguez and Tuckwell approximation [4] known as the G method [3], which shares the same rationale presented in [12]. The motivation behind this approach is to simplify the analysis of the stochastic system to a set of ODEs that describe the evolution of the averages, variances and covariances of the stochastic variables. This approach assumes that variables are normally distributed, which turns the approximation into an exact computation for polynomial models [3], [4].

The remainder of the paper is divided into three sections. In the first, model and methodologies are introduced. The second section outlines the main results by focusing on the stochastic slow manifold and, finally, conclusions are presented.

II. Methods

A. Reference Model and Simplification

In the present work the reference model, which was initially proposed in [1], is

$$\frac{dA}{dt} = S + f\frac{A^n}{A^n + K^n} - k_i A = S + G(A),$$

where A is the protein expressed concentration, S the external applied stimulus, f the positive feedback strength and k_i the degradation rate.

To apply the G method without introducing truncation errors, we approximate the cubic-shaped function $G(A)$ with a third-order polynomial $P(A)$ via a least-square procedure. The obtained estimates are reported in Table I. The considered deterministic model is therefore

$$\frac{dA}{dt} = S + p_3A^3 + p_2A^2 + p_1A + p_0 = S + P(A).$$

To understand the role of the noise, the external stimulus S is perturbed by coloured noise modelled via an Ornstein Uhlenbeck random process (OU process), leading to the following SDE system,

$$\frac{dA}{dt} = S + y_t + P(A),$$
$$dy_t = -\frac{1}{\tau}y_t dt + \frac{\gamma}{\tau}dW_t.$$

Here, dW_t is a white noise term with mutually uncorrelated samples and null expected value. Hence, y_t is an OU process, which acts on the stimulus applied to the model. The statistical properties of the OU process are:

$$\mathbb{E}[y_t] = y_0 e^{-\frac{t}{\tau}},$$
$$\mathbb{E}[(y_t - \mathbb{E}[y_t])^2] = \frac{\gamma^2}{2\tau}\left(1 - e^{-\frac{2t}{\tau}}\right). \quad (1)$$

Therefore, the parameters γ and τ act on the variance and on the convergence time. For sake of simplicity, in all simulations, the Initial Condition (IC) for y_t was $y_0 = 0$ yielding $\mathbb{E}[y_t] = 0$.

The parameters chosen for the reference model and the ones derived for the simplified version are reported in Table I, where p_3, p_2, p_1 and p_0 have no direct physiological meaning. The parameters S and γ are varied to understand how they influence the model dynamics.

TABLE I: MODEL PARAMETERS

f	K	n	k_i	τ
0.5	0.5	5	0.8	500
p_3	p_2	p_1	p_0	τ
-8.206	11.799	-5.189	0.514	500

B. Numerics

Computations were done with XPPAUT [2], and Matlab [5] was used for data post processing steps and visualisations. The SDE system was solved with a forward Euler method with time step equal to 0.01 time units. The ODE system was solved with an adaptive step-size, fourth order Runge-Kutta method.

C. Stochastic Analysis via G Method

Consider the SDE system with the polynomial approximation. We wish to evaluate and analyse how variations of γ and S change the model dynamics. The system is reduced to a set of ODEs using the approximations introduced by Rodriguez and Tuckwell [4] and its further development known as the G method [3]. To apply this latter, we assume that the dynamical variables are normally distributed. This assumption is perfectly satisfied for the variable y_t thanks to the statistical steady-state properties of the OU process. By applying the G method, the following ODE model can be derived,

$$\frac{d\mu_A}{dt} = S + p_3\mu_A^3 + p_2\mu_A^2 + (p_1 + 3p_3\sigma_A)\mu_A + (p_0 + p_2\sigma_A),$$

$$\frac{d\sigma_A}{dt} = 2\Sigma_{AY} + 2[3p_3\mu_A^2 + 2p_2\mu_A + p_1]\sigma_A + 6p_3\sigma_A^2,$$

$$\frac{d\Sigma_{AY}}{dt} = \frac{\gamma^2}{2\tau} + \left[3p_3\mu_A^2 + 2p_2\mu_A + p_1 + 3p_3\sigma_A - \frac{1}{\tau}\right]\Sigma_{AY}.$$

Here, the terms μ_A and σ_A represent, respectively, the mean and variance of A, whereas Σ_{AY} denotes the covariance between the protein concentration and the OU process. In the ODE system above, the mean and variance of the OU process are assumed to be in steady state, $\mathbb{E}[y_t] = 0$, $\mathbb{E}[y_t^2] = \gamma^2/2\tau$. These ODEs are analysed to infer the behaviour of the SDE system.

To illustrate how these equations are obtained, we present the derivation of the first equation. We have

$$\frac{d\mu_A}{dt} = \mathbb{E}\left[\frac{dA}{dt}\right] = S + \mathbb{E}[y_t] + \mathbb{E}[P(A)] = S + \mathbb{E}[P(A)],$$

where the right-hand-side can be computed by applying a Taylor series expansion around the mean, μ_A, of $P(A)$ and then the relationship is reduced by exploiting properties of higher order moments of the normal distribution. The Taylor expansion is

$$\mathbb{E}\left[P(A)|_{A=\mu_A}\right] = P(\mu_A) + \sum_{k=1}^{\infty}\frac{1}{k!}P^{(k)}(\mu_A)\mathbb{E}[(A-\mu_A)^k].$$

The derivatives of order higher than the degree of $P(A)$, as well as odd order moments, vanish. Therefore,

$$\mathbb{E}\left[P(A)|_{A=\mu_A}\right] = P(\mu_A) + 3p_3\mu_A\sigma_A + p_2\sigma_A.$$

We will denote this expression by $\mathcal{F}(\mu_A, \sigma_A)$.

III. RESULTS

A. Simulations

Depending on the values of the parameters S and γ, the system exhibits different kinds of behaviour. These resemble fluctuations around a stable equilibrium point (Figure 1a), simple transitions (Figure 1b), or oscillations (Figure 1c).

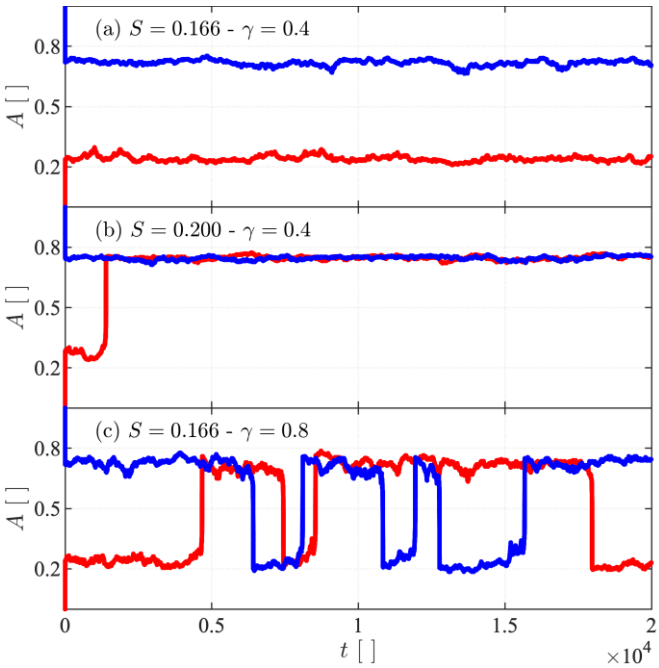

Fig. 1: Simulations of the stochastic polynomial model with parameters as in Table I and as specified. The red and blue traces indicate, respectively, simulations with $A(0) = 0$ and $A(0) = 1$.

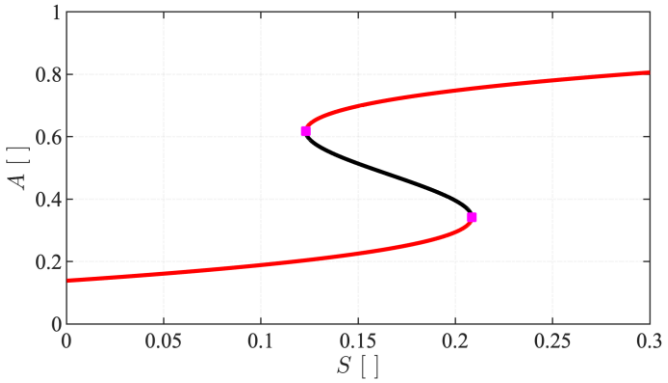

Fig. 2: Polynomial Xiong-Ferrell model bifurcation diagram. Two saddle node bifurcations are highlighted by the magenta squares. The right and left knees coordinates are respectively (0.123, 0.617) and (0.208, 0.342). The red and black branches indicate stable and unstable equilibrium points, respectively.

B. Deterministic Analyses

The bifurcation diagram associated to the deterministic polynomial model is shown in Figure 2. The model presents bistability for a range of the externally applied stimulus S. Therefore, for S in this interval the deterministic model evolves towards the upper or lower equilibrium point depending on the IC. The interval is limited by the values of S where the unstable and stable equilibria meet in saddle-node bifurcations. For values of S outside the bistable interval the trajectory evolves towards the unique stable equilibrium point admitted by the system. The s-shaped curve describing the equilibria can be found in closed form directly from the model's definition,

$$S = -p_3A^3 - p_2A^2 - p_1A - p_0 = -P(A).$$

C. Stochastic Analyses

1) Multiple Time Scale Interpretation

Consider now the SDE system and notice that the two variables evolve on different time scales. In fact, denoting the inverse of τ by ε, the system can be rewritten as

$$\frac{dA}{dt} = S + y_t + P(A),$$
$$dy_t = \epsilon[-y_t dt + \gamma dW_t].$$

Here, $\epsilon = 0.002 \ll 1$. Consequently, the variable y_t can be classified as slow while A as fast. This fact allows us to interpret the stochastic model as a multiple time-scale dynamical system.

The critical manifold $\mathcal{C}_0$ is obtained by setting $dA/dt = 0$ for $\epsilon = 0$. In this case, y_t can be treated as a parameter, which shifts the deterministic bifurcation diagram horizontally. Indeed, on average (over y_t) $\mathcal{C}_0$ coincides with the deterministic equilibrium curve. Moreover, its division into repelling and attracting submanifolds coincides with the stable and unstable branches shown in Figure 2.

This slow-fast interpretation of the model allows us to predict geometrically the evolution of the system in the presence of stochastic fluctuations, similarly to the analysis for deterministic slow-fast systems [6]. The trajectory rapidly approaches the attracting $\mathcal{C}_0$ submanifolds. Here, the dynamics is governed through its slow variable, thus noise-driven, and the system moves along $\mathcal{C}_0$ until it reaches a saddle-node bifurcation. Here, it may jump to the other attracting branch, and these large excursions are explained through the model's fast dynamics. See Figure 3 for examples of stochastic simulations starting from different ICs and for different parameters (corresponding to the traces in Figure 1) resulting in different types of behaviour.

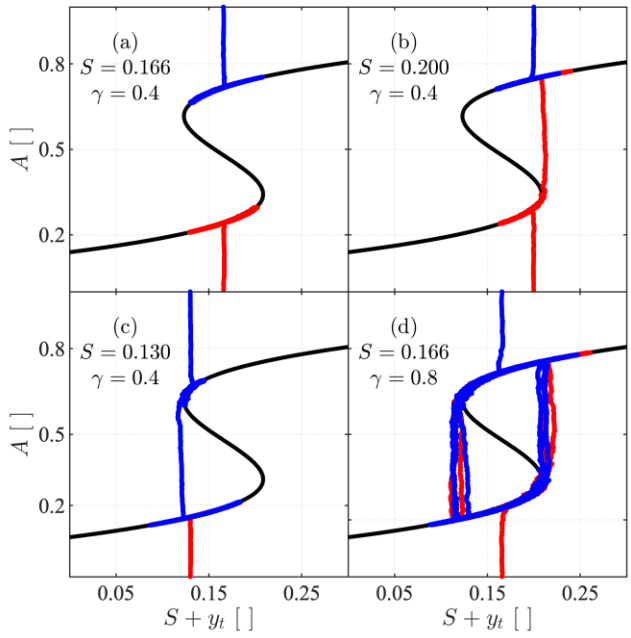

Fig. 3: Model simulations are started from $A(0) = 0$ (in red) or $A(0) = 1$ (blue). The black curve represents the average $\mathcal{C}_0$ in the singular limit, i.e., $S = -P(A)$. In (a) the system's trajectory fluctuates around a stable steady state. In (b) and in (c) only the right or the left SN is crossed, therefore single transitions are detected. In (d) the system's evolution crosses alternatively the two SNs, activating oscillations.

2) Critical Manifold Delocalization

The above reasoning is correct in the limit $\epsilon \to 0$. By relaxing this constraint, we expect that the system will evolve on a stochastic, slow manifold lying close to $\mathcal{C}_0$, i.e.,

$$S = -y_t - P(A) + O(\epsilon),$$

where the external stimulation S associated to an equilibrium point is stochastic and inherits A's random properties in addition to direct influence from the OU process.

From the previous relationship both the expected value and the variance of S, and hence of the stochastic slow manifold, can be derived. By applying the expectation operator and using $\mathbb{E}[y_t] = 0$ we get

$$\mathbb{E}[S] = -\mathbb{E}[P(A)],$$

where the right-hand-side was calculated in Section II.C. Thus,

$$\mu_S := \mathbb{E}[S] = -\mathcal{F}(\mu_A, \sigma_A),$$

and it follows that on average the slow manifold coincides with the manifold of equilibrium points of μ_A in the ODE system obtained with the G method.

By using the same approach, the variance of the external stimulus intensity S can be derived. We only outline the result as it is quite cumbersome.

$$\sigma_S = \mathbb{E}\left[\left(S - \mathbb{E}(S)\right)^2\right] = \mathbb{E}\left[\left(P(A) + y_t - \mathcal{F}(\mu_A, \sigma_A)\right)^2\right]$$
$$= \mathbb{E}[P^2(A)] - \mathcal{F}^2(\mu_A, \sigma_A) + \frac{\gamma^2}{2\tau} - 2\mathbb{E}[y_t P(A)],$$

where the first term is polynomial since $P(A)$ is polynomial, and hence its mean value can be computed exactly using the G method. The last term involves the covariance between A and y_t, Σ_{AY}, which is calculated using the G method as outlined in Section II.C. Therefore, both the variance and the expected value of a generic equilibrium point in the stochastic $\mathcal{C}_0$ can be computed from the ODE system obtained with the G method in Section II.C. This latter system can be analysed with bifurcation software such as the AUTO package in XPPAUT.

3) Two-Parameters Bifurcation Diagram

Intuitively, the system might jump to the other stable branch before reaching a saddle-node due to noise "pushing" the trajectory on the other side of the separating, unstable equilibrium. Such events correspond to a "translation" of the saddle-node point due to noise. Using the G-method ODE system and AUTO, we therefore follow the location of the saddle-node bifurcations when varying the noise strength γ. In Figure 4 we show the resulting two-parameters bifurcation diagram. As mentioned above, the result from the G method corresponds to the location of the average stochastic slow manifold. The chart shows how the saddle-node bifurcations move in the two-parameter plane by displaying both their average location and a centred symmetrical interval,

$$\left[\mu_S - \sqrt{\sigma_S}, \mu_S + \sqrt{\sigma_S}\right], \quad (2)$$

for each noise intensity level γ.

The background probability heatmap is generated from post processed data retrieved from Poincaré maps of 60 simulations executed for each (S, γ) combination, of the polynomial model. For each combination, half of the simulations were started at $A(0) = 0$ while the remaining ones had IC $A(0) = 1$. The total simulation windows were 10000- and 20000-time units, where the former was used for simulations with γ lower than 0.5, and the latter for γ above this value.

From Figure 4 the changes in model behaviour can be directly seen. In fact, a crucial point can be recognized. At the

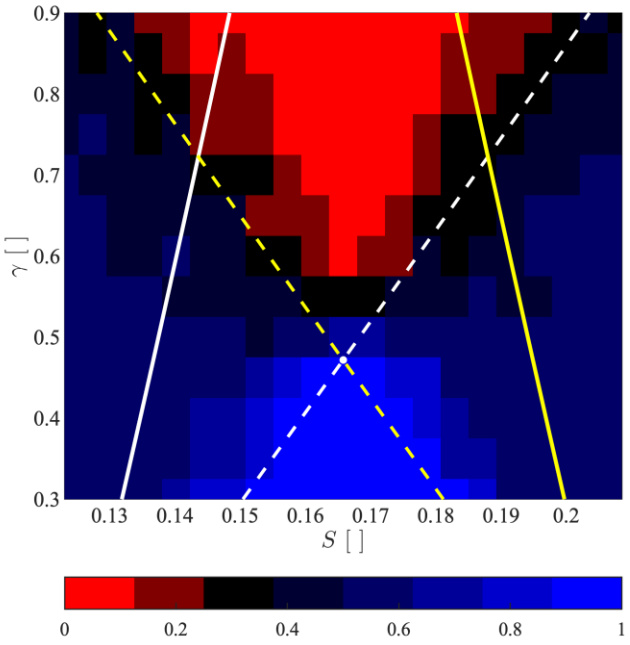

Fig. 4: Two-parameter bifurcation diagram of the G-method dynamical system with γ and S as bifurcation parameters. The continuous lines indicate the SN locations; the dashed lines the left-SN-upper and right-SN-lower boundary of the interval specified in (2). Right- and left-SN are colour-coded yellow and white, respectively.

cross between the two dashed curves, we observe a large increase probability of transition. This intersection separates the (S, γ) plane into four regions, which are discussed below.

The first section considered is the one in which the probability of observing a fluctuation around a steady state equilibrium point, with no large transition occurring, is great; this is the triangular zone below the crossing point. Indeed, the system behaviour is expected to evolve close to the upper or lower branch depending on the system's IC. An example is shown in Figure 3a.

The second and the third zones are located on the right and on the left of the dashed lines crossing point. In these areas, the empirical probability that an event will occur is ~50%. However, the only detected phenomenon are stochastic transitions. Deep in the right/left regions, the observable transitions are the one associated to the simulations that starts from, respectively low/high IC for A. This explains why a 50% probability of transition occurrence is detected. In fact, by considering the right region, only transitions in simulations that are started from the lower initial value will be activated. In contrast, for high initial value of A the noise does not present sufficiently large variance to make the system jumps back to the lower stable branch, so no transition is detected. The opposite rationale can be applied for the left zone. Examples of the system's evolution are given in Figure 3b and 3c.

The fourth section is the one associated to the upper triangular zone. In this region the SNs intervals specified in Eq. (2) overlaps and for these combinations of (S, γ) parameters the system has a higher propensity of generating stochastic oscillations due to model bistability, and not related to a Hopf bifurcation, as showed in Figure 3d.

These results reflect how the system is expected to evolve as the parameters are changed. In fact, increasing γ, which directly affects the steady state noise variance, as reported in Eq. (1), increases the noise-strength leading to a higher expectation of generating transition and stochastic oscillation. On the other hand, the activation of such phenomenon depends, once selected γ, also on the stimulus S since this latter defines, in the deterministic framework, the system's equilibrium points and therefore the nature of the evolution.

To conclude, note that the two-parameter bifurcation diagram of the ODE system is not enough to understand the SDE behaviour. This fact is because the information displayed is associated to $\mathbb{E}[S]$, which overestimates the value of γ at the crossing point. However, with additional information on the saddle-node standard deviation, the degree to which our analysis explains the results of the SDE model increases dramatically.

IV. Conclusion

Our method of analysing the model based on estimating the variance of the S coordinate of $\mathcal{C}_0$ in the stochastic system provides the basis to understand the underlaying dynamics by identifying the stochastic system's phenomenological bifurcation. In fact, as showed in Figure 4, the analytical results predict how to tune the parameter values of the system in order to maximise the probability of activating a given model activity, e.g., noise-induced oscillations. In synthetic biology, this method may play an important role. In fact, the coloured noise variance may be controlled via the introduction of new gene circuits that acts on the overall interfering network reducing or amplifying the noise strength.

In further studies, this methodology should be applied directly to the reference model in [1] and understand if, even in presence of error due to truncations of the Taylor expansion, the noise-induced activity maps may be sufficiently accurate and reliable.

***Abstract*—Local Field Potentials from the basal ganglia are currently used in state-of-the art closed loop deep brain stimulation devices to guide automatic adaptation of DBS parameters. However, algorithms and methodologies for LFP-based closed loop DBS are still under investigation, especially to define reliable strategies to detect patient's clinical state. To support this research process, in this paper we describe the development of a LFP feature dataset that can be used in classification studies, and three different applications of the dataset. The dataset includes three types of LFP features: power spectral density estimates, burst features and spectral entropy. Relevant clinical and technical features were included to allow supervised learning. The dataset was created using data from 34 patients, for a total of 314 minutes of recording that resulted in a dataset of 21765 lines and 45 columns. The three applications showed that the dataset can be used to study classification algorithms, and that some positive results can be achieved with the present implementation. However, it requires to be further enhanced with more patient's data and conditions.**

***Keywords*—LFP, DBS, Machine Learning, Closed Loop DBS.**

I. Introduction

DEEP Brain Stimulation (DBS) is a neurosurgical procedure that involves the implantation of electrodes into the basal ganglia of the brain connected to an implantable pulse generator that provides a pulsed current to stimulate a target area. DBS is used to treat the symptoms of advanced Parkinson's Disease (PD), Tourette's Syndrome and other neurological disorders [1]. In Parkinson's disease, the target of election is the subthalamic nucleus (STN) [1]. New closed loop techniques [2]–[4] are capable of using the implanted electrode to record Local Field Potentials (LFPs) in the targeted area of the brain, and adapt the stimulation to the patient status. While closed-loop DBS devices are already tested in humans [3], there is increasing scientific enthusiasm on the possibility to record LFPs in a 24/7 fashion from implantable devices in chronic patients. Considering the large amount of data expected in the next year, machine learning techniques were proposed to analyze LFP data in order to better understand and regulate the effects of DBS stimulation [5], [6]. To do so, reliable datasets including characteristic features should be made available.

In this study we create a dataset based on LFP signals taken after a few days from the surgical implantation of DBS electrodes in PD patients in stable and replicable condition. As a proof-of-concept, the dataset will be used to model fast machine learning algorithms to classify various characteristics of the LFPs, aimed to 1) identify the patient, 2) identify the contacts from which the signal is acquired (See Figure 1) and 3) identify the hemisphere in which these signals were generated. These three cases were chosen because they could be of interest for closed-loop applications. More specifically, the first one is related to patient's data protection, and, in turn, assist in deidentification or normalization procedures. The second one could help the automatic definition of the best stimulation contact or it could be useful during electrode implantation to define the best implantation site. The third objective is a generalization of 2) but could be useful to assert the laterality of the brain to further improve the research in the field.

II. Methods

The dataset was created using retrospective data from 34 rigid-akinetic patients with advanced PD who underwent DBS electrode implantation surgery. The procedure and the experiments were carried out at the Neurosurgery Unit at Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico Hospital in Milan, Italy. The patients were selected during three deep brain stimulation clinical studies [2], [3], [7]. All studies were approved by the institutional review board of the Policlinico Hospital and conformed with the Declaration of Helsinki. All patients provided written informed consent to the experimental procedures. Of the 34 patients here considered, 12 were included in the first study [7], 12 in the second one [3], and 10 in the third study [2]. No surgical complication was experienced by the patients selected.

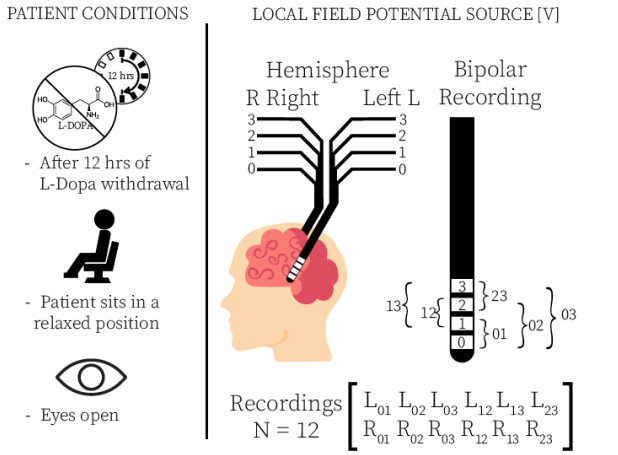

Figure 1: on the left the patients conditions, on the right the contact pair denominations and the electrode geometry.

A. Study Protocol:

The experimental sessions took place 5 days after the surgery, during normal hospital stay; all the experimental sessions took place with the contacts externalized before the connection to the subcutaneous pulse generator. The recordings used in this paper were collected in the morning after 12 hours withdrawal

of L-Dopa in a true "OFF" clinical status. Subjects sit on a chair in a relaxed position and with their eyes open during the recording sessions (Figure 1). The OFF recording lasted approximately 3 minutes. Immediately after the recording, the patients were disconnected from the acquisition amplifier and a UPDRS part III (UPDRSIII) evaluation was administered by a neurologist to quantitatively assess the clinical status. Normal therapy procedures were resumed soon after.

B. *Signal acquisition and pre-processing:*

Signal Acquisition: bipolar signals were recorded from a pair of contacts belonging to the same electrode (see Figure 1). LFPs were recorded using a standard amplifier (Model Grass ICP511, Astromed, USA) with gain 80 db, passband 1-100 Hz, 50Hz notch filter on. They were digitalized by a Micro1401-3 Analog to Digital converter (Cambridge Electronic Design, UK) at 256 samples/s and 16-bit resolution. The signals were displayed and saved using the Spike 2 software (Cambridge Electronic Design, UK) and the Matlab Software (The MathWorks, Inc., version 7.10.0, R2010a) was used to post-process the signals and to extract the features. The patients were included only if satisfactory multi-contact data were recorded (i.e. at least two recordings from at least two contact pairs from each hemisphere).

Pre-processing: this phase was divided in three steps: inspection, filtering, and normalization.

All the signals were manually inspected to remove initial dc drifts, when found. These artefacts duration was no more than 2 seconds. After the manual inspection, all signals were filtered by a bandpass FIR filter, Kaiser window, with a 3-dB cutoff between 1 Hz and 45 Hz.

Normalization: after filtering, each signal was normalized using a modified Min-Max procedure, designed to avoid offset, as shown in equation (1).

$$Min-Max: n_{MM}(t) = \frac{s(t)-\min(s(t))}{\max(s(t))-\min(s(t))} - \bar{s} \quad (1)$$

$n_{MM}(t)$: normalized signal, min-max

s(t): LFP signal

$\bar{s}$: the mean of s(t), this was subtracted to the Min-Max normalization to ensure a true zero offset of the signal.

Epoch subdivision: LFPs were then divided into overlapping (90%) 10 s epochs. The epochs therefore overlap themselves by 9 seconds, with one second offset.

The normalization was carried out using the entire signal to preserve the total power ratio between epochs making the PSD feature comparable between windows.

C. *Feature selection and estimation*:

To create the dataset, we selected the three main groups of features used in LFP research: (1) Power Spectral Density estimate (PSD) features, related to the mean power of physiological spectral bands of human brain, which is one of the classical approaches to study LFPs, (2) Burst features, that characterize LFP signals in PD patients [8] and are related to short-time increases in signal amplitude, and (3) Spectral Entropy features, which gives indications on the actual chaotic status of the system, used in [9], [10].

PSD features: for each 10-s epoch we obtained the signal periodogram using the Welch's Method (windows size: 256 samples, overlap 50%, spectral resolution: 1 Hz) [11]. The frequency space was divided in the classical physiological bands (see TABLE I) and the single bin values were summed to estimate the power spectral density in each band, thus obtaining a single feature for each band in each epoch.

Burst Features: in STN-LFPs, rapid amplitude changes in specific bands (e.g., the beta band 13-35 Hz) are very common, and their presence is an important pathological indicator [8]. The burst extraction process adapts the methodology presented in [12], and was conducted on each LFP epoch in each frequency band. The procedure consisted in calculating the root mean square of the upper envelope of the epoch with 64 samples sliding window. If the upper envelope exceeded the 65th percentile of the mean of the epoch and there were at least two consecutive peaks of the original signal crossing the threshold, then a "burst" was identified (see FIGURE 2).

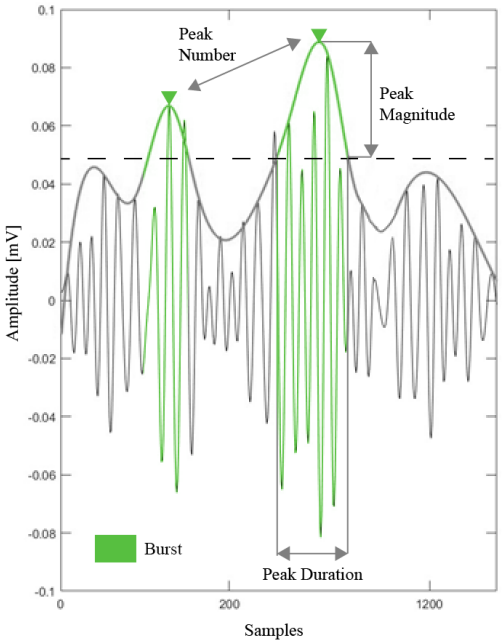

Figure 2: Burst features. The black bold line represents the upper Hilbert envelope of the signal. The dotted line represents the 65th percentile of the signal. The burst feature includes the mean and standard deviation of peak magnitude and peak duration of every epoch.

After obtaining and counting the bursts of every epoch of each frequency band, we calculated the mean and standard deviation of the peak amplitude, of the burst duration in seconds and of the area between the envelope curve exceeding the threshold. These five features plus the number of burst for every epoch were added to the dataset (see TABLE I).

Spectral Entropy features:

These features were calculated epoch by epoch based on the Shannon Entropy concept, as in equation (3):

$$H_{sp} = -\frac{\sum_{m=1}^{N} P(m)\log_2 P(m)}{\log_2 N} \quad (2)$$

Where P(m) is the probability distribution defined as

$$P(m) = |X(m)^2| / \sum_i |X(i)^2| \quad (3)$$

X(m) is the discrete Fourier transform of the sampled signal filtered by the physiological band. The function used to calculate these features is Matlab's "pentropy".

The total entropy features per epoch are 7, one for each physiological band (see TABLE I).

TABLE I
DATASET FEATURES

Physiological bands	PSD estimate features	Burst features*	Spectral Entropy features	Total
δ (1-4 Hz)	1	5	1	7
θ (4-8 Hz)	1	5	1	7
α (8-11 Hz)	1	5	1	7
Low β (11-25 Hz)	1	5	1	7
High β (25-35 Hz)	1	5	1	7
γ (35-45 Hz)	1	5	1	7
Categorical Features				
Patient Index				1
Contact Pair				1
Hemisphere				1
Total	6	30	6	**45**

Burst

* Burst features include epoch mean and standard deviation of peak magnitude, epoch mean and standard deviation of peak duration and epoch peak number.

Dataset creation: the final dataset was created aggregating all the three groups of features (14 features for each frequency band, 42 features for each epoch) and adding the categorical patient index, the DBS contact (see FIGURE 1) and the source hemisphere (right or left) in total, the dataset contains 45 columns.

D. *Training and testing*:

Categorization objectives: as a proof-of-concept regarding the use of the dataset for the definition of algorithms useful for closed-loop DBS, in this study we created 3 different machine learning categorizers: 1) capable of distinguishing the signal between different patients, 2) capable of distinguishing the signal from different contacts pairs (see Figure 1) and 3) capable of distinguishing the LFPs from different brain hemispheres. The first objective has 30 different categories (number of patients), the second one has 6 categories (not all the combination of the contacts where used, see Figure 1) and the third one only 2 (right or left hemisphere). After some qualitative tests we decided to use the Random Forest Classifier (RFC) with 42 estimators, implemented in Jasp (JASP Team, Version 0.16.4. 202. https://jasp-stats.org/) and in Python using the Sci-kit Learn library (version 1.2, https://scikit-learn.org/).

Training features: To train the algorithm, due to the relatively large and correlated dataset, we used a randomized 20% holdout validation. To train 1) and 2) we used all the 44 features without the objectives (Patient or Contact Pair respectively). To train 3) we excluded the also the Contact Pair as it is strictly correlated with the Hemisphere.

Testing the machine learning algorithms: algorithm 1) was tested with an additional randomized 20% holdout test data. Algorithms 2) and 3) were tested against a single holdout patient, in two different tests. The first test consisted of holding out 100% of the signals from the patient; the second test fed 25% of the initial signal data (about 10 seconds) of the holdout patient to the training algorithm and holds out the latter 75% to test against the response of trained algorithm. These two tests (100% patient holdout and 75-25% patient holdout) were used to simulate a machine working on a completely new patient or an algorithm trained on the spot with his/her LFP data. Due to this self-training nature of the 75-25% test, on-the-spot training time were also reported. Due to the simplicity of the algorithms we used only a single thread of the CPU of a single machine. The processor used is an Intel(R) Core i9-10900X CPU @ 3.70GHz, 3696 MHz with 64 GB of RAM.

TABLE II
TEST RESULTS – RANDOM FOREST CLASSIFICATION

1) IDENTIFY THE PATIENT

Number of rows			Accuracy		
Train set	Validation set	Test set	Validation	Test	OOB
13932	2806	4353	0.976	0.975	0.932

2) IDENTIFY THE CONTACT PAIR

		Mean rows		Mean accuracy	
		Train set	Test set	Validation set	Test set
100% Patient Holdout	Mean	21135	362	0.921	0.338
	St.D.	472	74	0.007	0.22
75-25% Patient Holdout	Mean	21278	152	0.920	0.530
	St.D.	381	98	0.006	0.200

3) IDENTIFY THE HEMISPHERE

		Mean rows		Mean accuracy	
		Train set	Test set	Validation set	Test set
100% Patient Holdout	Mean	21135	362	0.958	0.567
	St.D.	472	74	0.004	0.225
75-25% Patient Holdout	Mean	21278	152	0.958	0.771
	St.D.	381	98	0.003	0.162

OOB = Out-of-bag; St.D. = Standard Deviation.

III. RESULTS

The final dataset was created using 188 signals from 6 contact pairs in 34 patients. The average number of epochs per patients was 603.9 epochs with a standard deviation of 470.5 epochs.

. Using the pre-processing and feature estimation procedures previously described, we obtained a dataset of 21765 rows and 45 columns. Using this dataset as input, As shown in Table II the three algorithms perform within various degrees of accuracy.

1) Identify the patient:

The task to identify the patient given a random epoch of a signal was relatively easy for the algorithm, scoring 0.932 of Out-of-the-bag accuracy and 0.975 on the holdout test accuracy. The most prominent features were the mean of the peaks in the γ frequency (with a 0.201 total increase in node purity) followed by category features that indicates the contact pair from which the signal is recorded (0.168 total increase in node purity). Other important features for the classification reside in the β band (total increase in node purity, mean peak in high β: 0.152; power spectrum in high β: 0.143 spectral entropy in low β: 0.111).

2) Identify the contact pair:

The algorithm did not perform well given a completely new patient, albeit supplying the training even with a small (about

ten seconds) of a signal from the patient improved the classification behavior. Both 100% and 75-25% holdout showed anyway low scores (100% patient holdout: 0.338 ± 0.22 and 75-25% patient holdout: 0.530 ± 0.200.

3) Identify the hemisphere:

Whereas the 100% patient holdout still fails (0.576 ± 0.225), in the 75-25% holdout the mean accuracy is 0.771 ± 0.162 (see Figure 2). The training time of the RFC for this last test in the 75-25% test is 3.26 ± 0.16 seconds using a single CPU thread. Thus, it is feasible to train the algorithm during the data acquisition as it adds only a small delay.

IV. Discussion and Conclusions

In this paper, we described the implementation of a LFP-based dataset, composed of relevant features calculated from signals belonging to 34 patients in the medication OFF state. These allowed to obtain a dataset of 45 features and 21765 lines which was subsequently used to train three Random Forest algorithms dedicated to three classification tasks, one for the identification of the patient to which the signal belongs, one to identify the contact pair from which the signal was recorded, and one to identify the hemisphere.

Our results, even though limited by the small number of patients and by the use of a single condition (OFF medication), showed that the approach is feasible and can be applied to improve the knowledge coming from LFPs recorded in DBS patients to classify characterizes relevant either for closed-loop systems or for automatic programming.

However, while the results of the first task (patient's identification) were positive, the results of the other two highlight the challenges to work with LFPs. First, LFPs, even when normalized, remain heterogeneous between patients. This of course allows identifying signals belonging to a specific patient (as in task 1). This possibility could be exploited in a useful way, as a digital imprint, or, on the other hand, it could represent a threat to the privacy of the individual. As a further challenge, the inter-patient signal heterogeneity is also detrimental when trying to find common feature patterns across signals belonging to different patients. One of the reasons behind inter-patient variability is the precise targeting of the electrode, that it could vary not only from patient to patient, but also from hemisphere to hemisphere.

In addition, the use of an overlapping moving window introduced correlation between features. Also, only a min-max normalization was applied while future studies could consider z-scores or other normalization. Furthermore, LFPs length spans only 30 seconds, to record only a static patient status, whereas prolonging this acquisition time could open the possibility of study a time-evolving signal.

Despite these limitations, the third algorithm was able, albeit with some uncertainty, to distinguish between left and right hemispheres, indicating a possible lateralization of the STN activity, thus providing new insights into basal ganglia neural circuitry. This suggests that building datasets of known features from available LFPs in different patient conditions could support not only the research on signal classification and, in turn, on closed-loop DBS but also on deep brain structure neurophysiology.

In the future, including more data on such dataset it would be possible to apply not only simple and fast machine learning algorithms, but also other machine learning methods, including deep learning techniques.

How to assess vascular dysfunction during septic shock and resuscitation

M. Carrara[1], P. Antenucci[1] and M. Ferrario[1]
[1] *Politecnico di Milano, Department of Electronics, Information and Bioengineering*

***Abstract*— Septic shock is known to induce a severe vascular dysfunction which could also persist after hospital discharge and have long term sequela, increasing the cardiovascular complications and the mortality risk of survived patients. Typically, this vascular dysfunction consists in stiffening of large vessels (e.g., the aorta) and a loss of peripheral resistance, which can finally lead to a condition of peripheral vascular decoupling. These alterations are commonly overlooked during resuscitation, although they can be easily derived from routinely acquired signals such as invasive blood pressure. Several techniques to estimate arterial properties such as arterial compliance, total peripheral resistance, and time constant τ based on the Windkessel model of the cardiovascular system will be discussed and results obtained from different data and experiments will be presented to show the feasibility and the effectiveness of the proposed indices.**

***Keywords*—arterial compliance, peripheral resistance, Windkessel cardiovascular model, vascular decoupling.**

I. Introduction

SEPSIS and septic shock remain the main causes of mortality in intensive care, despite continuous efforts to improve the therapeutic protocols. Survived patients typically cohabit with a critical cardiovascular condition which determine a higher risk of fatal and non-fatal cardiovascular events [1]. The vascular endothelium is highly deteriorated by sepsis, leading to a dysfunction of arterial properties and the related vasodilatory and vasoconstrictive mechanisms [2]. Specifically, a stiffening of large vessels, such as the aorta [3], and a loss of peripheral resistance are often observed during septic shock, and these vascular alterations can lead to a condition of peripheral vascular decoupling [4], i.e., an inversion of the physiological amplification of pulse pressure from central to peripheral sites. Moreover, the blood pressure waveform has been shown to be profoundly altered by sepsis [5], hinting that blood flow transmission and reflection are also impaired.

Current clinical guidelines are mainly concerned to recover septic shock patients from hypotension and hypovolemia and global hemodynamic indices, such as mean arterial pressure, are still the key therapy targets [6]. However, even subtle changes occurring in the arterial pressure waveform can give insight on peripheral vascular tone, backward pressure waves, and large arteries compliance, but they are not addressed in current clinical guidelines and no therapy recommendations are available.

Our hypothesis is that invasive blood pressure, which is routinely collected in intensive care unit (ICU), contains dynamic signatures of the cardiovascular status that can give insights on vascular function and blood flow propagation, adding important information to average hemodynamic indices typically measured. Lumped-parameters models, such as the Windkessel model, can be used to extract these dynamic indices.

The aim of this paper is to describe some techniques useful to study the alterations in vascular properties and arterial waveform induced by sepsis/septic shock during different experimental protocols. The results presented were obtained from different data and experiments to show the feasibility and the effectiveness of the proposed indices.

II. Methods

A. The arterial Windkessel model

The two-element Windkessel model [7], reported in Fig. 1, describes the hemodynamics of the arterial system in terms of total peripheral resistance (TPR), mainly accounted by the smallest arteries and arterioles, and total arterial compliance (AC), mainly determined by the elasticity of the large arteries.

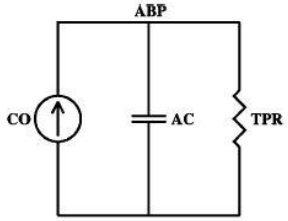

Fig. 1: The two-element Windkessel model of arterial tree. CO, cardiac output; ABP, arterial blood pressure; TPR, total peripheral resistance; AC, arterial compliance.

According to the model, TPR can be estimated as

$$TPR = \frac{P_{ao,mean} - P_{ven,mean}}{CO} \approx \frac{P_{ao,mean}}{CO} \quad (1)$$

where $P_{ao,mean}$ and $P_{ven,mean}$ are the mean value of aortic and venous arterial blood pressure (ABP), respectively, and CO the cardiac output. The compliance is defined as the ratio of a volume change, ΔV, and the resulting pressure change ΔP; the total arterial compliance (AC) is assessed as follows when ABP is measured in aorta:

$$AC = \frac{\Delta V}{\Delta P} = \frac{SV}{PP} \quad (2)$$

where SV is the stroke volume and PP is the pulse pressure, obtained as the difference between the systolic and the diastolic values within a pulse. According to the model, the time constant τ of the arterial tree, representing the time constant of the exponential diastolic decay, can be computed by the following equation:

$$\tau = AC \cdot TPR \quad (3)$$

This relationship holds on a beat-to-beat basis if we consider the ABP waveform measured centrally where the cumulative effects of wave reflections are attenuated [8]; in this case, ABP should decay like a pure exponential during each diastolic interval with a time constant τ. However, this relationship is also consistent if we consider a time scale sufficiently long such that the wavelengths of the propagating waves are much larger than the dimension of the arterial tree. At such time scales, the arterial tree acts as a single blood reservoir, and the Windkessel model is therefore valid. So, for example, if pulsatile activity abruptly ceased, then peripheral ABP may eventually decay like a pure exponential as soon as the faster wave reflections died out [9]. Based on this concept, we computed the time constant τ on long time intervals (6-min windows) of the measured ABP waveforms according to the method proposed by Mukkamala *et al*. [9]: i) a cardiac contraction signal $x(t)$ is created by placing impulses at the time instants of the onsets of ABP upstroke with an area equal to the ensuing PP; ii) a relationship between the cardiac contraction signal $x(t)$ and the ABP waveform named $y(t)$ is assessed by computing the impulse response function $h(t)$, which minimizes in the least squares sense the convolution with $x(t)$ in order to best fit $y(t)$. By mathematical definition, the estimated $h(t)$ represents the ABP response to a single cardiac contraction (normalized approximately by the average PP); iii) the Windkessel time constant τ is finally determined by fitting the portion of the estimated $h(t)$ after its maximum value with an exponential decay. This optimization problem is solved via linear least squares estimation by log-transforming $h(t)$.

B. *Peripheral pulse pressure amplification*

In physiological conditions the amplitude of arterial pulse, i.e., the PP, has increasing values from central to peripheral sites due to waves reflection. Indeed, since blood pressure measured in the periphery is close to the reflection sites, the backward wave has to travel back a shorter distance before summing up to the forward wave; moreover, the lower compliance of peripheral arteries leads to higher PP values. Generally, this phenomenon is called *peripheral amplification of the pulse pressure*.

C. *Datasets*

The first dataset analyzed includes 6 pigs undergoing to an experimental protocol of polymicrobial septic shock and standard resuscitation performed at *Université Libre de Bruxelles.* More details about the experimental protocol can be found in [5]. Briefly, the animals were analysed at baseline (T1), after severe septic shock development (T2), and after resuscitation with fluids and noradrenaline according to standard guidelines (T4, ~5/6h after T2). The time point after fluids only (T3) was skipped as some animals required immediately administration of noradrenaline. Moreover, the phase of sepsis development, i.e., from the insult, consisting in autologous feces inoculation into the peritoneum, until time point T2, was analysed and indices were computed every 5 minutes. ABP were continuously recorded in central aorta (sampling frequency 500Hz) and in peripheral femoral (sampling frequency 500Hz) and radial artery (sampling frequency 250Hz).

The second dataset consists of 9 pigs undergoing polymicrobial sepsis and resuscitation up to 74h after sepsis development; this allowed to disentangle the early and late response to the therapy. Seven pigs were treated as sham controls, i.e., monitored for the same time window allowing to appreciate the sepsis effects excluding confounding factors related to the experimental setups. The experiments were performed at *Insespital, University Hospital of Bern*, and more details about the experimental protocol can be found in [10]. ABP was continuously recorded in carotid artery at a sampling rate of 100 Hz. The animals were analyzed at baseline (T1), after sepsis development (T2), after 24h (T3), 48h (T4) and 72h (T5) of resuscitation according to clinical guidelines.

III. Results and Discussion

The results obtained from the first dataset are presented below. Fig. 2 shows the trend of central and peripheral PP and vascular properties, such as AC and TPR. Septic shock induced a profound dysfunction of the vascular system with stiffening of central vessels (reduced AC), peripheral vasodilation (decreased TPR), and alteration of PP amplification; indeed, the baseline condition of peripheral PP higher than central PP is lost after septic shock development.

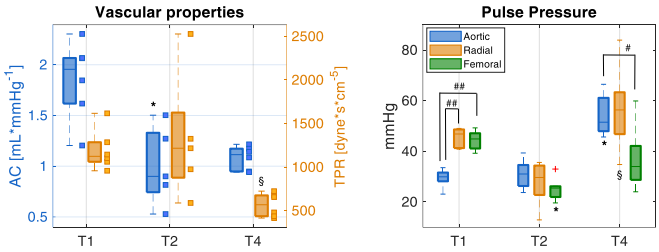

Fig. 2. Left panel: distributions of total arterial compliance (AC) and total peripheral resistance (TPR) values. The values relating each pig are marked by the little squares. Right panel: distribution of central and peripheral PP values. Wilcoxon signed test: ∗p-value < 0.05 with respect to T1, § p-value < 0.05 with respect to T2 (Friedman test p-value < 0.05). Mann–Whitney U-test: #p-value < 0.05, ##p-value < 0.01 between the specified variables.

This vascular dysfunction progressively develops during sepsis progression, as shown in Fig. 3 reporting the trend of aortic and femoral PP values at baseline (T1), and from the insult until full development of septic shock (T2). The different duration of each pig's trend highlights the heterogeneity of the response to sepsis induction. However, it is possible to observe in all animals the "crossover" between the two PP trends (i.e., femoral PP becoming lower than aortic PP), supporting the evidence that the peripheral vascular decoupling is a hallmark phenomenon occurring during sepsis development. The main responsible for this PP reversal is a decrease in peripheral PP, whereas the aortic PP maintains approximately constant values throughout the entire phase. Fig. 4 shows the trend of aortic PP and time constant τ at baseline (T1) and from the insult until T2. It is interesting to notice that the same "crossover" described before is still visible, driven by a reduction in the τ values. A decrease in the Windkessel constant could be due to vasodilation, i.e., a decrease in TPR, or stiffening of large arteries, i.e., a decrease in AC, or both phenomena.

This compromised vascular condition was not relieved by therapy administration, although the clinical hemodynamic targets were achieved in all animals, e.g., mean arterial pressure (MAP) >65mmHg. At this time point the aortic PP has significantly increased compared to T1 or T2, whereas the femoral PP has not been restored.

This can be macroscopically appreciated from the changes in morphology of aortic ABP waveforms, as shown in Fig 5: the shape of the aortic waveform mostly at T4 resembles the typical pressure waveform of a high cardiovascular risk subject, such as aged people [11], although these changes were developed only in a few hours of experiment.

These results were confirmed in the second dataset, where the resuscitation phase was longer, up to 74h after sepsis development.

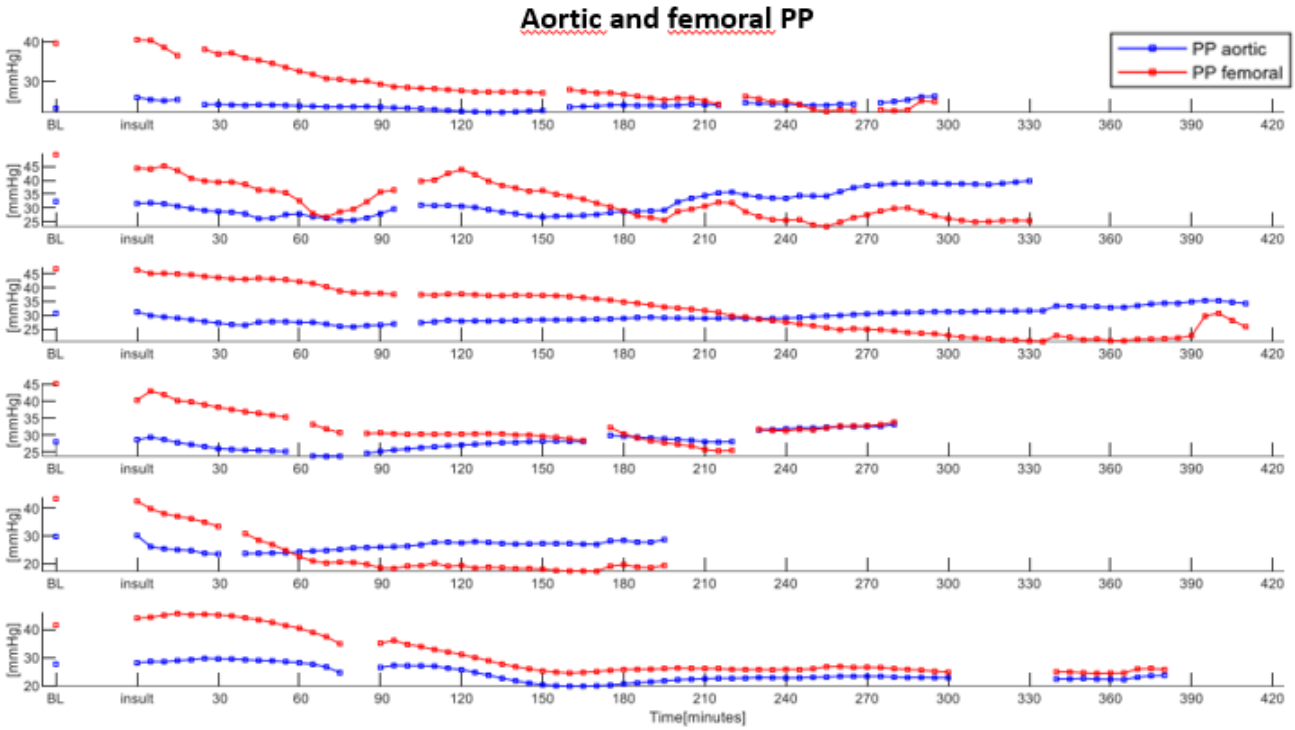

Fig. 3. Trend of aortic PP (blue squares) and femoral PP (red squares) for each animal at baseline (BL), which corresponds to T1, and from the inoculation of the feces (insult) and onwards until T2.

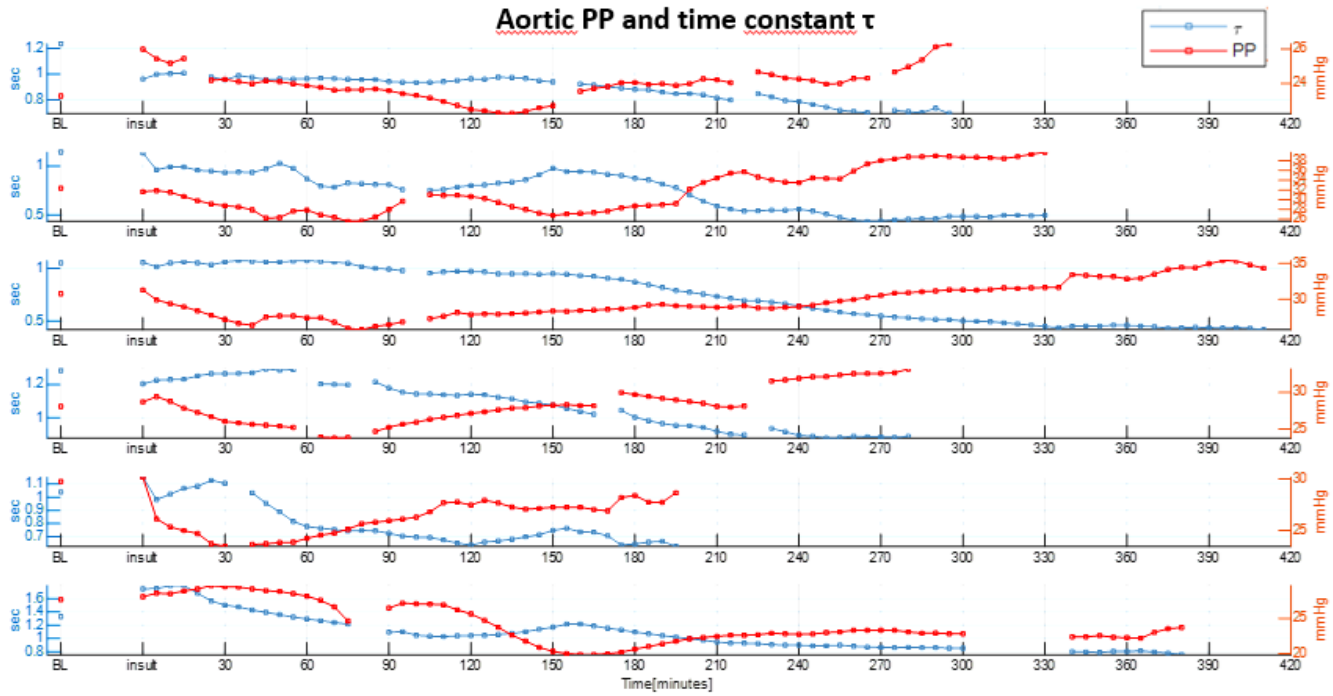

Fig. 4. Trend of aortic PP and time constant Windkessel τ for each animal at baseline (BL), which corresponds to T1, and from the inoculation of the feces (insult) and onwards.

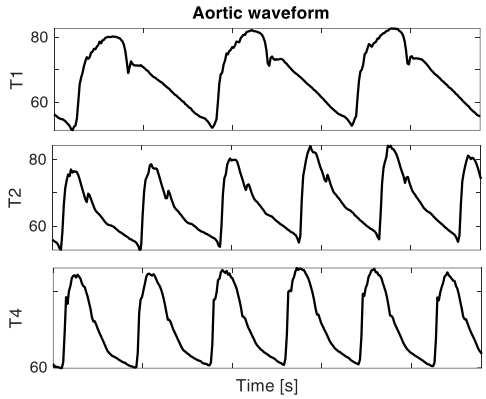

Fig. 5. Example of few beats extracted from aortic waveform at each time point for one animal from the experiments performed at *Université Libre de Bruxelles.*

Fig. 6 shows how the vascular alterations occurring in the early phase of sepsis development characterize not only the first hours of therapy administration, when recovery from hypotension is of primary importance and massive fluids and vasopressors infusion are crucial for survival, but they persist also after days, when hemodynamic stabilization has been optimized.

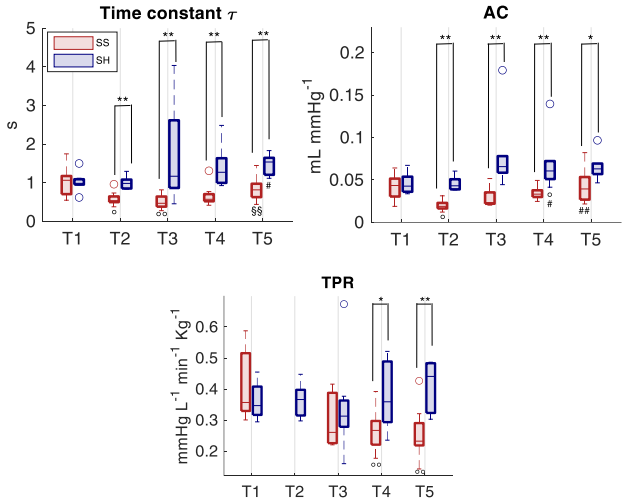

Fig. 6. Distributions of values of vascular indices for the two groups Comparison between Sepsis and Sham: *p-value < 0.05, **p-value < 0.01, ***p-value < 0.001 (Wilcoxon rank sum test). Wilcoxon signed test: °p-value < 0.05, °°p-value < 0.01 with respect to T1, #p-value < 0.05, ##p-value < 0.01 with respect to T2, §p-value < 0.05, §§p-value < 0.01 with respect to T3 (Friedman test p-value < 0.05).

These vascular alterations can be observed from the graph of carotid ABP waveform (Fig. 6). The ABP morphological characteristics in a sham pig at T5 are similar to baseline (T1), on the contrary, the ABP waveform in a septic pig is completely different from baseline and sham pig; in particular, a much steeper decay of the diastolic phase can be observed, consistently with the lower values of τ and AC previously described.

I. Conclusion

The indices described proved to be highly informative in the study of therapy response in septic shock, providing important insights into the cardiovascular status, not achieved by standard hemodynamic measures commonly used according to international guidelines. The results were confirmed both in short-term (~5/6h after resuscitation) and long-term experiments (up to 72 h of continuous resuscitation). Indeed, the same mean ABP value in two different subjects can hide two different cardiovascular conditions or can be achieved by very different therapeutic strategies. A complex pathological condition like septic shock needs an extensive monitoring without neglecting important information from commonly measured signals like arterial blood pressure.

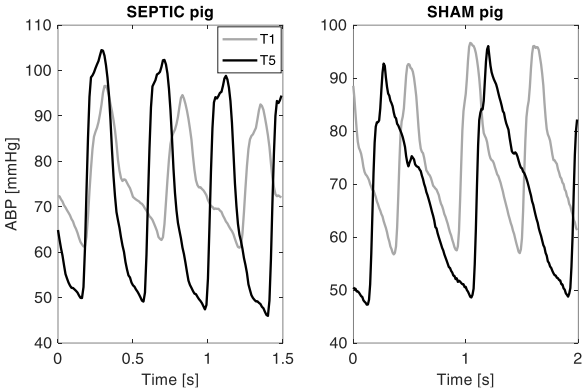

Fig. 6. Example of carotid arterial blood pressure waveform of a septic pig and a sham pig, at T1 (baseline) and T5 (72 h after the start of resuscitation) from the experiments performed at *University Hospital of Bern.*

Abstract **- Among all the available managements for the stress urinary incontinence, the Artificial Urinary Sphincter (AUS) is clinically considered the first-line treatment by inducing the lumen occlusion through a fluid-inflatable cuff applying a permanent pressure around the urethra.**

Over the decades of worldwide implantation of AUS, the success rate has emerged as deeply influenced by the mechanical stimulation of urethral tissues, which may be susceptible to potential degenerative phenomena, to urethral damage, with incontinence and necessary surgical revision.

To minimize the risk of urethral damage, this research work proposes a novel in silico strategy for AUS design, aiming to provide a device that is capable to apply a more uniform and appropriate occlusive action around the urethra.

Computational mechanics analyses are developed to evaluate the interaction between the urethra and the AUS device during the lumen occlusion and its subsequent opening because of bladder induced pressure, aiming to define the design parameters required for the continence condition, according to the tissue tolerability. The functionality of the novel device is compared with the reference AUS AMS800.

Keywords **- Stress urinary incontinence, artificial urinary sphincter, finite element method, computational structural mechanics**

I. INTRODUCTION

STRESS Urinary Incontinence (SUI) is a widespread pathological condition implying the involuntary leakage of urine in response to increasing intraabdominal pressure (e.g. coughing, sneezing or exercising), due to the deficiency of the urinary sphincteric mechanism. Nowadays, about 400 million people worldwide are affected by urinary incontinence, with SUI accounting for 24% to 45% in women [1] and about 10% in men [2], impacting significantly on quality of life and financial burden.

Since the 1970s, Artificial Urinary Sphincters (AUSs) have been developed for the SUI treatment as prosthetic devices which mimic the functionality of a natural urethral sphincter inducing the lumen occlusion during the storage phase of micturition. The operating principle consists generally in applying a pressure by means of a cuff inflated by saline solution, placed around the bulbar urethra or the bladder neck. Several variants of AUS are on the market and under experimental evaluation, distinguished in terms of control mechanism, pressure transmission and cuff shape and size.

In most cases, the pressure is set in the range 50-80 cmH_2O [3] and it is defined as a constant value by surgeons during the implantation. The pressure values are based on clinical experience in order to guarantee continence condition in daily situations. To date, despite successful post-surgery outcomes, the recurrent incontinence following the implantation of AUS is still an open clinical question [4]-[6]. High rates of surgical revision have been reported due to AUS failure because of the reaction of urethral tissues to pressure loading [3], [7]-[9].

In detail, the resulting negative outcome is twofold. First of all, urethral tissue in correspondence to the AUS cuff may undergo degenerative processes in terms of infection, atrophy and/or erosion. In some regions of interaction, tissue could be pinched during the inflation of the cuff and compressive action may cause a hypoxia condition [10]. In case of damaged tissue, the AUS may no longer guarantee the continence condition, even if it was initially adequate. All these complications involve pain and discomfort for the patient that should undergo a new surgery, unless significant tissue damage compromises the implantation of another device. Hence, the application of an artificial urinary sphincter requires a careful evaluation of the interaction phenomena between the device and the biological structures and tissues in contact.

The sphincter is permanently placed around the urethra by continuously applying an occlusive pressure, often higher than what is actually needed, in order to always guarantee continence, even in case of increased abdominal and bladder pressure. Only during voiding phase of micturition, typically around 6-7 times a day, the urethral duct is not exposed to the pressure load. In addition, the AUS is generally placed in urethral regions other than where the natural urethral sphincter is anatomically located and thus the tissues are not physiologically designed to be subjected to such occlusive stress and strain conditions. Therefore, as an essential requirement for the AUS reliability and durability, the biological tissue tolerability has to be necessarily considered in terms of compressive strain, compressive stress and hydrostatic pressure intensity and distribution.

For all these reasons, a novel in silico approach to the design of the AUS device is developed. A computational modelling strategy was defined, allowing to analyse the interaction phenomena between AUS and urethra, and thus to evaluate the device functionality. In detail, the cuff pressure that is required to ensure continence and the mechanical stimulation of urethral tissues, which may induce damage and/or vaso-constriction phenomena, can be evaluated. This approach was exploited to analyse a new AUS, which has been conceived introducing a novel conformation of the cuff as a fluid-inflatable cylindrical chamber to be placed circumferentially around the bulbar urethra.

The in silico procedure required the development of computational models of the male bulbar urethra and the AUS.

Models exploitation made it possible to investigate the urethral mechanical response under different occlusion conditions and intraurethral actions, by varying the material properties of the prosthetic device.

II. Materials and Methods

Over the years, the bioengineering methods provided valid support tools, in a wide range of medical fields, to study the functionality of biological tissues, plan surgical procedures and evaluate the efficacy and reliability of therapies and prosthetic devices. These methods are based on a tight coupling of experimental investigations, including the histo-morphometrical and mechanical characterization of biological systems and computational techniques. These latter allow to extend the experimental results to a wider scenario, simulating multiple situations and providing information on relevant aspects that are not accessible by clinical investigation. In this sense, the Computational Structural Mechanics (CSM) approach allowed to interpret the mechanical response of urethral tissue to the lumen occlusion process induced by the artificial sphincter, aiming to evaluate the reliability of the novel device.

A. Numerical model of the urethral duct

The bulbar urethral model was developed as a fully three-dimensional 50 mm length and 5 mm radius cylinder, with an elliptical lumen defined by internal major and minor axis of 8 and 1.6 mm, respectively (UGS NX3, Siemens PLM Software, Plano, Texas, USA). Lumen shape was previously investigated [10] according to the complex configuration in the bulbar area and here simplified by a regular elliptic shape, as it appears in other urethral regions, and also in consideration of a major pressure requirement for occlusion. Moreover, this shape minimizes the computational effort, suggesting the feasibility of real-time simulations for the surgical practice.

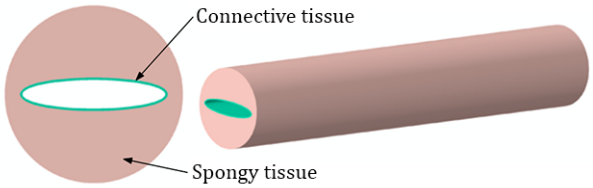

Fig. 1: Geometrical model of the urethral duct as a bi-layered structure.

The urethral wall was assumed to be composed by a thin layer of dense connective tissue that surrounds the lumen and an outer thick layer of spongy tissue all around (Figure 1). The mechanical behaviour of biological tissues was described by a specifically developed hyperelastic formulation [10]. The constitutive parameters were defined on the basis of inverse analysis of experimental data from uni-axial tensile tests and structural inflation tests performed on urethral samples [11].

A tie contact condition on the interfacing surfaces between the two layers and fixed-end constraints on cross-sectional surfaces at the two extremities of the urethral model were imposed to prevent relative and rigid body motion, respectively. The self-contact interaction between lumen surfaces was defined by a hard contact formulation with friction coefficient of 0.02 [10], [12], [13], considering that the tissue is physiologically wet. The urethral model was finite element discretized assuming different seeds for the two layers, by means of 145,920 and 200,640 linear hexahedral elements, corresponding to 184,000 and 213,440 nodes, respectively for the connective tissue and spongy tissue layers. Discretization was performed in the framework of Abaqus/CAE 6.14 (Dassault Systèmes, Vélizy-Villacoublay, France). To prevent mesh instability, the enhanced hourglass control formulation was adopted [14], [15].

B. Numerical model of the novel artificial urinary sphincter

The novel prototype of AUS has been conceived with an operating principle based on a hydraulic mechanism, as the majority actually on the market. The inflation of a fluid-filled cuff around the urethra provides for the lumen occlusion. However, on the basis of the current critical issues reported in literature, the novelty lies in the shape of the urethral cuff designed to improve the distribution of the pressure action by wrapping the duct more uniformly and safely, without pinching the tissue. In detail, as a matter of example, a 3D CAD model of the cuff was developed by assembling an inflatable chamber and an external supporting band. Both models were designed as a hollow cylinder with a constant curvature (Figure 2).

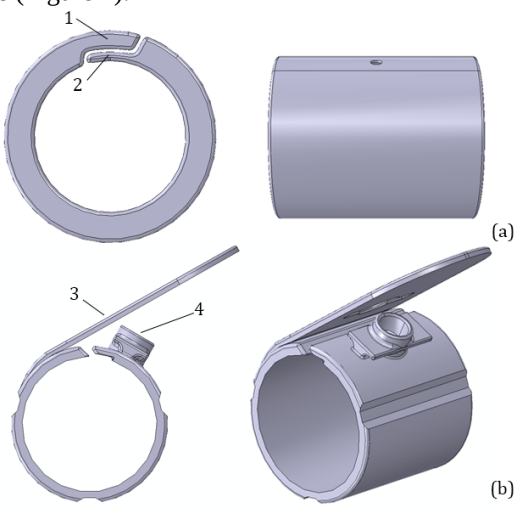

Fig. 2: Geometrical model of the novel artificial urinary sphincter composed by an inflatable chamber (a) and a supporting band (b).

The chamber and the circular band dimensions can be defined on the basis of the specific urethra requirements. In the initial configuration, the chamber end parts, labelled as 1 and 2, are detached and so the cuff is open, as shown in the Figure 2a. In the operative configuration, the band parts, labelled as 3 and 4 in Figure 2b, are intended to come into contact, inducing the closing of the cuff. In this manner, and according to wall stiffness distribution, it is expected that the inner wall of the chamber ensures a circular configuration around the urethra.

Regarding the design of the novel device, a relevant aspect was assumed by the mechanical characterization of its components. An elastomeric material was assumed for both the inflatable chamber and the supporting band, by considering an hyperelastic formulation defined in terms of the strain energy potential as:

$$W(\mathbf{C}) = K_v(J-1)^2 + C_1(\tilde{I}_1 - 3) \qquad (1)$$

where J is the deformation Jacobian, $\tilde{I}_1$ is the first invariant of the iso-volumetric part of the right Cauchy-Green strain tensor $\mathbf{C}$, K_v is a parameter related to the bulk modulus, C_1 is the material parameter related to the initial shear stiffness as $\mu_0 = 2C_1$. Different shear moduli were considered (Material 1, 2 and 3), as reported in Table I. The Material 3 was set to the same stiffness of the most used AUS worldwide, the AMS800 (Boston Scientific, Boston, USA) [10].

TABLE I: CONSTITUTIVE PARAMETERS

Material	*C_1 [MPa]*	*K_v [MPa]*
1	0.20	3.87
2	0.30	5.80
3	0.43	8.31

The contact interaction between the chamber and the band and also between each part was imposed in the normal direction by means of a hard contact formulation, and in the tangential direction with a friction coefficient of 0.1.

The finite element mesh of the supporting band was developed by means of 373,911 four-nodes tetrahedral elements having a mean size of 0.25 mm and a total of 79,182 nodes. On the other hand, the inflatable chamber was meshed by 51,503 three-nodes triangular shell elements, due to its small thickness to area ratio, and a total of 25,759 nodes. The enhanced hourglass control formulation was considered [13], [14].

C. Computational analyses of lumen occlusion

The two developed models were assembled together by positioning the sphincteric model around the middle region of the urethral duct, as shown in the Figure 3.

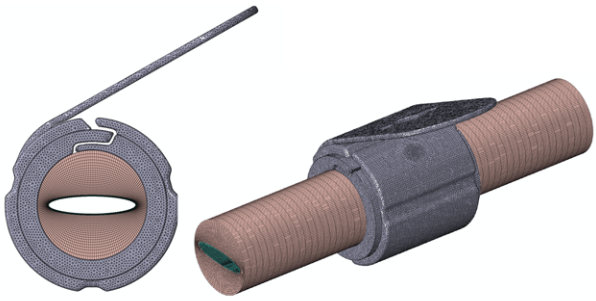

Fig. 3: Application of the novel device on the central zone of urethra.

In terms of contact property, a tangential behaviour was defined on the device regions in interaction with the urethral duct by means of friction coefficient of 0.02 [10],[12]. In addition, hard contact was considered in the normal direction on all the surfaces to prevent potential penetration phenomena.

To evaluate the minimum pressure that the novel AUS has to apply on the urethral duct for ensuring the continence, the lumen occlusion induced by the sphincter and the subsequent lumen opening due to the urine action were simulated for different constitutive parameters characterizing the device components. In detail, CSM analyses were performed by a three-step procedure. The first step simulated the cuff closing by applying a displacement boundary condition to carry the band tab portion in the operative positioning. Subsequently, during the second step, the chamber was inflated to a target pressure. Holding constant the occlusive action, during the third step, a radial pressure on the lumen inner surface was progressively increased up to the lumen opening.

The occlusive and intraluminal pressures were applied by means of hydrostatic pressure conditions. Load uniform distribution and velocity of 400 cmH_2O/s were assumed. Different target values of cuff pressure were considered in the range between 0 and 80 cmH_2O, on the basis of the occlusive pressure applied by the current AUSs. With regards to the urine action, the intraluminal pressure was considered within the physiological range during the voiding phase of micturition [16]. Since geometrical non-linearity effects and complex contact and self-contact conditions were expected during the analysis, the Abaqus/Explicit 6.14 (Dassault Systèmes, Vélizy-Villacoublay, France) non-linear dynamic explicit solver was adopted. The analyses were performed using a HPC server equipped with four Intel Xeon E7-8890 v4 and 512 GB RAM, allocating 30 to 50 threads for each target cuff pressure's simulation, resulting in an average analysis duration of 72 hours for each simulation.

III. RESULTS

The in silico approach to AUS design was exploited to investigate a novel device.

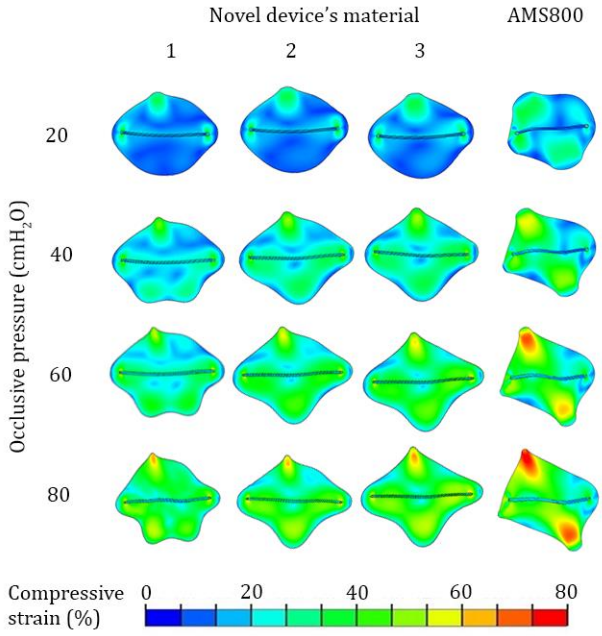

Fig. 4: Contours of compressive strain field at different level of cuff pressure for the different materials of the novel AUS and for the AMS800.

Numerical results of interaction phenomena between the urethral duct and the novel AUS were analysed during the lumen occlusion and opening processes considering different material parameters characterizing the device's components.

In particular, the compressive strain fields on the section of maximum stimulation of urethral model are reported for different occlusive pressures, as 20, 40, 60 and 80 cmH_2O, in relation with the three materials considered (Figure 4). In

comparison, the same mechanical fields for the AMS800 device are reported [10]. The results highlight an increase of compressive strain, proportional to the value of the applied cuff pressure and dependent on cuff material.

While minor difference emerges between the different materials of the novel device, it can be noted that, comparing them to the AMS800, less extensive areas are subjected to high values of compressive strain for occlusive pressures higher than 60 cmH_2O. This is an important aspect to consider because high values of compressive strain (and so of compressive stress) entail a risk of tissue degenerative phenomena. Moreover, for an occlusive action of 80 cmH_2O, the AMS800 involves more regions of urethra under hydrostatic pressures above 70 cmH_2O, which can obstruct most of the urethral vessels, where the blood flow reaches pressures between 13 and 105 cmH_2O [10].

For each material, the analyses allowed studying the relationship between sphincteric loading and urine action required to open the lumen. In particular, for each cuff material and each cuff pressure the corresponding lumen opening pressure was defined as the minimum intraluminal pressure needed to open the urethra. The resulting curves for the novel device are reported in Figure 5, in comparison to AMS800.

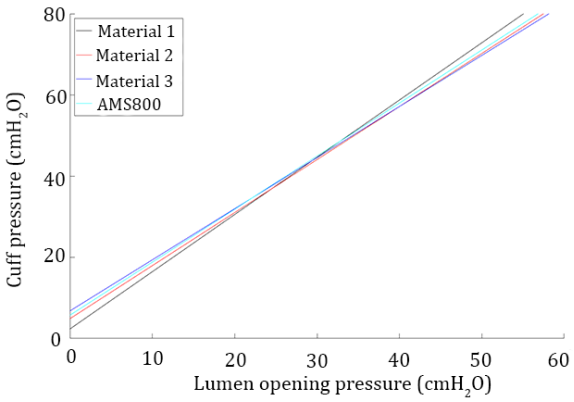

Fig. 5: Relation between lumen opening pressure and cuff pressure.

IV. Conclusion

AUS device is the gold standard treatment for severe SUI, with particular regard to male subjects. Nonetheless, the non-physiological mechanical effects on urethral tissues frequently entails complications. Aiming to a more reliable approach, a novel AUS has been defined by means of in silico methods, also supported by experimental tests. The methodology allows analysing interaction phenomena between AUS and urethral tissues and structure. The main outputs of the investigation consist in: i) the trend of cuff pressure that is required to ensure continence depending on bladder induced pressure, as a measure of functionality of the device, ii) the mechanical stimulation of urethral tissues depending on cuff pressure, in relation with the potential damage and/or vaso-constriction phenomena. The analysis shows that all the material configurations of the novel device have almost the same continence performance as the AMS800 (Figure 5). On the other side, it appears that the novel AUS device improves the distribution of the mechanical action on urethral tissues compared to the reference AUS case (Figure 4).

Even if supported by specific experimental tests, economic and time costs of the computational approach appears affordable and reliable, also overcoming ethical tasks. It represents a relevant support for clinical-surgical practice in the evaluation of the most appropriate solution to be adopted. The flexibility of the approach also leads to the possibility of prompt analysis of specific cases proposed for surgery.

***Abstract*—Upper limb amputation is a major injury that can strongly affect the daily life of a person. Prosthetic hands that can execute multiple movements are available, but they are expensive and difficult to control. Natural control via pattern recognition is promising but it is applied in real life prosthetics only in limited ways. Additive manufacturing and machine learning can revolutionize prosthetics with affordable and open-source solutions that can include 3D printed prosthetic hands, sockets and dexterous highly functional control. Nevertheless there are still intermediate steps to do into this direction. The objective of this paper is to introduce an ongoing project aimed at the development of low cost and dexterous prosthetic hands to be used in real life conditions based on open 3D models, additive manufacturing and machine learning. The results at the current state of advancement of the project include several versions of the prosthetic hand (powered by six servomotors and based on open design), of the control system (based on open electronic prototyping platforms) and of the socket. Preliminary tests of the hand demonstrate its dexterity, its potential and requirements to improve force. Once fully completed and released, the presented 3D printed, dexterous, open-source prosthetic hand has the potential to improve the life of hand amputees worldwide and to foster improvements in research and for future commercial prosthetic hands.**

***Keywords*—Electromyography, prosthetics, additive manufacturing, machine learning.**

I. Introduction

Upper limb amputation is a serious injury that can have a significant impact on a person's everyday life. According to estimates, 41,000 Americans were thought to have lost most of their upper limbs due to amputations above or below the elbow in 2005 [1].

Hand prosthetics is rapidly advancing, also thanks to machine learning and 3D printing. The combination of these solutions may revolutionize the domain if it is demonstrated to properly work on real life tasks and in a robust way. Although surface Electromyography (sEMG) commercial dexterous prosthetic hands (i.e., prosthesis that can do several movements) do exist, they are quite expensive and frequently difficult to control [2]. Their usage is thus often limited, because the control is frequently not sufficiently easy for usage in practical situations. Over the past ten years, a number of open models for 3D printed hand prosthetic hands have been created. Although 3D printing is one of the key technologies expected to revolutionize prosthetics in the future, open-source strong and dexterous prostheses have been limitedly developed.

Particularly if the amputation is bilateral, hand amputations are among the most physically and mentally debilitating injuries. At the moment, there are three types of hand prostheses: myoelectric, kinematic, and aesthetic. Cosmetic prosthetics provide psychological and esthetic support. Kinematic prostheses also have functional capabilities, since the user may control the opening and shutting of a gripper hand by the motion of the shoulder. In most myoelectric prostheses, two electrodes on the forearm allow the user to control a battery-operated hand using an electrical signal produced by the remaining muscles [2]. Prosthetic hands that can execute multiple movements are available, however they are frequently quite expensive. Few myoelectric hand prosthetics that are now on the market have the ability to replicate a variety of actions, e.g. Touch Bionics i-limb Quantum; Otto Bock Michelangelo; Steeper Bebionic v3; Vincent hand Evolution 2 [2]. Such prostheses are typically priced between $50,000 to $75,000, and the cost can further increase when pattern-recognition-based control systems are included. In such, still relatively rare, systems, typically, two or three sEMG electrodes are placed in the socket in relation to particular muscles to regulate them. The prosthetic hand opens and closes using myoelectric impulses, or a rise in the amplitude of the electrical signal released by the muscles. By using particular (for example, sequential) control procedures, the number of motions can be enhanced. Controlling prostheses needs a high level of competence and a dedicaterd training process, making such control tactics still far from being identifiable as natural.

The limited capabilities and acceptance of sEMG prostheses are a result of control issues among other challenges [3], but there are the premises for improvements in a near future. Effective tools for prosthesis control, pattern recognition and machine learning are primarily used in scientific studies [4] and there are currently not many commercially available systems. These techniques typically usually employ a higher number of sEMG electrodes to capture the myoelectric signals produced by the muscles. Utilizing algorithms for pattern recognition, the sEMG activity is examined to categorize the

movement that the subject intends to make in real time [5],[6]. Since 2013, Coapt-engineering[1] made a brand-new real-time pattern recognition-based hand prosthesis control system commercially available. Despite the incredible advancement for the domain, this system still does not replicate a biological hand's natural control and allows controlling usually a limited number of movements [2].

In recent research works, additional sources of information [6]–[8] have been suggested to be incorporated into the conventional myoelectric control, enhancing the controller with autonomous decision-making. Cognolato et al. enriched sEMG with eye tracking and computer vision data [9], [10].

A number of 3D printed hand prostheses have been developed in recent years thanks to 3D modeling and printing [11]. Numerous websites offer open designs that enable users to build their own 3D printed prosthesis[2]. Additive manufacturing processes and rapid prototyping techniques provide many options to quickly design, develop, build, and test functional prosthetic hands in a reasonable amount of time. In comparison to current commercial prostheses, 3D printed prosthetic hands may offer benefits like lower costs and patient-specific size adaptation. Additionally, an open-source architecture enables quick adaption to technological and scientific breakthroughs. An excellent example of the capabilities of this kind of approaches is provided by the HANDi HAND, which was created at the University of Alberta (Canada) [12], which has a number of actuators and a range of sensors (including pressure and positioning sensors) and that was tested in real life conditions by our group [13]. However, the majority of open hand prosthesis designs have only limited functionality (open-close), they are not robust enough to be used in real-world situations often having limitations in stiffness, grasp strength, assembly precision or structural strength and they have only received sporadic testing when combined with pattern recognition on practical tasks [13].

II. Methods

The prosthetic hand presented in this work was designed to allow for the most common hand movements for activities of daily living, with particular focus on the most used movement macro-classes [14]. The prosthetic hand was designed following the requirements of patients and it is composed of a dexterous robotic hand, a socket including eight sEMG electrodes and a control system.

A. Dexterous hand prosthesis

In most cases the available open source hand prostheses designs have limited functionality (open-close), they are not sufficiently robust to be used in real life conditions and they have been limitedly tested in combination with pattern recognition on real life tasks. The prosthetic hand presented in this work was designed to facilitate daily tasks as much as possible.

It is based on previous 3D printed open source hand prosthesis, the HANDi HAND, designed at the University of Alberta (Canada) [12], that includes six actuators and a variety of sensors (including pressure sensors and encoders for finger positioning). However, following a set of real life tasks tests [13], the hand was strongly redesigned to increase ergonomics, functionality for activities of daily living and usability: limitations such as the finger orientation, the zip-tie return spring, surface grasp friction and strength were addressed and intentionally improved.

The prosthetic hand includes six servomotors: five for finger flexion, one for thumb ab-adduction. The fingers are positioned to be similar to real prostheses and to allow functionally grasping objects and they are designed to allow the user predicting their positioning more intuitively. The internal transmission and gear systems were designed from scratch with a desmodromic transmission to reduce friction and to increase grasp force and mechanic life. Several servomotor models were tested as well with the aim of increasing strength. The prosthesis was produced through SLS (Selective Laser Sintering) technique, which allowed the use of complex and detailed geometry. The material used for the dorsal part of the hand is Nylon (PA 12), which provides good mechanical properties and strength. SLS (Selective Laser Sintering) technology uses a laser to sinter and fuse together layer after layer of powdered material, thus creating more robust components compared to the more commonly known FDM (Fused Deposition Modeling). Another advantage is that the non-sintered powdered material acts as support during the 3D-printing process. This allows to produce more complex shapes and eliminates the need for physical supports during the production of the component. The design of the hand will be released open-source as soon as it is finalised.

B. Socket

The socket was designed and made by Playcast Srl[3]. The design of the virtual model of the socket was made on the basis of real data using an innovative 3D scanning technique which was applied to the patient's amputated forearm. The obtained 3D reconstruction is very accurate and in high resolution, allowing limited changes to create the socket using proprietary design tools of the company. Among the changes, adaptation to include eight sEMG electrodes was required to allow empowering machine learning based algorithms and to include the prono-supination mechanism. The socket was then printed with additive manufacturing using the FDM technique and using recycled plastic, with low impact on the environment and it is fully recyclable. The socket is composed of three pieces: one is adherent to the distal stump and activates the hand pronosupination; two make up the outer shell of the socket, facilitate the wearing process and transmit the loads to the elbow epicondyles, by means of low shore paddings. The two pieces are held together by velcro straps.

C. Control system

The prosthetic hand is controlled via eight Otto Bock

[1] http://www.coaptengineering.com/

[2] E.g. http:// openbionics.org/ ; http://enablingthefuture.org/

[3] https://www.playcast.it/

13E200 EMG sensors, which detect the contraction of the remnant muscles in the proximal stump. The signal is transmitted to an open-source electronic prototyping platform (Arduino Mega).

The various possible movements associated with different patterns of contraction of the muscles in the forearm are then analysed to control the prosthesis. Custom made classification algorithms (developed by Dynatec studio[4]) classify the signal associated to four hand postures (fist, wrist flexion, wrist extension, fingers spread, rest) on the Arduino, which is also used for controlling the servomotors for positioning the hand prosthesis. Among the possible grasps performed by the prosthesis, the following ones were tested in different sessions: cylindrical, tripod, index finger extension, rest, lateral, tip pinch.

III. Results

A. *Dexterous hand prosthesis*

The developed hand prosthesis represents an effective application of additive manufacturing to the development of dexterous and high functionality prosthesis controlled via machine learning (Fig. 1).

The prosthetic hand was designed to allow for the most common hand movements for activities of daily living, to facilitate daily tasks as much as possible.

The design and the positioning of the fingers allow a functional and effective grasping of objects of different shapes, including bottles, balls, credit cards, pens. Moreover, the ongoing process of redesigning the fingers has allowed to increase the predictability of their positioning during grasps. The desmodromic design of the internal transmission and gear systems allowed to control actively both the flexion and extension of fingers and allowed to reduce friction and to increase the life of the components.

Among the servomotor models that were tested, six Hitec HS-65MG provided the best compromise between component durability and strength. More powerful servomotors were tested though. Those would likely benefit the usability of the prosthetic hand, but at the current status the authors could not find more powerful components able to provide sufficient durability and reliability.

In general, the 3D printed prosthetic hand showed very good usability in terms of ergonomics, usability and capability to interact with the environment for grasping objects (Fig. 2). It costs less than 600 €, weights 350 grams and it is capable of performing the most useful grasps for activities of daily living and to effectively grasp objects. The current challenge for the team is to improve the grasp strength, to satisfy the requirements of everyday life. According to users, the prosthesis represents an important step in the direction for future prosthetics.

B. *Socket*

The socket was designed by Playcast Srl and offers high adaptability, low making times and costs, relatively good usability and the possibility to include several sEMG electrodes to empower machine learning based control algorithms.

The socket was designed and made with 3D scanning and printing, which allowed to strongly reduce the time required to make it. The obtained 3D reconstruction is very accurate and in high resolution, leading to a good fit to the forearm of the patient. It allows to include eight surface electromyography electrodes and it can be easily connected to the robotic hand prosthesis. The socket includes a wrist rotation system and demonstrated good usability in preliminary tests, it is easier to wear than traditional ones and it offers sufficient comfort for experimental tests. In order to improve the electrode contact with the skin, an elastic armband was used provide pressure on the top of the electrodes.

The socket offers several advantages over traditional ones due to Voronoi holes pattern. First, it is breathable and fully washable; second, it does not require qualified personnel to be made; lastly, it is cheaper than a traditional system and it is made of 100% recyclable plastic, with positive outcomes for the environment). In addition the production cost is limited (less than 600 €) and it weighs only 350 grams.

Improvements are currently being implemented aiming at extending the usability, which is currently limited, for allowing everyday life usage.

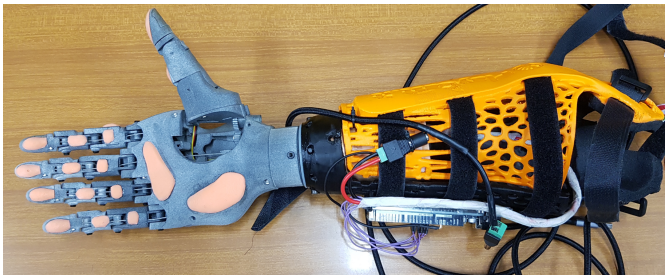

Fig. 1: 3D printed robotic hand and socket.

Fig. 2: Examples of hand grasp tests.

C. *Control system*

The control system is based on eight Otto Bock 13E200 EMG sensors (weight 4.5 g each), one Arduino Mega (cost less than 50 €, weight less than 50 g), one battery and custom-made machine learning algorithms. It demonstrated to perform well in practical tests, allowing to easily open and close the prosthesis in 3 different movements selected among the

[4] https://www.dynatecstudio.it/

taxonomy of hand movements [14]. The control system employed in this study experiments used a gesture recognition approach that made it possible to swiftly and automatically identify the required grasp. In addition to controlling the gesture used to open the prosthetic hand, the system was tailored to the characteristics and demands of the patients, enabling them to grip objects.

Controlling the prosthesis in the different movements was very fast and reliable, making its usage almost instantaneous, smooth and pleasant according to the users. The authors are current working to solve challenges mainly related to forearm positioning issues, which are well known in the domain of dexterous prosthetics.

IV. Discussion & Conclusion

The promising findings presented in this paper point to the viability of flexible robotic prosthetic hands based on additive manufacturing, 3D scanning and machine learning based control systems. These technologies are currently more widely available than in the past due to the components' and devices' rising affordability.

Despite the requirement to improve the socket usability and the prosthesis strength, the system demonstrates high usability capabilities and well represents the capabilities of the forementioned modern technologies for the future of prosthetics.

The whole system weighs less than 900 g plus the battery and costs less than 1’400 € excluding the electrodes. The electrodes currently represent the most expensive part of the system, but those could be replaced with open-source low cost solutions in the future. These facts suggest that the experimental setting can be successfully replicated and applied in situations where cost is a major concern, such as in the pediatric population, in underdeveloped nations, and in research teams with limited resources.

Adaptation of cardiac deformation pattern during exercise in children

D. Collia[1], and G. Pedrizzetti[1]
[1] *Department of Engineering and Architecture, University of Trieste, Italy.*

***Abstract*—In the cardiovascular system, the geometric remodeling of the cardiac chambers is the main mechanism allowing increased performance of athletes during exercise as well as underlying the pathological progression leading to heart failure. In this study we analyze cardiac mechanics in healthy children during four phases of physical exercise, *Rest*, *Mid*, *Peak* and *Recovery*, by 3D echocardiography. The analysis is performed in comparison with a set of normal children with the objective to identify the modifications induced by exercise that lay at the basis of cardiac remodeling induced by physical exercise. The ventricular functional performance is analyzed in terms of tissue deformation with the aim of verifying the activation of cardiac fibers through the response in terms of strain tensor its principal strain values and directions. This evaluation brings indications for identifying clinical markers that anticipate exercise-induced remodeling and that can also be useful for a deeper understanding of remodeling in cardiovascular pathologies or during therapeutic protocols.**

***Keywords*—Strain, cardiac mechanics, left ventricle, cardiac fibers, myocardial deformation.**

I. INTRODUCTION

The function of the human heart is that of a mechanical pump that creates and sustains blood motion through a sequence of passive relaxations and active contractions of the cardiac tissue. In particular, the left ventricle (LV), which represents the most important chamber according to the pumping purpose, fills with low pressure blood flowing from the left atrium (diastole) and contracts vigorously to eject blood at high pressure into the aorta (systole). This process is characterized by an intense dynamic interaction between the flowing fluids and the surrounding tissue; minor alterations to such a dynamic balance affect the reciprocal adaptive behaviors and can induce long-term progressive geometric changes [1], [2].

Progressive modifications of cardiac geometry are accompanied by an alteration of its functional parameters along a process known as cardiac remodeling. Typically, cardiac remodeling develops as a adverse consequence of almost all cardiac dysfunctions and leads to the syndrome of heart failure, the principal social threatening cardiac dysfunction [3], [4]. However, cardiac remodeling mechanism can also develops favorably as a result of virtuous factors like physical exercise. This type of remodeling is characterized by a structural and functional adaptations that facilitates the performance of the heart related to increased demand of blood flow like, at the extreme end, those found in the athlete's heart [5], [6]. Understanding the primary causes leading to either pathological or favourable cardiac remodeling is of paramount importance in multiple aspects of cardiology like anticipating disease progression, supervise healing response to physical exercise, monitor athletes during extreme performance, or even children during growth. At the present time, reliable models of remodeling are still largely unsatisfactory are not consistently predictive [7].

Within this general picture, the present study analyzes the structural adaptation of the left ventricles in a pediatric population during physical exercise. The LV function is analyzed from geometry extracted from three-dimensional (3D) echocardiography during four phases of exercise (*Rest*, *Mid*, *Peak* and *Recovery*). The study is performed through the evaluation of the strain tensor that permits evaluating both the entity and the direction of contraction and provides a comprehensive description of LV dynamics during the various cardiac phases of physical exercise in response to an adaptive effort.

This study aims to identify the alterations of LV function associated with exercise, which underlay the longer-term macroscopic adaptations induced by physical exercise therapy or found in athletes' heart. Results are also expected to be informative on the general phenomena associated to remodeling.

II. MATERIALS AND METHODS

The analysis is performed in a group of healthy children undergoing physical exercise test, it also includes an independent large group of age-matched subjects as control reference. All participants had normal cardiac function and absence of any identified disease. All subjects underwent three-dimensional (3D) echocardiography following a non-invasive protocol performed in collaborating clinical institutions for screening purpose. The 3D echocardiography requires that recordings are spatially focused on the LV to get high time resolution. The recorded 3D imaging datasets were analyzed by the same clinical institutions by a dedicated software (4D LV Analysis, TomTec Imaging System GmbH, Unterschleissheim, Germany) to extract the moving ventricular geometry. In that software, the boundary (endocardium) between ventricular tissue and blood pool is first drawn manually through the graphical user interface at one instant, then the software tracks the anatomical features over the entire heartbeat by an optical flow method. This analysis produces a triangulated surface of the moving endocardial geometry where vertices identify material points. The present study is dedicated to the

preliminary, blind analysis of these endocardial surfaces as provided by the clinical institutions in anonymous form.

Each subject enrolled in the study was recorded at four time phases during physical exercise: *Rest*, *Mid*, *Peak* and *Recovery*. The control reference group used for comparison was recorded at rest. All recordings are analyzed individually, then the modifications during physical exercise as well as the comparison with the reference normal group are performed statistically in terms of synthetic parameters of volumes, ejection fraction (EF) and strain. In addition, to improve the statistical comparison between the different phases in terms of spatially extended pattern, the geometries were averaged among the group during each phase of the physical exercise. To perform this averaging procedure, all ventricles in a set are translated to a common center, then anatomical landmarks (mitral annulus, center of aortic outlet, and apex) are identified and a 3D rotation is performed to bring all ventricles to a common axis and with the valve position aligned.

The dynamic properties of the cardiac tissue are principally studied in terms of tissue deformation or strain. Strain during cardiac deformation is described mathematically by the machinery of finite deformation [8], [9], which is briefly recalled here. Consider an initial state, say at a reference time $t = 0$ typically taken at end-diastole, where the material points in the tissue are described by their coordinates $\mathbf{X}$, and a deformed state at a second time t where each material point has moved to a new position $\mathbf{x}(\mathbf{X}, t)$, such that evidently $\mathbf{x}(\mathbf{X}, 0) = \mathbf{X}$. The transformation from $\mathbf{X}$ to $\mathbf{x}$ is described by the deformation gradient $\boldsymbol{\mathcal{F}}$ defined as

$$\mathcal{F}_{ij} = \frac{\partial \mathrm{x}_i}{\partial \mathrm{X}_j}. \tag{1}$$

Tensor $\boldsymbol{\mathcal{F}}$ can be separated through the polar decomposition in rotation and deformation

$$\boldsymbol{\mathcal{F}} = \boldsymbol{\mathcal{R}}\boldsymbol{\mathcal{U}}; \tag{2}$$

where $\boldsymbol{\mathcal{R}}$ is the rotation matrix, and $\boldsymbol{\mathcal{U}}$ is the right stretch tensor that contains the information about the deformation occurred during the time interval $(0, t)$. Along this approach, the straightforward definition for a *strain tensor* is

$$\boldsymbol{\mathcal{S}t} = \boldsymbol{\mathcal{U}} - \boldsymbol{\mathcal{I}}; \tag{3}$$

which is known as the Lagrangian strain, because it is computed following the material points identified in the original configuration. The strain tensor defined by (3) is also known as *Biot strain tensor* and as engineering strain, because this definition is commonly used in engineering for small deformation. This definition corresponds to the most intuitive description of deformation. For example, in one-dimensional (1D) deformation, a segment of length L_0 is stretched (compressed) to a deformed length $L_1 = L_0 + \Delta L$ and the strain measures the relative change of length $\mathcal{S}t = \frac{\Delta L}{L_0}$, which is a measure of the effective elongation (shortening) of an originally undeformed fiber. This definition of strain is that considered as a standard in cardiology at least for 1D strain in clinical imaging [10].

Several other definitions of strain based on the knowledge of the general transformation (1) are present in literature [9], [11], [12]; they may be less intuitive for the description of strain while they may present some other theoretical advantages; however, they are not common in clinical cardiology. In any case, results obtained with different definitions are comparable and interchangeable because all standard definitions of strain tensor associated to a common $\boldsymbol{\mathcal{F}}$ present the same eigenvectors while the eigenvalues are mathematically related one to the other.

Cardiac contraction starts at $t = 0$ from an undeformed reference configuration taken at the end of diastole, the instant in which the volume is maximum, and ends at the end of systole, when the volume is minimum and strain eigenvalues are negative. LV deformation is evaluated in terms of principal strain (PS), the most negative eigenvalue of the strain tensor (3), and secondary strain (SS), which is the second eigenvalue. The principal direction of contraction is obtained by the eigenvector corresponding to the PS. Evaluations are reported in terms of spatial pattern of PS value and direction evaluated at end-systole, and in terms of global (spatially-averaged) strain values (GPS, GSS) during tuime along the heatbeat. For comparability with existing studies, the global longitudinal and circumferential strain values (GLS, GCS) are also computed.

III. Results

The population is first compared during the rest phase with respect to the reference control group. Results confirm that the analyzed population is representative for normal children in terms of geometry (volumes) and contraction properties (EF and strain).

During exercise, the ventricle must pump a greater amount of blood per minute to the body, this objective is achieved by increasing the heart rate and by increasing muscular contraction resulting to a smaller LV volume at the end of systole. Overall, the increase of contraction is associated with an increase (more negative) PS as exercise progresses. This increased contraction corresponds to a spatial distribution of PS that becomes more uniform. The spatial distribution of PS during the four phases of the physical exercise is shown in figure 1, for one representative subject. The color map is drawn above *strain-lines* everywhere tangent to the corresponding eigenvector.

At the *Rest* phase, the LV strain directions range from circumferential to right-handed or left-handed helical directions in the various regions of the ventricle. This pattern is the result of the contraction of myocardial fibers whose arrangement vary from helical in the inner layer (sub-endocardium) through circumferential (mid-myocardium) to counter-rotating helix at the outer layer (sup-epicardium) [13], [14]. Subsequently, increasing the workload (*Mid* and *Peak* phases) the direction of deformation tends to become more circumferential; this is the result of the activation of multiple myocardial layers with different fiber directions across the entire thickness to achieve higher performance. In other terms, the concurrent contraction along multiple directions results in a strain tensor whose PS is

approximately aligned with the circumferential direction and a SS that is more longitudinal. This picture can be reinforced by the analysis of the time course of GPS and GSS: immediately at the onset of contraction the former presents a sharp decrease, such a strong contraction in the dominant direction provokes an initial stretch in the perpendicular direction and GSS increase to a positive peak; soon afterwards, all fibers become active for the contraction, both GPS and GSS decrease and reach, at end systole, their stronger exercise-induced value. Finally, in the *Recovery* phase it is interesting to note that although global contractile values return similar to those at rest, this normal degree of contraction is achieved with a different pattern of contraction that witnesses the persistent modification to LV function induced by exercise.

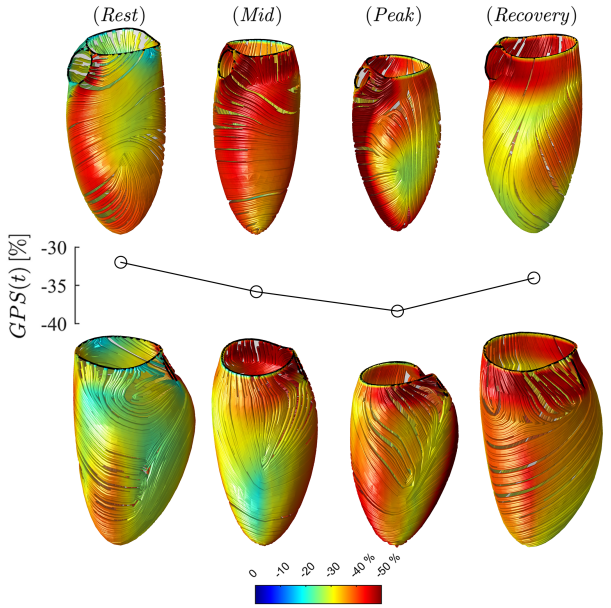

Fig. 1: Color map of the first principal strain (most-negative eigenvalue of the strain tensor) at the end of systolic contraction. Colors are drawn over the strain-lines (tangent to the corresponding eigenvector) for (*Rest*), (*Mid*), (*Peak*) and (*Recovery*), each one shown in two opposite facing views.

IV. Conclusions

The study of LV strain during physical exercise allows to identify the mechanical response induced by this type of stress and the likely longer-term remodeling that can be induced by its continuous application.

The present results, although preliminary, show evidence of modification in the cardiac deformation pattern induced by physical exercise. This modification is characterized by an increase of cardiac deformation along all directions with principal direction of contraction that becomes approximately circumferential.

The interpretation of strain results suggest that physical exercise stimulates the activation of myocardial fibers across the entire thickness [15]. This result is consistent with the increased myocardial thickness observed in athlete's heart and indicates that such an increase corresponds to increased muscular mass that is fully reversible and well different from a pathological hypertrophy. This result also supports therapies based on physical exercise indicating how they train the myocardium over the thickness and improves its efficiency [16].

On the methodological perspective, the present approach appears promising to evaluate the presence of early alterations of cardiac function that may be informative on the possible progression of remodeling during healing or disease.

Abstract **– Anomalous Aortic Origin of the Coronary Artery (AAOCA) is a rare congenital heart disease and is a major cause of sudden cardiac death (SCD). Surgical operation is indicated for symptomatic forms or in the case of ischemic signs. Surgery aims to relieve the site of coronary compression along the anomalous segment. Several surgical techniques are available to resolve the coronary compression causing myocardial ischemia.**

This study aims to develop and create a computational tool to support surgeons when planning which technique to adopt to obtain the best fluid dynamic result.

We created a model based on Computational Fluid Dynamics (CFD) to compute post-operative coronary flow based on pre-operative data.

Although limited to preliminary investigation, the proposed model can replicate the three surgical modalities used in the clinical practice to treat AAOCA, computing the post-operative flow.

Future developments will target the fine-tuning of the model towards a patient-specific analysis, including clinical measurements, and the model validation to enhance its credibility.

Keywords **– anomalous coronary, computational fluid dynamics, surgical planning, decision support.**

I. Introduction

AAOCA is a rare congenital heart disease and is one of the leading causes of SCD in athletes and young subjects. It can remain silent for life for most of the sedentary and non-sports population [1] but the occurrence of SCD is unpredictive and not directly related to the amount of effort.

Surgical treatment aims to remove or resolve lumen reduction along the anomalous segment of the coronary artery. There are several surgical techniques (e.g., unroofing, reimplantation, patch osteoplasty) [2]–[6] adopted to treat such peculiar coronary compression [1], [7]. The unroofing consists of the longitudinal opening of the intramural segment up to the coronary take-off (Fig. 1a). Patch osteoplasty requires an extensive incision of the coronary artery and aorta on the anterior surface and the placement of a pericardial patch to recreate the roof and continuity of both structures (Fig. 1b). Reimplantation consists of a section of the anomalous coronary artery that is detached from the aorta at take-off; the coronary is re-implanted in another region of the aorta that is not subject to compression (Fig. 1c).

Due to the rarity of the disease and the impossibility to perform randomization based on the surgical operation a systematic comparison of techniques has not yet been conducted. The impossibility to determine which intervention is the most appropriate to recreate the physiological condition surgical planning still carries a degree of uncertainty.

Based on these considerations, our goal is to create a patient-specific computational tool that supports the surgeon in outlining the most appropriate surgical plan to restore normal coronary flow.

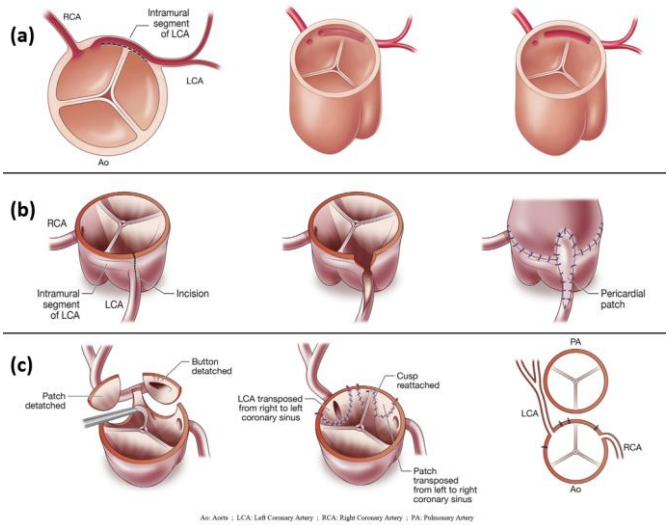

Fig. 1: Surgical techniques available to resolve the coronary compression causing myocardial ischemia: (a) unroofing, (b) patch osteoplasty, (c) reimplantation [8],[9].

II. Materials and Methods

We have divided the process into three steps (Fig. 2). In the pre-processing step the geometric models, i.e. the 3D computational domain, were created starting from the segmentation of the preoperative Computed Tomography (CT) images. The preoperative and healthy models were created using the Rhinoceros 6 software; the three different postoperative parametric models were built using Grasshopper (a Rhinoceros 6 plug-in).

In the processing step, the Navier-Stokes equations have been resolved using SimVascular software. The blood was

assumed to be a Newtonian fluid with a viscosity of 0.04 g/cm and a density of 1.06 g/cm^3 [13]. Boundaries conditions (BC) consisted of a 0D model to recreate peripheral circulation: the aorta outlet was modeled with a Windkessel 3-element circuit [10], and the coronary outlet was modeled with a 6-element circuit with an intramyocardial pressure generator [11].

Finally, in the post-processing step, the results were extracted, and we analyzed coronary flow (Q), pressure drop (ΔP), and wall shear stress (WSS) of the anomalous segment to evaluate all the techniques and find the one that provides the best result.

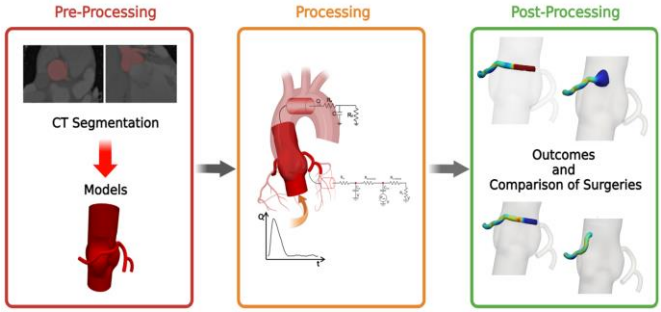

Fig. 2: Implemented Computer-Aided Engineering (CAE) process composed of three steps: pre-processing i.e. models creation, processing i.e. computational problem solving, post-processing, and comparison of results.

III. Results

A. Simulation results

We compared the preoperative model and the healthy model. This comparison makes the reduction in Q and P due to the anomalous segment evident (Fig. 4a-4b). The figures show a distance of ≈ 41 mmHg between healthy and preoperative models in the pressure plot and a distance of ≈ 1.08 mL/s in the flow plot (Table I).

We also compared the three different surgical models with healthy and preoperative cases. A comparison of flow rate and pressure is shown in Table I and Fig. 4c-4d. A flow rate improvement of ≈ 86% in the patch model, ≈ 83% in the reimplantation model, and ≈ 80% in the unroofing model can be observed. Instead, for pressure, the increase is ≈ 92%, ≈ 88%, and ≈ 83% respectively. All these values are supported by the Euclidean distance between the healthy and postoperative models (Table I).

In Fig. 3 we can observe shear stress. The preoperative model shows WSS > 44 dyne/cm^2, and that in all postoperative models decreases (10 < WSS < 25 dyne/cm^2). We have considered low, middle, and high WSS 5.7±2.3, 18±4.7, and 43.9±21.4 dyne/cm^2 respectively [12]. Low values cause increased vessel wall thickness, while high values cause inflammation and calcific plaque formation. Both compromise coronary flow. Instead, middle values are physiological values.

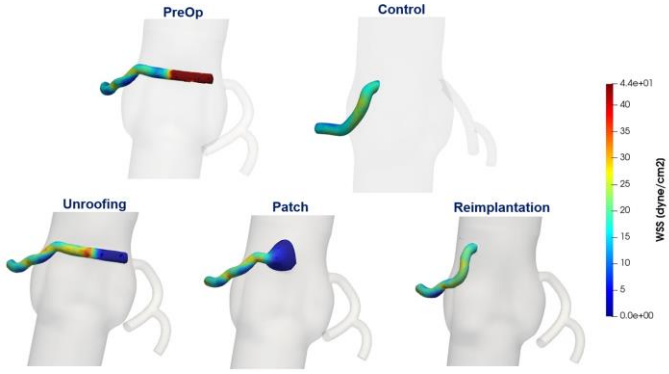

Fig. 2: Heatmap of time average WSS.

TABLE I: POSTOPERATIVE RESULTS FROM IDEAL MODELS

	$Q_{Eu.Dist.}$	$P_{Eu.Dist.}$	$Q_{Diff.\%}$	$P_{Diff.\%}$
PreOp	1.076	40.997	///	///
Unroofing	0.215	6.987	-79.985	-82,958
Patch	0.149	3.310	-86.164	-91,927
Reimplantation	0.185	4.862	-82.856	-88,140

Euclidean distances between health flow and pressure and pre- or postoperative flow and pressure, and quantification of improvements through difference of Euclidean distance flow and Euclidean distance pressure $(((PostOp\text{-}PreOp)/PreOp)*100)$.

B. Patient-specific example

We have also tested the ideal model in a patient-specific case. The preoperative simulation shows a pressure drop of 30 mmHg. We obtained a ΔP of 1.8 mmHg in unroofing simulation, 4.2 mmHg in patch simulation, and 1.8 mmHg in reimplantation simulation. We can observe a flow improvement in all the investigated post-operative scenarios; in particular, the model suggests for the reimplantation case that the flow is almost doubled when compared to the pre-operative condition.

IV. Discussion

Several intervention techniques exist to treat AAOCA, and this study aims to develop a novel computational tool to support surgical planning.

We created an ideal model to test the feasibility of the project and the possibility of correctly replicating the surgical intervention. The tool can distinguish the healthy model from the pathological model (Figs. 4a-4b) in which it replicates a restricted coronary flow pattern. The three surgical models were able to recreate unrestricted coronary flow with characteristics like the healthy model (Fig. 4c-4d). In this preliminary analysis, we can observe that all techniques restore adequate coronary flow although the characteristics of each postoperative flow suggest that the patch osteoplasty gives the best results by achieving the most unrestrictive and less turbulent flow.

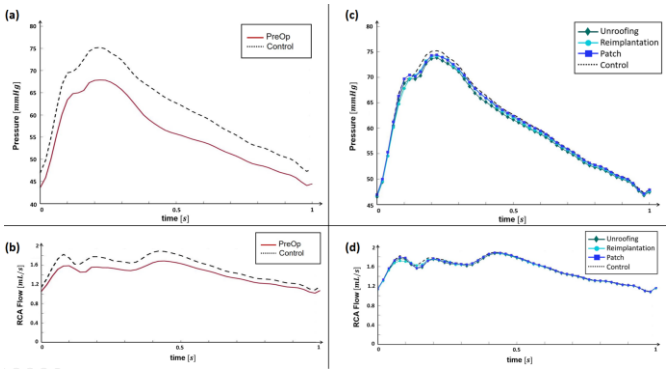

Fig. 4: Comparison of health model and preoperative model in terms of pressure (a) and flow (b); comparison of health model and all three postoperative models in terms of pressure (c) and flow (d).

In the second part, we tested the tool with patient-specific data. Again, we can distinguish the preoperative model from the postoperative model and the different types of surgery (Fig. 5). We can observe that patch osteoplasty and unroofing are better than the reimplantation technique. Clinically, unroofing is less difficult than patch osteoplasty, so unroofing is the treatment suggested.

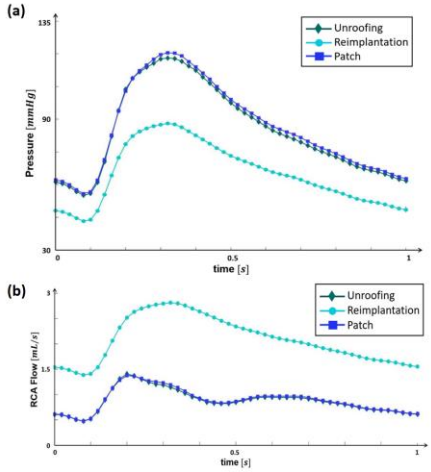

Fig. 5: Pressure (a) and flow (b) patterns of the three different surgical treatments.

V. Limitation and Conclusion

The study contains several limitations mainly related to the assumption and simplification adopted to replicate the complex physical phenomenon: we assume that the wall compliance is negligible imposing rigid wall conditions [13].

Finally, AAOCA concerning the right coronary (R-AAOCA) with intramural (IM) segment is more frequent than left coronary anomalies and the no-IM segment [14]. For this reason, the ideal model and patient-specific model concerning an R-AAOCA whit IM segment case.

This study provides the first biomechanical tool based on computational simulations to highlight the coronary flow differences when adopting different surgical techniques. So, the study is propaedeutic to predict hemodynamic indicators to support the surgeon in the choice of AAOCA surgery and identify which one can return the best fluid dynamic results in a patient-specific scenario.

As a future development, the results of the computational tool will be compared with data from post-operative AAOCA patients. A validation plan will be created; specifically, the study will be extended to all types of AAOCA.

Acknowledgment

The development of this study was possible through the collaboration of Università degli Studi di Pavia with IRCCS Policlinico San Donato. The IRCCS Policlinico San Donato is a Clinical Research Hospital recognized and the study was partially supported by the Italian Ministry of Health.

3D Finite Element Analysis of a Percolating Cluster inside the Mineralized Collagen Fibril

A. Pica[1], A. Marinozzi[2], F. Marinozzi[1], and F. Bini[1]
[1]*Department of Mechanical and Aerospace Engineering, "Sapienza" University of Rome, Rome (Italy)*
[2]*Orthopedy and Traumatology Area, "Campus Bio-Medico" University, Rome (Italy)*

***Abstract*—Bone is characterized at the nanoscale by the mineralized collagen fibril (MCF), mainly composed of apatite minerals and collagen. Among several factors, the 3D architecture of the nanostructure affects the tissue mechanical performance. In the present study, we developed a structural analysis of a model of apatite embedded in the collagen matrix, characterized by a percolating cluster, i.e. a spanning network of connected apatite minerals within the MCF. The geometric model is obtained after applying $6 \cdot 10^6$ translational and rotational perturbations to an ordered arrangement of mineral. The mechanical behaviour of the percolating cluster is compared with a model characterized by an ordered arrangement of mineral. The 3D Finite Element models are analysed under tensile and compressive simulation conditions. Normal and shear stresses are compared among the models. The outcomes suggest that the presence of a percolating cluster causes a general stiffening of the model, representing a condition of high susceptibility to fracture.**

***Keywords*—3D FEM, percolation theory, bone nanostructure.**

I. Introduction

BONE exhibits a hierarchical organization from the nano- to the macro-scale [1]. The nanoscale building unit of bone is the mineralized collagen fibril (MCF) that is composed of inorganic apatite minerals, type I collagen fibril, water and a small percentage of non-collagenous proteins (NCP) [2]. The highly organized embedded nanometric building blocks of collagen molecules and apatite crystals lead to enhanced features of the MCF with respect to the characteristics of the single constituents. The collagen component provides elasticity to the structure, while the apatite minerals contribute to the MCF stiffness and strength. In addition, water diffusion has a crucial role to bone mineralization ensuring the maintenance of an adequate supply of nutrients, growth factors and ions [3]. Water also mediates the interactions between apatite minerals and collagen [4]. Among several factors, the 3D architecture of the nanostructure affects the tissue mechanical performance.

Collagen molecules self-assemble in a staggered manner into fibrils with diameters ranging from 50 to 200 nm and length of about 1000 nm [5]. The arrangement of apatite crystals at the length scale of the MCF is still a subject of debate, although improvements concerning the techniques of visualization have been made [1], [6]. Apatite crystals are located both within and between collagen fibrils, i.e. intra and interfibrillar mineralization respectively. The organization of these crystals is usually illustrated in literature according to the model of 3D deck of cards arrangement in which the platelets lie almost parallel throughout the collagen fibril [7]. According to [8], [9], the mineral arrangement has a staggered structure in the longitudinal direction of the collagen fibril and parallel layers in the equatorial plane of the MCF. Recently, tomographic investigations highlighted that the mineral phase is present as individual crystallites and also as aggregates [1], [6]. For instance, Xu et al. [6] identified stacks of up to 8 apatite platelets at the length scale of single MCF. In this context, Landis et al. [10] also suggested that apatite crystal fusion can influence the biomechanical properties of bone.

In addition to experimental investigations, computational and numerical modelling based on probabilistic methods [11]–[13], molecular dynamics simulations [5] and finite element (FE) methods [14]–[17] have been developed to assess the contribution of the nanoscale components to the mechanical performance of bone. For instance, FE studies of Vercher-Martinez [15] have outlined that the arrangement of apatite minerals, the distance between apatite crystals and the mineral overlapping have considerable influence on the mechanical behaviour of the MCF.

Recently, Bini et al. [18] analysed the mineral network within the MCF applying the percolation theory. The percolation phenomenon is characterized by the onset of connected networks that span the domain of interest from one side to another. Applying the Monte Carlo technique, Bini and co-workers [18] investigated the formation of spanning networks of apatite crystals for different mineral volume fractions characteristic of the human bone tissue. In this framework, we aim to analyse here the mechanical behaviour of a percolating cluster of apatite platelets by means of FE analysis. The outcomes are then compared with the mechanical behaviour predicted for apatite platelets arranged in an ideal staggered configuration.

II. Methods

The mechanical behaviour is investigated by considering a geometrical model of the apatite cluster. The mineral configuration is generated by applying the Metropolis algorithm [19] to better mimic the mineral arrangement within the MCF. Apatite crystals start in an ordered, aligned configuration according to the model proposed by Hodge-Petruska [8] and Jäger and Fratzl [9]. Subsequently, each platelet is displaced and inclined by random amounts. The method is described in detail in a previous study of Bini et al. [18]. In the present work, we considered a cluster of apatite minerals (Fig. 1) spanning the equatorial plane of the MCF, specifically in the width (w) direction (see Fig. 4 of [18]). We assume all random values for the geometrical parameters that describe the apatite minerals within the ranges indicated in Literature [2]. Namely, the average width, thickness and length dimensions of the apatite platelets involved in this model are 43.5 nm, 3.65 nm and 101.8 nm, respectively. In this

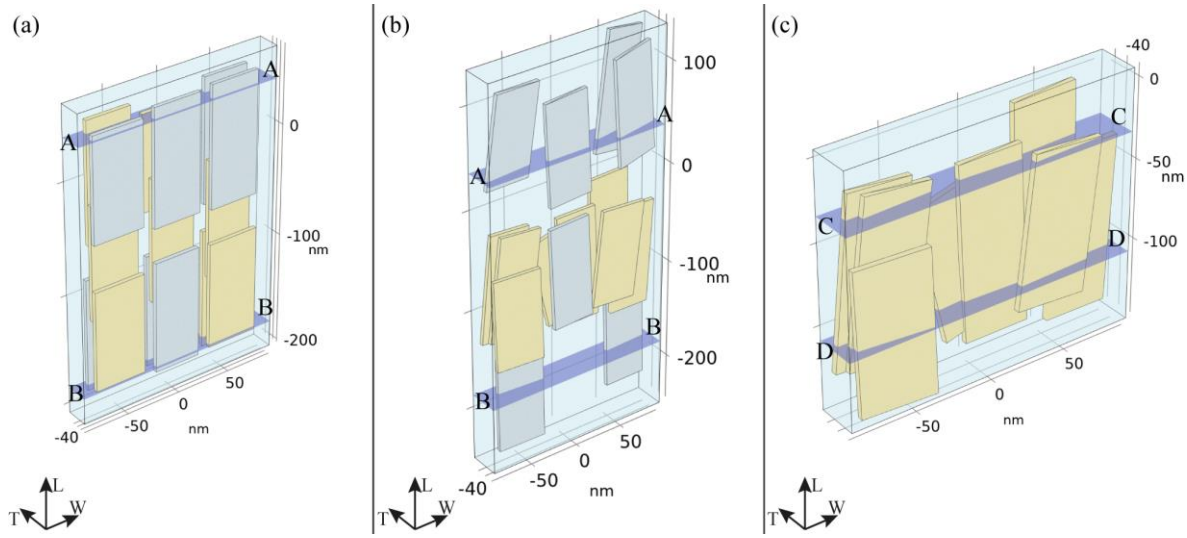

Fig. 1: 3D geometric model. In (a) starting configuration of apatite minerals (light grey and light yellow) embedded in the collagen matrix (light blue) aligned with the axis of the coordinate system. In (b) configuration of minerals after roughly $6 \cdot 10^6$ moves and rotations. In (c) percolating cluster. Light yellow platelets represent components of the percolating cluster.

study, the cluster was individuated in a MCF with a diameter of 200 nm and a mineral volume fraction of 37 percent [18], and it was generated after roughly $6 \cdot 10^6$ inclinations and rotations of the platelets [18].

The model with ordered apatite platelets (Fig. 1a) is determined considering the initial configuration of the mineral platelets that compose the percolating cluster. Analysing the initial arrangement, it was observed that these minerals are part of three repeating unit cells, each composed of 5 apatite crystals [9] (Fig. 1a). In Fig. 1b, we depict the platelets composing the three unit cells after the roughly $6 \cdot 10^6$ inclinations and rotations of the platelets. Given the variable dimensions of the apatite minerals, we considered two section planes (AA and BB in Fig.1) in order to obtain the maximum cross section of mineral on which the external stimulus is acting. Thus, sections at a distance of 10 nm from the superior and inferior boundaries have been performed in the ordered module (Fig. 1a). For visualization purposes, the section planes AA and BB at the same longitudinal coordinates were reported also in Fig. 1b. Finally, we determined the geometrical model that takes into account only the cluster of apatite minerals (Fig. 1c). Two sections (CC and DD) at the superior and inferior boundaries, respectively, are considered in order to obtain the maximum cross section of mineral on which the external stimulus is applied. In addition, according to [15]–[17], the collagen is represented as a continuum matrix between the mineral platelets. The generated geometry is converted into a non-uniform tetrahedral mesh. In Table 1 we indicate the corresponding number of degrees of freedom achieved for each model.

The apatite mineral is modelled assuming linear elastic, isotropic and homogeneous material behaviour. The collagen matrix is assumed to act as a nonlinear, homogeneous, hyperelastic material. Specifically, we considered a Neo-Hookean nearly incompressible constitutive model for collagen with the following strain energy ($W_{collagen}$) [20], [21]:

$$W_{collagen} = \frac{1}{2}\mu(I_1 - 3) + \frac{k}{2}(J_{el} - 1)^2 \quad (1)$$

where J_{el} is the elastic volume ratio calculated as the determinant of the elastic deformation gradient, I_1 is the first invariant of elastic right Cauchy-Green deformation tensor. The parameters μ and k represent the Lamé parameter and the material bulk modulus respectively, and are calculated as follows [22]:

$$\mu = \frac{E}{2(1+\nu)} \quad (2)$$

$$k = \frac{E}{3(1-2\nu)} \quad (3)$$

where E indicates the Young's modulus and ν is the Poisson's ratio. Tissues properties are defined within the range available from literature. As typical values to perform the mechanical analysis, we assume Young's modulus of 1 GPa [23] and 114 GPa [24] for the collagen and apatite mineral, respectively. Concerning the Poisson's ratio, it is attributed a value of 0.23 to the apatite [23] and 0.35 for the collagen matrix [25]. In addition, we assume a critical energy release rate of 1 J/m^2 [24] for the apatite mineral and of 0.2 J/m^2 [24] for the collagen.

To analyse the mechanical behaviour, uniaxial tension and compression simulations are performed for both 3D models. Appropriate boundary conditions (Fig. 2) are applied to simulate tensile and compressive loading.

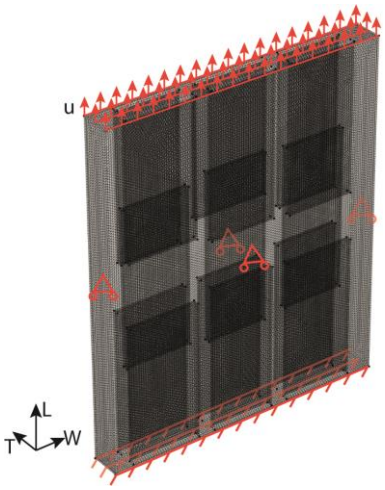

Fig. 2: Mesh and boundary conditions applied for the model considering the ordered configuration of apatite platelets.

TABLE I
FE MODEL STATISTICS

Model	*Number of mesh elements*	*Degrees of freedom*
Ordered configuration	1 411 586	21 887 053
Percolating Cluster	540 864	8 405 739

Displacements and rotations of the bottom surface are constrained [16], [23]. A roller condition is applied on the lateral surface of the collagen matrix [23]. The simulation is performed using monotonic displacement control with increments set in the order of 10^{-3} times lower than the average apatite length [26], until failure occurs. The same boundary conditions are implemented in both 3D models of ordered and disordered apatite platelets embedded in the collagen matrix.

The mechanical behaviour is investigated considering the phase field model. Further details of the phase field method can be found in [26], [27]. The phase field determines the damage through the minimization of an energy functional [26]:

$$E(u,\Phi) = \int_\Omega (1-\phi)^2 W d\Omega + \int_\Omega G_c \left(\frac{1}{2\ell_{int}}\phi^2 + \frac{\ell_{int}}{2}|\nabla\phi|^2\right) d\Omega \quad (4)$$

with u is the displacement field, G_c is the critical energy release rate, W is the strain energy density and ϕ is the phase field variable that varies smoothly from 0, i.e. undamaged material to 1, i.e. totally broken. The width of the transition zone of ϕ is controlled by the internal length scale ℓ_{int}. In this study, the parameter ℓ_{int} is chosen to be small relative to the apatite length, namely 3 percent of average apatite length, as in [28]. The phase field variable ϕ is solution of the differential equation:

$$\frac{\partial(1-\phi)^2}{\partial\phi} H_d - (\phi - \ell_{int}^2 \nabla^2\phi) = 0 \quad (5)$$

$$H_d = \max W \quad (6)$$

The function $(1-\phi)^2$ represents the degradation function that penalizes the material stiffness according to the value of ϕ. The governing equations for structural mechanics are reported in the following:

$$\nabla \cdot \sigma_d = 0 \quad (7)$$

$$\sigma_d = (1-\phi)^2 \sigma \quad (8)$$

where σ_d is the stress tensor of the damaged material, and σ is the undamaged stress tensor. For the linear elastic material the stress tensor follows the Hooke law:

$$\sigma = C : \varepsilon(u) \quad (9)$$

where C is the stiffness tensor and ε is the strain tensor.

For the hyperelastic material, the stress tensor follows from the definition of the second Piola-Kirchoff stress [29]:

$$\sigma = 2\frac{\partial W}{\partial C_{CG}} \quad (10)$$

where C_{CG} is the right Cauchy-Green deformation tensor.

To optimize the computational cost, the system of equations is solved using the Generalised Minimal Residual (GMRES) method by employing a geometric multigrid left preconditioner.

In Fig. 3 we represent the generated force in function of the prescribed displacement.

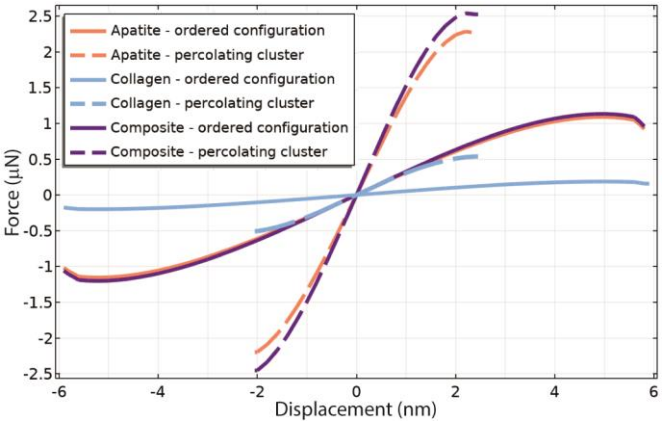

Fig. 3: Force-displacement curves for each component, i.e. apatite platelets and collagen matrix, and for the overall apatite – collagen composite of both models, i.e. ordered configuration and percolating cluster.

III. RESULTS AND DISCUSSIONS

In this study, we focused on the analysis of the mechanical behaviour of a percolating cluster of apatite within the MCF comparing it with an ordered configuration of minerals. Simulations were developed with different loading conditions, i.e. tension and compression, in order to capture variations in the stress distribution induced by the onset of the percolating cluster.

For the ordered apatite configuration, we calculate the normal and shear stresses (Fig. 4) and perform a comparison with earlier results reported in [17], where a FE analysis has been developed concerning one unit cell of MCF. The highest normal stress occurs in the mineral platelets, while maximum values of shear stress emerged in the collagen matrix in agreement with [7], [9]. The mechanical behaviour of the ordered configuration of apatite is consistent with previous data [15]–[17], thus supporting the efficacy of the model.

In the percolating cluster, for both tensile and compressive simulation, the normal and shear stresses (Fig. 5) show higher values than in the ordered configuration. As expected, the percolating cluster causes a general stiffening of the model. The peak values of stress occur in the region of

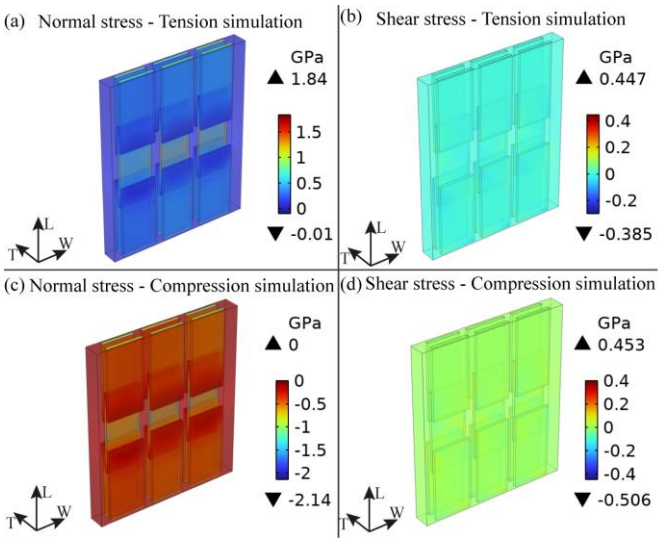

Fig. 4: Maximum normal (a, c) and shear (b, d) stress distributions achieved for the model with aligned apatite minerals during tensile (a, b) and compressive (c, d) simulation.

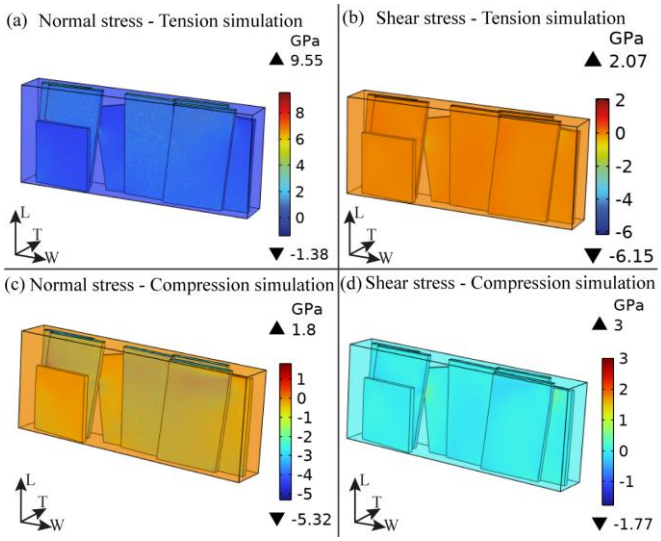

Fig. 5: Maximum normal (a, c) and shear (b, d) stress distributions achieved for the percolating cluster during tensile (a, b) and compressive (c, d) simulation.

interpenetration between apatite platelets [18].

Although highly consistent with available literature, the present FE analysis has some limitations. Since non collagenous proteins (NCP) represent less than 10% of the total organic components, these proteins were omitted here, following the study of [15], [23], [30]. Further studies will take into account also the NCP contribution to the mechanical behaviour of abnormal configurations of apatite, e.g. percolating clusters.

IV. Conclusion

In this study, we developed a FE analysis of an abnormal configuration of apatite platelets within MCF, namely a percolating cluster. We assessed the variations in the stress distributions that occur in the percolating condition. The 3D FE model represents a basis for further investigations concerning pathological conditions of bone tissue, characterized by increased mineral content and high probability of mineral fusion, as occurs in osteoporosis [31].

THE EFFECT OF CFR-PEEK CROSS-LINK IN SHORT FIXATION FOR THE STABILIZATION OF LUMBAR METASTASIS: AN IN-VITRO COMPARATIVE STUDY.

***Abstract*— The stabilization of the spine after the orthopaedic management of vertebral bone metastasis is a crucial step for the success of the surgery. Carbon fiber reinforced PEEK (CFR-PEEK) is being widely adopted for fixation instruments thanks to its good biomechanical performances and radio transparency. The study investigates whether the integration of a CFR-PEEK cross link in a short fixation could become a viable alternative to long gold standard fixation. An experimental *in-vitro* study was then conducted, comparing different surgical CFR-PEEK stabilizations by characterizing their kinetic (i.e., Moment vs ROM curves and long-chain stiffness) and kinematic (i.e., segmental angular contribution) responses in flexion-extension, lateral bending and axial rotation. To provide additional insights on long-term applicability, the event of a pedicle screw loosening was also replicated. The experimental results suggest that a CFR-PEEK short fixation augmented with cross-link can be a promising conservative strategy. This unprecedent biomechanical quantitative comparison of CFR-PEEK stabilizations could support future clinical studies.**

Keywords* — spinal instrumentation, lumbar spine, CFR-PEEK, short fixation, short stabilization, cross-link, vertebral metastasis, *in-vitro spine testing.

I. Introduction

VERTEBRAL metastases occur in more than the 5% of all patients with systemic cancer, and the lumbar segment is the most affected site of the spine [1]. In case of surgical treatment, spinal stabilization plays a crucial role in the success of the intervention. Gold standard spinal stabilization is established as a long posterior instrumentation fixing multiple levels above and below the metastasis [2], [3]. However, this practice has proved many drawbacks in terms of high invasiveness, excessive adjacent-level overloading and mobility reduction. Recently, carbon fiber reinforced (CFR-) PEEK has been introduced in spinal fixation instrumentations in place of metallic alloys, integrating good biomechanical performances with radio transparency property (which is of particular interest in oncologic surgery) [4]-[6].

To reduce the number of fixed vertebrae and the corresponding side-effects of current lumbar metastasis stabilization, this study explores the biomechanical effects of the combined use of CFR-PEEK cross-link and short fixation on the lumbar segment. Therefore, in the light of understanding the biomechanical applicability of this alternative, authors considered worthy to compare its kinematic and kinetic responses and those of the simple CFR-PEEK long and short fixations, with respect to control healthy and pathologic conditions, and to assess the effect of pedicle-screw loosening, which is the most common risks in short fixation. Hence, an experimental study was designed by recurring to a synthetic phantom loaded under flexion-extension, lateral bending and axial rotation. Hereby, this study presents for the first time a comparative biomechanical analysis of CFR-PEEK stabilizations for the management of lumbar vertebral metastasis and could support future clinical studies in oncological spinal surgery.

II. Materials and methods

A. Experimental setup

The study recurred to a Sawbones biomimetic phantom (SKU340) which replicated the lumbar segment and its adjacent vertebrae T12 and S1. The phantom presents all the passive elements of the spine, intervertebral discs, facet joints and the main ligaments (i.e., the anterior and posterior longitudinal ligaments, ligamenta flava, intertransverse ligaments, supraspinal and interspinal ligaments). The experimental set up is shown in Fig. 1. The phantom was disposed so as to have the L3 inferior endplate parallel to the global horizontal plane [7].

The loads were applied to the phantom through the linear-torsion test machine InstronE3000. The sacrum was always kept fixed to the machine and the loads were applied to the cranial vertebra through an already validated spine-loading apparatus [8]. In the case of axial rotation, the load was applied directly to the vertebra through a specific 3D printed coupling, while the bending along the sagittal and frontal planes were generated through an eccentric vertical load transmitted to the phantom through the combination of frictionless spherical and translational joints. The moment was calculated by assuming a constant arm with respect to the caudal constraint (flexion: 12.8±0.1cm, extension: 3.3±0.4cm, right lateral bending: 8.7±0.3cm, left lateral bending: 7.6±0.4cm). Loads were applied in slow-rate displacement-control to reduce any viscoelastic effect. Small range of motion was considered to prevent overloading. For sagittal and frontal bending, the

linear displacement rate was set at 20 mm/min up to 10mm, whereas for axial rotation the angular rate was set at 0.5°/s up to 3°. Three replicas were performed for each test; the initial position was always set to guarantee a slight contact with the machine, without introducing any relevant initial pre-stressed condition. Finally, adhesive reflective markers were positioned on the vertebral bodies and on the transverse process, and their displacements were recorded through a marker tracking system, synchronous with the tests. Markers were integrated with the load-displacement curves of the test machine to compute the moment at the S1 fixed joint.

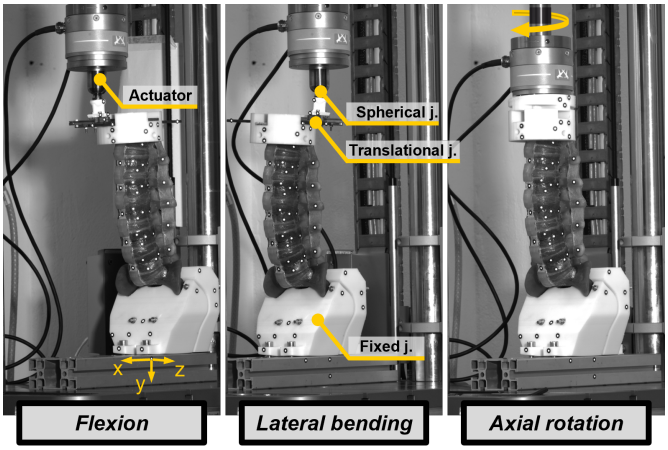

Fig. 1: The Sawbones mounted on the loading apparatus. The images are taken from one marker-tracking camera. The global reference system is also shown.

B. *Fixation layouts*

All the fixation layouts tested in this study were reproduced by experienced orthopaedic surgeons. The layouts were tested following a sequence which minimized the risk of phantom breakage (which did not occur). Hence, the tests started with the integral, non-instrumented phantom, considered as a 'healthy' control (*Ch*). Then, a metastatic lesion was mimicked in L3 by resecting the right half of its vertebral body. The posterior decompression performed surgically was also replicated by removing L3 pedicle and the posterior arch and taking care that no extra elements were affected. At that point, pedicle screws from Carboclear system (CarboFix Orthopaedic Ltd) were posteriorly inserted in L1, L2, L4 and L5 following anatomical trajectories. Dimensional consistency between pedicles and screws, as well as their mutual orientation, were confirmed by the surgeons by direct visualisation. From this condition, considered as a 'pathologic' control (*Cp*, Fig. 2), all the fixation layouts were tested: the long fixation (*L*, Fig. 2) was realised with bilateral CFR-PEEK rods connecting two spinal levels above and below the lesion in accordance with current clinical standard; the short fixation (*S*) connected only the spinal adjacent levels above and below L3, leaving L1 and L5 free to move. Then, a transversal rod-rod CFR-PEEK cross-link was added to the short fixation in correspondence of the metastasis, in a 'H' shape layout (*Scl,* Fig. 2). Finally, both short fixations were tested after the event of a pedicle screw loosening. When the screw anchorage in the vertebral bone fails, the load transmission through the screw between the vertebra and the rod is lost; a biomechanical equivalent mobilization was replicated experimentally by disconnecting the right rod-screw joint above the lesion (*S-m* and *Scl-m*).

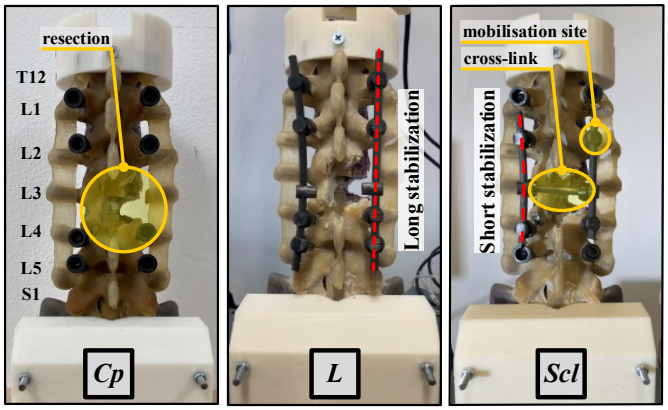

Fig. 2: Left - the Sawbones after the insertion of the pedicle screws, the reproduction of the posterior decompression and L3 vertebral body resection. Middle – Long fixation layout; the CFR-PEEK rods connect L1, L2, L4 and L5 vertebrae. Right: Short fixation layout with cross-link augmentation. The CFR-PEEK rods connect L2 and L4 vertebrae. The pedicle screw-rod joint detached to mimic the mobilization is also highlighted.

III. RESULTS

A. *Kinetic perspective*

Fig. 4 summarizes the Moment-Range of Motion (RoM) behaviour of all the layouts in flexion/extension and lateral bending. The experimental curves were realigned at 0.4Nm. Overall, the 'pathologic' control is always more flexible than the 'healthy' one, and the implementation of any fixation offers a stiffening of the phantom. The responses of short fixations (*S*, *Scl*) are always positioned in-between the other curves, thus permitting both a less marked stiffening compared to the long fixation and the restoration of a more favourable mobility. In accordance with literature, along the sagittal plane, either cross-link augmentation or mobilization influence the short construct behaviour. As far as the investigated small loads are concerned, symmetrical behaviour in lateral bending is maintained in all short layouts. In lateral bending, cross-link addition enables a stiffened response at parity of load. In the range of ±5Nm, the total range of motion is reduced of the 10.8% with respect to the *S* layout. Moreover, cross-link also contributes to the stability preservation in the case of pedicle-screw loosening, since it holds back the drop of stability by half, from +27% (*S-m*) to +13% (*Scl-m*).

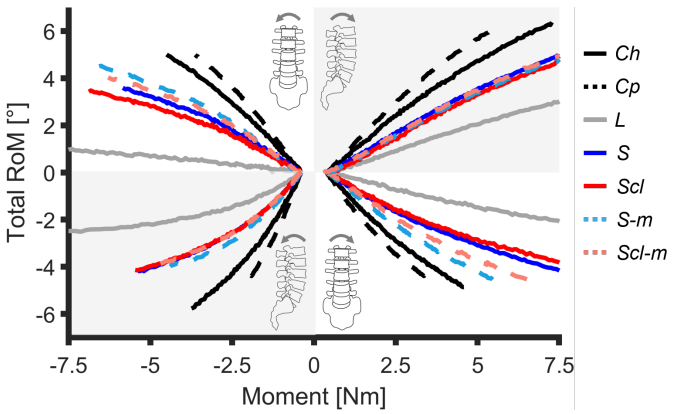

Fig. 3: Moment vs Total ROM curves of all the studied layouts. Mean values of the three replicas are represented. Each quadrant describes one different bending load: I and III flexion/extension; II and IV lateral bending on the resected and intact side, respectively.

In Fig. 4 is reported the torsional stiffness (K_T) calculated for each layout with a linear regression between the cranial vertebra rotation and the applied torque moment after having realigned the experimental curves at 0.6 Nm. The graph shows the results of all the constructs when rotated both on the intact and on the resected side. The symmetrical behaviour reported in the 'healthy' control is lost after the realization of the resection. Moreover, the 'pathological' control shows a stiffer response when rotated towards the resected side with an unbalanced deviation ΔK_T of 0.19Nm, and a significant drop of the torsional stiffness with respect to *Ch*.

If the simple short fixation doesn't succeed in recovering this gap, the addition of the cross-link makes the short fixation comparable to the intact phantom like the long fixation. Indeed, only these two layouts deviates less than the 8% from the values obtained with the *Ch.* The enhancement of cross-link augmentation in the short fixation is suggested also by the one-way ANOVA test which informs of a non-statistical difference between *S* and *Scl-m* layouts. That is to say that, in the case of pedicle screw loosening, if the simple short fixation becomes insufficient to guarantee an acceptable stability, on the other hand the addition of the crosslink makes the construct as stiff as the unimpaired short layout.

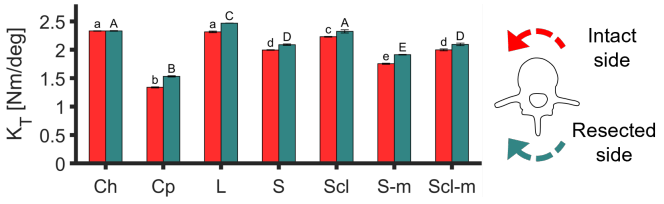

Fig. 4: Torsional stiffness of all the studied layouts. Labels indicate statistical significance among the stiffnesses along the intact (lower case labels) and resected (upper case labels) sides, according to Bonferroni post-hoc test.

B. Kinematic perspective

In order to quantify how the motion of vertebral joints across the lumbosacral segment varies with respect to the fixation layouts, the hybrid protocol [9] was adopted. The reference total RoM corresponded to the RoM achieved by the *Ch* layout under the following moments: 3Nm in flexion, 1.5Nm in extension, 1Nm in lateral bending. TABLE 1 describes the load necessary to reach the defined RoM, whereas Fig. 5 reports the motion contribution of each intervertebral joint. Negative values correspond to registered discord rotations with respect to the imposed motions.

TABLE 1: For each configuration, the table reports the applied moment necessary to achieve the RoM obtained by *Ch* at the indicated loads. Then, all the stabilizations were compared at parity of total rotation.

	Flexion	**Extension**	**Lat. bending resected side**	**Lat. bending intact side**
Ch	**3 Nm**	**1.5 Nm**	**1 Nm**	**1 Nm**
Cp	2.4 ± 0.05	1.2 ± 0.01	0.8 ± 0.02	0.9 ± 0.04
L	7.1 ±0.08	10.0 ± 0.09	3.0 ± 0.11	6.6 ± 0.70
S	4.1 ±0.09	2.5 ± 0.09	1.4 ± 0.09	1.4 ± 0.06
Scl	4.4 ±0.01	2.6 ±0.04	1.6 ± 0.10	1.6 ± 0.09
S-m	4.2 ±0.08	2.2 ± 0.10	1.2 ± 0.08	1.3 ± 0.05
Scl-m	4.1 ±0.07	2.5 ± 0.08	1.4 ± 0.07	1.3 ± 0.03

From a kinematic perspective, the introduction of the lesion mainly impacts on the joints below the lesioned vertebra (i.e., L3-L4 and L4-L5). Generally, the adjacent L3-L4 joint is less stiff, shielding the cranio-caudal motion distribution; for instance, in the case of flexion/extension L3-L4 contribution doubles, whereas L4-L5 one reduces from 20% to 3.2%. All the fixations (*L, S* and *Scl*) succeed in stabilizing the metastasis; nonetheless, the motion of the adjacent free joints is dependent on the fixation length: in the case of long fixation, L5-S1 is overinvolved with a bending contribution greater up to 5 times than *Ch* response. Conversely, in short layouts, L1-L2 and L5-S1 share more than the 80% of the total ROM; interestingly, although L4-L5 is not involved in fixation, its contribution remains extremely small, i.e., flexion: 5.7±2.5%, extension: 3.0±1.3%, lateral bending on the resected side: 4.0±3.1%, lateral bending on the intact side: -1.9±2.9%. Finally, L2 pedicle screw loosening doesn't provide evident effects during sagittal motion, while in lateral bending, a slight increased mobility is enregistered both at L2-L3 and at L3-L4 levels, revealing an increase of the relative rotations of the instrumented vertebrae and a reduced shielding effect on L4-L5 level.

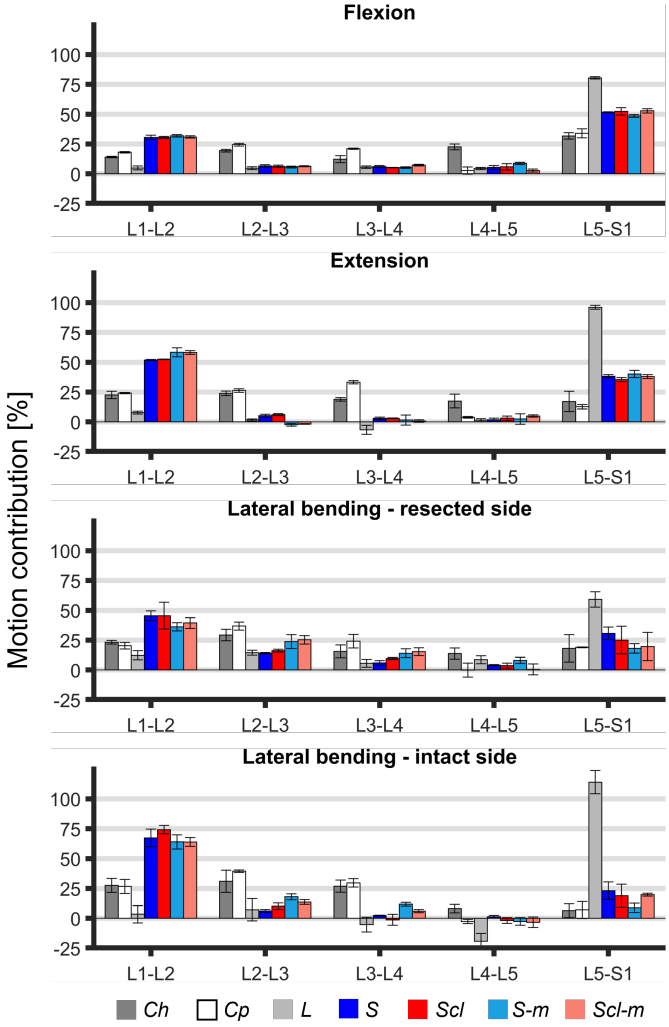

Fig. 5: Motion contribution of each vertebral joint, reported as percentage of the total L1-S1 range of motion (100%).

IV. DISCUSSION

This *in vitro* study aimed to compare different CFR-PEEK stabilization strategies from a kinetic and kinematic perspective, revealing that addition of a cross-link at the metastasis level could make short fixation a valid alternative.

Aware of the large spread of the use of synthetic phantoms in biomechanical studies [10], the authors recurred to a T12-S1 spinal segment Sawbones to conduct this study. Although this material doesn't replicate the diversity of real human specimen and doesn't permit to consider the local mechanical properties of pathologic bones, the differences expressed in the study can only be attributed to the relative differences of the fixation layouts, without any hardly controllable contribution such as disc degradation or the heterogeneity among samples.

In accordance with the literature referred to metallic cross-link use [11]-[13], *Scl* response in flexion/extension was analogous with *S* layout, both in terms of long-chain stiffness and in terms of segmental motion distribution pattern. Fig. 3 shows that cross-link in CFR-PEEK short fixation improves the frontal bending, by restoring a symmetrical behaviour on the two sides (thus, compensating the vertebral bone resection) and by limiting the effect of pedicle-screw loosening [14]. Fig. 4 puts light on the primary effect of cross-link in axial rotation. Indeed, if the K_T of simple short fixation is significantly reduced with respect to the 'healthy' control, the cross-link makes the construct comparable with long fixation and more conservative in terms of stability once mobilized. While rotating, the two longitudinal rods would get skewed, but the cross-link, that connects them transversally, counters this relative motion, making the whole construct stiffer.

Interestingly, Fig. 5 reports that in long fixation, vertebral levels below the resection had negative ROM contributions, that corresponded to vertebral rotations opposed to the main motion. These results suggest that the long fixation leads to local instabilities given by the altered distribution of the compressive loads and the over constrain of the construct [15]. The application of an eccentric load provoked a compressive stress state on the spinal segment, especially for the long fixation where the secondary effect of the compression summed to the moment was more pronounced (being stiffer, a higher load was necessary to reach the same ROM at parity of arm, TABLE 1).

Although the experimental test didn't apply a pure moment, the recorded maximum linear force applied to the phantom was less than 100N (except for the *L* layout which reached ~220N): these magnitudes are consistent with the compressive loads applied in lumbar *in vitro* studies, which range from 100N to 400N [16], [17].

Finally, since this study focused on small displacements range, eventual major deviations could have been hided; however, the spinal stability is strictly correlated to the neutral posture [18], [19], and it is only in this range that the activation of muscles can be neglected.

V. CONCLUSION

To conclude, in the framework of oncologic surgery, this work compares CFR-PEEK posterior stabilizations by recurring to a biomimetic lumbosacral phantom. Particular attention was paid on the effect of cross-link augmentation on a less invasive short segment fixation. Results quantitatively demonstrated that short fixations permit a less marked stiffening compared to the long one, restoring a more favourable mobility and less unbalance responses among lumbar vertebral joints. The most imputed drawback to short fixations is the loss of stability in case of pedicle screw loosening which can put dramatically at risk the surgical outcome. The study highlighted that cross-link could limit this crucial aspect. The *Scl* layout proved to be a promising conservative strategy, worthy to be further investigated also in *in silico* modelling and to be considered in future clinical studies in the ambit of oncologic spinal surgery.

***Abstract*—In many sports, including soccer, basketball, and volleyball, the vertical jump is considered a valid test to evaluate the performance of an athlete during the season or to assess the possibility of returning to training. A reliable measurement method is therefore required. The validity of countermovement jump (CMJ) heights made with inertial sensors is a prerequisite for the reliable implementation of their use in clinical practice. Twenty-seven athletes (20 M / 7 F, age: 27 ± 7 years) after a 5-minute warm-up performed five double-leg CMJ, with the hands on hips. The jump height was computed with Baiobit inertial measurement unit placed at waist level and with an *ad hoc* Matlab® script using force platforms data. An excellent reliability (ICC = 0.92, 95% CI 0.89-0.94), a positive correlation (r = 0.93, p <0.001), and a positive bias of 3.7 cm were found. The Baiobit sensor underestimates the CMJ flight heights.**

***Keywords*—Baiobit, countermovement jump, inertial sensors, validation.**

I. Introduction

Vertical jumps such as the double-leg countermovement jumps (CMJ) are jumps that allow measuring the power of the lower limbs and the reactivity of an athlete [1].
In many sports, including soccer, basketball, and volleyball, the vertical jump is considered a valid test to evaluate the performance of an athlete during the season or to assess the possibility of returning to training.

Although the golden standard for assessing vertical jumps is the use of force platforms in conjunction with optoelectronics, nowadays there is an increasing need to be able to assess the athlete in the field outside of the laboratory through the use of wearable sensors.

Coaches and physiotherapists often evaluate performance qualitatively, without the use of a valid and repeatable quantitative assessment. Therefore, an integration of engineering knowledge into the clinical sports application is required to better assess sports performance [2].

Wearable sensors are lightweight and practical to handle, so there is a need to verify that the measured variables are as reliable as those detected by the golden standard.
At the state of the art, numerous wearable systems have been validated [3]–[9], among which we can name Gyko [3], G-WALK [4], but only our previous study has validated the Baiobit sensor [6]. This work is therefore intended as a continuation of the previously conducted one which aims to validate this device.

II. Material and Method

A. Population

All the participants have read and signed the informed consent to participate in the study approved by the Ethical Committee of the Politecnico di Milano (submission no. 22/2021). All the tests were performed at the "Luigi Divieti Posture and Movement analysis laboratory".

The study inclusion criteria were as follows: (i) athletes trained for a minimum of 4 h per week, (ii) were aged between 18 and 40 years, (iii) had a BMI between 18.5 and 24.9 kg/m^2, and (iv) had no self-reported neurological or musculoskeletal disorder. The population included in the study, therefore, consisted of 27 athletes 20 males and 7 females (age: 27 ± 7 years, height: 1.86 ± 0.09 m, weight: 75 ± 12 kg, body mass index (BMI): 21.7 ± 2.0 kg/m^2) performing beach volley (4), triathlon (3), volleyball (11), basket (4), swimming (1), athletics (1), tennis (2) and jiu-jitsu (1) (Table I).

B. Equipment

A wearable sensor (Baiobit Rivelo Srl — BTS bioengineering Group, Milan, Italy, sampling rate = 100 Hz), two three-dimensional force platforms (AMTI, Wetertown, MA, USA, dimensions: 464 × 508 × 82.5 mm; sampling rate = 200 Hz) synchronized with two video cameras (BTS Bioengineering, Garbagnate, Italy) framing the sagittal and frontal planes and a laptop (Notebook HP EliteBook 840 G3) were used for data collection.

C. Procedures

Before the tests, data on participants were entered into the software of the wearable sensor (baiobit v1.2.6).

First of all, the subject was asked to put on sneakers and clothing appropriate for the test. A short 5-minute warm-up consisting of this exercise sequence was performed: (i) 10 squats with hands at the hips × 2 repetitions (ii) 6 forward lunges 3 on each side × 2 repetitions (iii) low skip for 7 meters × 2 repetitions. A 5 meters distance was walked between each repetition.

Then, using an adhesive clip, the sensor was fixed at the level of the S1 and S2 vertebrae on the subject's waist.

This was followed by a familiarisation phase in which the

subject was explained the type of test to be performed. Two trial jumps were executed before the actual protocol, which consisted of 5 double-leg CMJs with the hands on hips (Akimbo technique) to minimize arm swinging and each foot placed on one force platform. The execution technique was evaluated by the clinicians included in the study. In case of an incorrect jump, the test was repeated.

After the acquisition, the athletes underwent the international physical activity questionnaire (IPAQ) [10], [11].

TABLE I: SUBJECTS' DEMOGRAPHIC AND ANTHROPOMETRIC MEASUREMENTS, SPORT PRACTICED AND IPAQ SCORE CLASSIFICATION.

Sex	*Age* (*years*)	*Weight (kg)*	*Height (m)*	*Sport*	*IPAQ*
F	36	73	1.85	beach volley	VA
M	26	77	1.82	triathlon	SA
M	27	86	1.91	volleyball	VA
M	22	81	1.92	basket	VA
M	27	85	1.92	basket	VA
M	23	80	1.91	swimming	SA
M	28	97	1.91	jiu- jitsu	SA
M	28	65	1.78	triathlon	SA
F	24	47	1.64	athletics	VA
M	23	92	2.02	volleyball	SA
M	21	62	1.85	volleyball	VA
M	21	69	1.81	tennis	VA
M	20	83	1.94	basket	VA
M	37	93	1.95	beach volley	VA
M	24	71	1.76	tennis	VA
M	36	76	1.89	volleyball	VA
F	19	69	1.86	volleyball	VA
F	31	76	1.90	volleyball	SA
M	41	80	1.83	triathlon	VA
M	38	75	1.83	beach volley	VA
F	22	59	1.74	volleyball	SA
F	19	68	1.82	volleyball	VA
M	24	87	1.97	volleyball	SA
M	39	72	1.82	beach volley	VA
M	21	70	1.86	volleyball	VA
F	21	54	1.68	volleyball	SA
M	23	85	1.92	basket	VA
20M 7 F	27 ±7	75 ±12	1.86 ± 0.09		18 VA 9 SA

VA = very active; SA = sufficiently active.

D. Data analysis

Using Baiobit, the CMJ heights were recorded and manually imported from the Baiobit software into an Excel worksheet. The ground reaction forces were recorded from the force platforms in .tdf files.

Using open source Matlab® code developed by Harry et al. [12], it was possible to derive the height of the CMJs from the force data.

E. Statistical analysis

Before statistical analysis 5 jumps were removed. The Shapiro-Wilk test was used to assess the data normality (α = 0.05). As the data have a normal distribution, they are reported as mean and standard deviation. A paired t-test was applied to assess the difference between the CMJ heights calculated in the Matlab® script and from the sensor's software.

To define the correlation and level of agreement between the gold standard (the force platforms) and the Baiobit inertial sensor system, Pearson's correlation coefficient and Winer's adjusted intra-class correlation coefficient (ICC; 2.1) with an absolute agreement and a 95% confidence interval (CI) were used respectively. Table II shown the ICC criteria classification.

TABLE II: INTRACLASS CORRELATION COEFFICIENT CLASSIFICATION.

ICC < 0.50	poor reliability
0.50 < ICC < 0.75	moderate reliability
0.75 < ICC < 0.90	good reliability
ICC > 0.90	excellent reliability

Fig. 1 shows the Bland-Altman plot of the CMJ heights. On the x-axis is the average between the gold standard (forces platforms) and Baiobit and on the y-axis is the difference between the two measurement methods [1].

The statistical analysis was performed in SPSS (IBM Statistic 26).

III. RESULTS

From the results of the IPAQ (Table I) 9 out of 27 participants have a sufficiently active lifestyle (SA) while 18 out of 27 have a very active lifestyle (VA). No one had an inactive life.

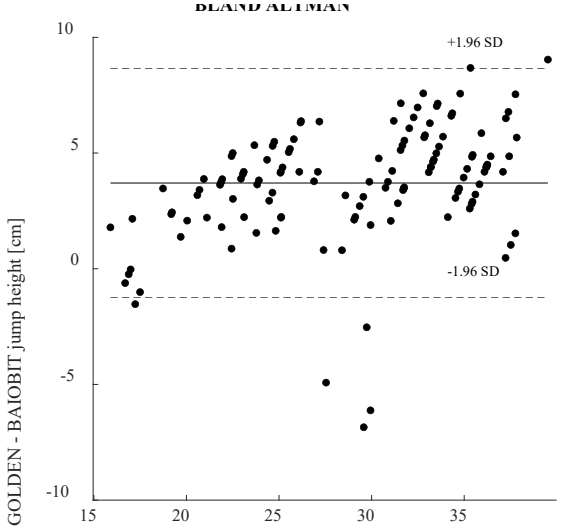

Fig. 1: Bland Altman plot comparing the Golden standard vs the Baiobit

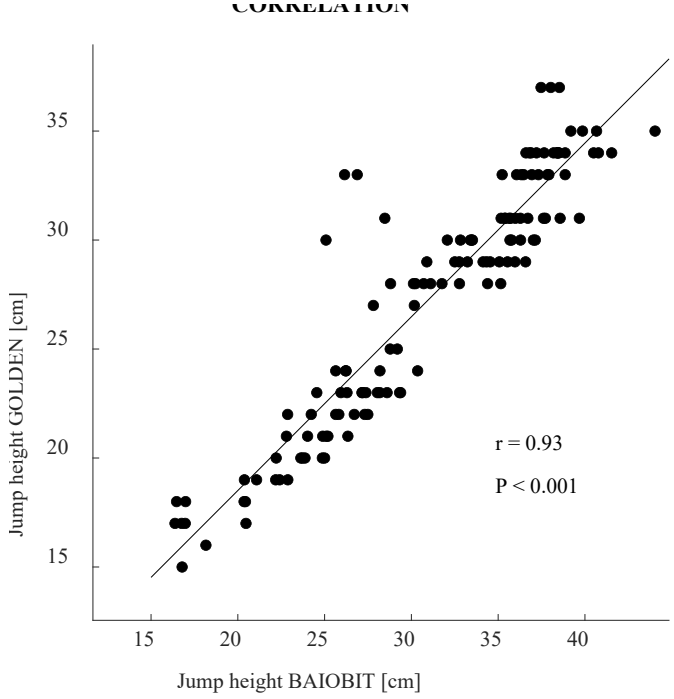

Fig. 2: Correlation plot between the Golden standard (force plates) and the Baiobit

Bland-Altman and correlation plots are shown in Figg. 1 and 2, whereas in Table III are represented the obtained results. The mean and the standard deviation of the CMJ height recorded by force platforms were equal to 30.9 ± 6.7 cm, while the height measured by the Baiobit sensor had a mean of 27.2 ± 5.7 cm. The difference between the two measurement methods is equal to 3.7 cm. Therefore, it can be stated that Baiobit underestimates the CMJ height.

In addition, a positive correlation was found between the Golden standard and Baiobit with a Pearson's coefficient equal to r = 0.93 (p <0.01). The ICC was rated as excellent (ICC = 0.92, 95% CI = 0.89-0.94).

TABLE III: VALIDITY OF THE AMTI FORCE PLATES AND BAIOBIT SENSOR FOR JUMP HEIGHT.

AMTI force plates [cm]	30.9 ± 6.7
Baiobit sensor [cm]	27.2 ±5.7
Systematic bias [cm]	3.7
Random error [cm]	±4.9
Lower LOA	-1.2
Upper LOA	8.6
ICC (95% CI)	0.92 (0.89 – 0.94)

ICC = Intraclass Correlation Coefficient; CI = Confidence Interval

The validation of wearable systems has already been addressed in numerous studies [3]–[9]. This analysis is in agreement with Edward R. Brooks et al. [9] who evaluated the repeatability and validity of an inertial measurement unit with respect to force platforms (r = 0.95, ICC = 0.91).

The study is not without its limitations, among which we find the inhomogeneity of the sample analyzed; athletes from different sports were recruited, with a predominance of male ones (20M vs 7F).

A possible future development of the project is to evenly distribute the number of males and females and select only one sport practiced.

IV. CONCLUSION

The study validated the Baiobit wearable system against the use of AMTI force platforms (Golden standard). An excellent reliability (ICC = 0.92), a positive correlation (r = 0.93), and a positive bias of 3.7 cm were found.

The Baiobit sensor underestimates the CMJ flight heights.

ACKNOWLEDGMENT

We thank Rivelo Srl—BTS Bioengineering Group for providing us with the Baiobit inertial measurement unit.

***Abstract*—Acquiring knowledge on head traumas is useful since they represent a dangerous outcome of traumatic events. Injury criteria aim to link clinical evidence of injury with experimentally measurable physical quantities, however, recent studies based on numerical methods have pointed out that also other factors could be key contributors to brain injury probability and severity. Providing an experimental measure of more advanced injury criteria is challenging, and only few research groups have started to address the problem. Starting from an existing and validated biofidelic dummy head, advances in the mechanical components and sensors embedded inside the model have been carried out, aiming to improve both bio-fidelity and to address the measure of more advanced criteria. After realizing the prototype, preliminary drop tests were performed impacting the helmeted head over an anvil. Data collected showed increase of injury criteria values with the impact force. Results proved the possibility of using the surrogate for investigating simple and advanced injury criteria, and future works will aim to set test parameters to levels compatible with helmet standards.**

***Keywords*—head injury, protective headgear, surrogate head, impact test.**

I. Introduction

HEAD traumas represent a critical issue to society and are one of the most frequent consequences of severe injury or death after traumatic events [1]. Such traumas could include skull fracture and Traumatic Brain Injuries (TBI) and are caused by different mechanical stresses happening to the head, such as blunt, ballistic, penetrating, and concussive impacts. Aiming to reduce the incidence and severity of these harms, head protective gear has been developed and its usage encouraged or regulated. The causes lying underneath TBIs have been investigated through the years by taking advantage of cadaveric studies and more recently of numerical models of the human head [2], [3]. This led to the introduction of injury criteria to assess likelihood of injury based on global and measurable quantities such as accelerations and angular velocities. On this matter, Peak Linear Acceleration (PLA) was one of the first criteria to be introduced in the past [4]. Then, to account also for the duration of the impact. Head Injury Criterion (HIC) was defined as the integral of the acceleration inside a defined time window and proposed as a standard by the National Highway Traffic Safety Administration (NHTSA) in 1972. Only recently, thanks to advances in the numerical modelling of the head, scientists acknowledged the importance of angular acceleration in the likeability of brain trauma. This led to the introduction of criteria based on angular velocity such as the BrIC [5]. However, while the above criteria could be computed from quantities collected during experimental tests, more advanced criteria, based on internal stresses and strain of the brain, only exist in the numerical domain [2], [6].

To improve the quality of experimental tests, some research groups have started to develop more biofidelic surrogate heads, accounting for soft tissues such as brain and skin. Ouellet et al. developed a surrogate composed of a plastic skull, a soft brain, and a scalp to study blast injuries [7].

Petrone et al. started the development of their surrogate, which was assembled and validated in impact tests [8], [9]. Despite the novelty of the work, major improvements could still be made to increase the bio-fidelity, robustness, and sensor capabilities of their dummy head.

The aim of the present work is to improve the above surrogate [9] with the redesign of some mechanical components, and the inclusion of more advanced sensors to allow the measurement of brain stresses during impact tests [10]. The improved surrogate will be subjected to preliminary drop tests to test the response of its sensors.

II. Methods

A. Mechanical design

Models of the components of the head surrogate were obtained by MRI scans of a male human adult. Scans were imported in MeshMixer (Autodesk, USA) and simplified for manufacturing the prototype. More in detail, the skull model was divided into two halves, and a matching indent was designed to provide a robust mechanical coupling. Then, to secure the two parts of the skull, a set of screws were secured to brass inserts fixed in the superior part. To manufacture the skull, the model was printed in Polyamide 12 using selective laser sintering technique.

To produce the soft tissues, instead, we produced a set of plastic moulds in which we could pour our surrogate material.

The brain was manufactured in PlatsilGel OO30 silicone rubber (Polytek, USA). The rubber was furtherly softened by adding Smith's Prosthetic Deadener (Polytek, USA) to the mixture. After the curing process was completed a layer of open-cell foam was wrapped and glued around the brain to mimic the sub-arachnoidid space of the human meninges. The scalp was casted in PlatsilGel 10 silicone rubber (Polytek, USA).

Once assembled, the surrogate was filled with distilled water, acting as a surrogate for the Cerebral-Spinal Fluid (CSF). Figure 1 shows the three main elements composing the surrogate.

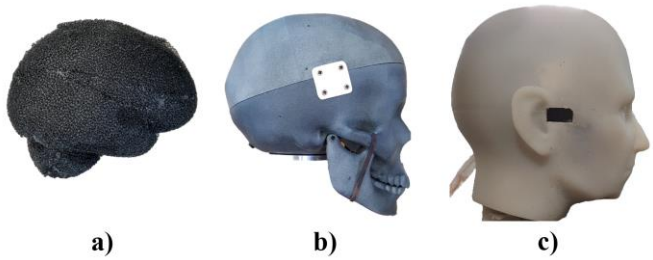

Fig. 1: surrogate head assembly: a) brain with meninges; b) skull; c) scalp

B. Sensors

The head was instrumented with several sensors positioned on the different parts of the surrogate. A triaxial accelerometer was positioned on the side of the skull of the surrogate, coincident to the sagittal projection of the Centre of Mass (COM). Inside the brain, a triaxial accelerometer and a gyro were embedded during the casting process in the brain COM. Moreover, next to the inertial sensors we positioned a Multi-Axial Pressure Sensors (MAPS) which provided a measure of normal and shear stresses in the brain COM, as well as the Von Mises Stress [10]. Figure 2 shows sensors on the head components.

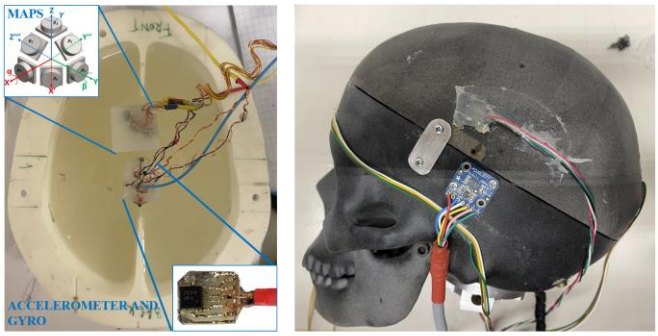

Fig. 2: head sensors: a) sensors casted inside the brain; b) accelerometer positioned on the skull

C. Drop tests

The dummy head was subjected to drop tests, impacting over an instrumented anvil equipped with a 44 kN load cell (FUTEK, USA). Drop tests were performed both with and without the CSF inside the skull/brain cavity. A Vega mountaineering helmet (Salewa, Italy) was fit on the head. The helmeted head was suspended with a thin rope and released from different heights to impact with increasing energies of 10, 13, and 16.7 J. Data of the anvil and head sensors were synchronously collected with a SoMat eDAQ lite (HBM, Germany) at 5 kHz.

D. Data Analysis

Data of the impact test were analysed in MATLAB R2022a (MathWorks, USA). First, data were low-pass filtered using a zero-phase Butterworth filter (2nd order, 500 Hz cut-off frequency). Then, we cut collected data from the first increase in force on the anvil to the subsequent 25 ms.

Raw data from the accelerometer of the brain was combined to obtain the resultant acceleration from its three cartesian components. From the resultant signal we computed the peak (PLA) and the HIC with a 15 ms window. Data from the six channels of the MAPS were combined and shear and normal components of stress, plus Von Mises stress, were computed.

III. RESULTS

Results of drop tests are reported in Table 1 and in Figure 3 and 4. Figure 5 shows injury criteria with respect to the impact force on the anvil, for the CSF test conditions.

We could observe that injury probability increases with the impact force for each of the mentioned criteria. Maximum values of force and VM stress were observed for the 13.3 J, CSF impact conditon, while PLA and HIC were maximum for the 16.7J, Dry condition.

TABLE I: RESULTS OF THE DROP TESTS

Test	*Peak Force [N]*	*PLA [g]*	*HIC [g]*	*Peak Von Mises Stress [kPa]*
10 J, CSF	2352	55.59	39.6	37.5
13.3 J, CSF	3393	79.57	60.2	64.8
16.7 J, CSF	2750	76.04	68.0	47.7
10 J, Dry	2253	59.07	94.3	22.5
13.3 J, Dry	2948	79.82	104.2	28.2
16.7 J, Dry	2774	99.87	140.2	34.4

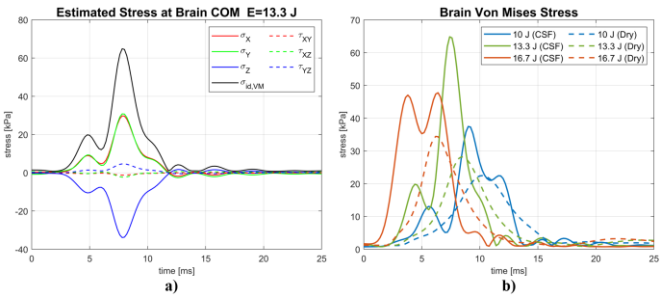

Fig. 4: brain stresses measured with MAPS: a) example of the six components of stress; b) Von Mises stress for the different tests performed

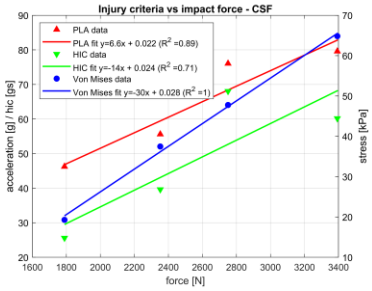

Fig. 5: injury criteria values with respect to impact force on the anvil of the head filled with CSF

IV. DISCUSSION

Advances coming from modelling new structures of this head surrogate are pulling towards an increased bio fidelity, as consequence of the newly introduced components and their interaction. However, its validation needs further and more advanced studies that will be addressed by either replicating cadaveric tests or by a numerical modelling of the surrogate.

Results of drop tests gave a first glance of the capabilities of the new head. Indeed, the presence of accelerometric sensors inside the brain allowed to compute its PLA and HIC [4]. Usually not possible when dealing with rigid head forms.

About the measure of Von Mises stress which was previously peculiar to numerical models [2], [6], we observed little or no shear components, which is compatible with the position of the sensor inside the brain and with the test performed without rotational components. Normal stress showed a high compressive load in the direction of the impact, and a consequent expansion in the orthogonal directions.

Interestingly, impact energy and measured quantities didn't grow together, but a maximum of force and Von Mises was observed for the intermediate energy impact (13.3 J). Instead, injury criteria were observed to increase with respect to the impact force, fitting well a linear trend, with peak Von Mises stress having the best fit.

When CSF was removed from the skull cavity, HIC and PLA increased. Instead, impact force and peak Von Mises stress reduced with respect to the trials with CSF. Although this phenomenon needs further investigation, tests carried out with CSF are more physiologically representative and of more interest to our study.

This preliminary work showed a possible application of this surrogate head for studying impacts and investigating the protective performances of head protective gear. Nevertheless, further tests will need to explore much higher energies and impact locations/conditions to comply with helmet standards.

***Abstract*—Biomechanical analysis of paralympic amputee sprinters has implications for the design of prosthetic components and for the improvement of the athletic performance. Thus, the purpose of this study was to carry out the kinetic analysis of a unilateral transfemoral amputee sprinter running on track through measurement of reaction forces and inertial data with a wearable acquisition system. The outcomes here presented find agreement with literature findings and, on top of that, add new information that strengthen knowledge in the prosthetic field and can be used for future works.**

***Keywords*—Running Biomechanics, Paralympic Sprinters, Transfemoral, In vivo tests, Ground Reaction Force, Wearable system.**

I. INTRODUCTION

THE last few decades saw huge technological advancements in the field of running specific prostheses (RSP), assistive technologies specifically designed to help athletes with lower limb amputation reaching their maximal performance in sprinting competitions. Running prosthetic feet (RPF), carbon fibre blades with a spring-like function, have been introduced since the ‘90s and their design has been improved in order to better compensate for replacement of an active ankle foot complex. Researchers focused not only on the RPF properties, but also on the nature of loads that the ground applies through the foot to the leg and eventually to athlete’s body, named ground reaction force (GRF). The knowledge of the acting loads is crucial for evaluating athletes’ technique, designing safe feet, and for biomechanical modelling.

It has been observed [1] that laboratory measurements with subjects running on a treadmill are not fully realistic, as athletes are often not used to perform in such artificial environment on the limited running surface of the treadmill. On the contrary, several studies dealing with measurement of GRFs during overground running make use of force platforms placed on the running track [2][3]. Except in cases where the number of platforms is very high [4], the results of this type of studies depend to a large extent on the probability of obtaining good steps (athlete hitting the plate and whole foot placed on the plate).

Coming from these considerations, a previous study of the research group [5] aimed to develop an instrumented RPF, equipped with strain gauges bending bridges, capable of measuring GRFs without the force platforms. The advantages of this method were the collection of multiple steps and the minimum impact of the wearable system. On the contrary, strain gauges applied directly to the carbon blade made the RPF not interchangeable, requiring the prior instrumentation and calibration of each foot to be tested.

The purpose of the present study was to describe an alternative wearable acquisition system that represent the evolution of the previous work, allowing both the high precision data collection of multiple steps, coupled with the efficiency in the foot interchangeability and the athlete comfort, who could run on a familiar running surface.

II. MATERIALS AND METHODS

A. Participants

An elite Paralympic female athlete (55 Kg, 1.60 m) with left unilateral transfemoral amputation, gold medallist in the 100 m race of the Paralympic Games, voluntarily participated in this study. The RSP comprise of a custom-made socket, the mono axial Ottobock 3S80 prosthetic knee, and the Ottobock 1E91 standard RPF, category 3.5.

B. Instrumentation

The RSP was instrumented with a 6-axis ultra-thin load cell (diameter 65mm, thickness 9mm, mass 0.19kg), mounted in between the prosthetic knee and the clamp of the Running Prosthetic Foot (RPF), and a high-shock tolerant six degrees of freedom inertial sensor (DTS, CA, USA), taped to the inner surface of the proximal straight portion of the RPF, almost under the clamp (Fig. 1). Both sensors were connected through wires to an ultra-small, standalone acquisition system (DTS, CA, USA), which was placed inside a small running backpack, together with its Lithium-Polymer battery, which supplied 9V DC power to the acquisition system and a power bank used to power the load cell. The load cell allowed the measurement of reaction forces and torques, while the inertial sensor was used to measure the triaxial linear acceleration and triaxial angular rate at the clamp of the RPF.

Tests were performed in the indoor athletics track located in Padova Palaindoor. In order to validate the inertial sensors, the installation comprised of a total of 28 motion capture cameras (Vicon Motion System, Oxford, UK). 22 of them mounted on tripods placed all along the runway, covering approximately 20-metres-long acquisition volume, and 6 cameras installed on a double portal structure, placed in the centre of the runway, made of aluminium trusses with an overall size of 2.5 x 3 x 3.5 metres (length x width x height).

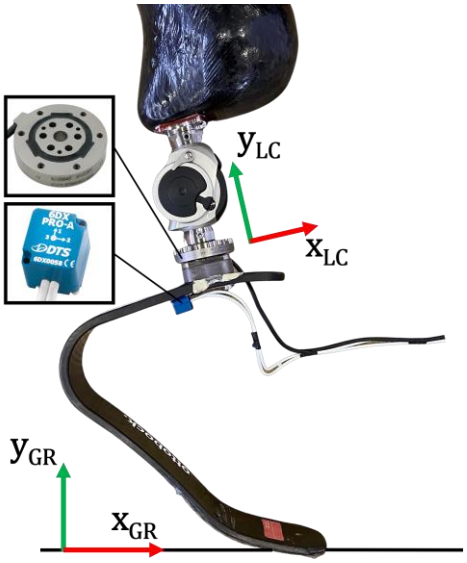

Fig. 1: Instrumented prosthesis: 6-axis load cell and inertial sensor set up. The coordinate systems LC and GR are represented by the longitudinal and shear directions and by the vertical and horizontal directions, respectively.

C. *Experimental protocol*

The inclination of the socket with respect to the vertical line passing through the greater trochanter and the centre of the prosthetic knee was regulated by the orthopaedic technician. The alignment adopted in the tests was A3 [6] which consists in a hip pre-flexion angle equal to 15°. Sixty-five retroreflective markers (14mm diameter) were attached to the subject on significative anatomical landmarks and specific locations of the prosthetic components, according to the established protocol. The athlete wore the running backpack and warmed up to familiarize with the track and the prosthesis setup. A push button panel, placed inside the backpack, was implemented to trigger and stop the DTS recording mode, while the Vicon was controlled from the software.

Two types of trials were performed: Steady State Running (TSSR) and Start (START). In TSSR trials the athlete sprinted from the start line, maintained a constant speed of approximately 60% of personal maximal speed while running across the Vicon acquisition volume, and finally decelerated towards the lane end. The start line and the lane end were positioned outside the acquisition volume. In START trials starting blocks were included and placed inside the acquisition volume. The athlete again sprinted to reach 60% of maximal speed, maintained a constant speed and slowed down towards the lane end. The participant performed three TSSR and three START trials. Kinematic data were collected at 300 Hz, whereas kinetic and inertial data were collected at 2000 Hz.

D. *Data analysis*

Reaction Forces and angular velocities were collected in the Loadcell Coordinate System (*LC* in Fig. 1), i.e., an orthogonal triad composed of the *x*, *y*, and *z* axes. The x-axis of the CS represented the anterior-posterior Shear direction (+ forward), y-axis the Longitudinal direction (+ upward) and the z-axis the medial-lateral direction (+ rightward). In order to synchronize data collected with Vicon system, it was first necessary to downsample the DTS acquisition frequency from 2000Hz to 300Hz, and then calculate the cross-correlation between signals. The angular rate signal of the RPF, obtained from Vicon as the first derivative of the angle of its reference system with respect to the global reference system, was aligned with the angular rate signal recorded with the DTS inertial sensor, until the maximum cross-correlation was observed and the time shift between the two systems was measured. Since per protocol the DTS recording was the first triggered, and therefore signals were longer than Vicon, it was trimmed accordingly. Subsequently, kinetic data were filtered using a zero-lag 4th order, low pass Butterworth filter with cut-off frequency of 52 Hz, which resulted the optimal value from the spectral analysis. Running cycle events (touch down and take-off) employed in the step segmentation were detected from the filtered Longitudinal force data using a 5 N threshold. As a result, loadcell and inertial data were segmented into the different individual steps the test consisted of, and the ground reaction force (GRF) components were computed using the clamp orientation matrix, calculated from the Vicon data. Alternatively, the angle between the longitudinal axis of the loadcell and the vertical axis in the global CS on the sagittal plane, named the loadcell angle (θ_{LC}), was calculated as the integration of the angular rate measured from the inertial sensor. Approximating methods, such as the trapezoidal method, imply an increasing error when estimating an integral. The initial and final value retrieved from Vicon, however, allowed to identify the error trendline and compensate the calculations. Finally, only in TSSR tests the steps were averaged, because in START tests high standard deviation levels were considered to be not representative.

Kinematic data labelling, on the other hand, was realized using Vicon Nexus 2.12.1 software. In order to smooth the data and remove noisy trajectory oscillations, data were low-pass filtered using a Butterworth fourth-order filter. The data analysis was then carried out in MATLAB.

III. RESULTS AND DISCUSSION

The MoCap acquisition volume is bound to the number and disposition of cameras deployed. Extensive installations can be rarely afforded, as they are expensive, and require large amount of space and time for the preparation. As a result, the acquisition volume could not be moved and did not cover the full track length. Data recorded with Vicon during START and TSSR tests only included the acceleration phase from starting blocks and the steady state phase of a sprint, respectively, cutting off the rest of the performance.

The wearable system, on the contrary, is only limited by the battery duration. Moreover, the measurements are no longer related to an acquisition volume, enabling to record the trial in its entirety. The analysis of the instrumented RPF kinetic and inertial data provided an explanatory overview of the trial performance (Fig. 2). By looking at the reaction forces signals, each step was easy to discern from the others and allowed to differentiate the three stages of a sprint, i.e., the accelerating, the steady state, and the breaking phase.

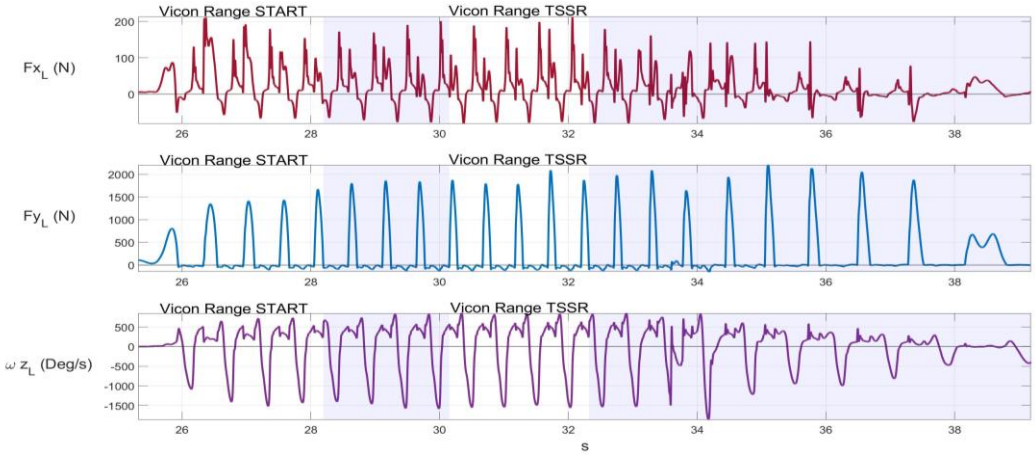

Fig. 2: Overview of an entire running test in the CS LC. Starting from the top the Shear force is depicted, then the Longitudinal force and the angular rate with respect to the z axis. The Vicon acquisition volumes are delimited in the white boxes.

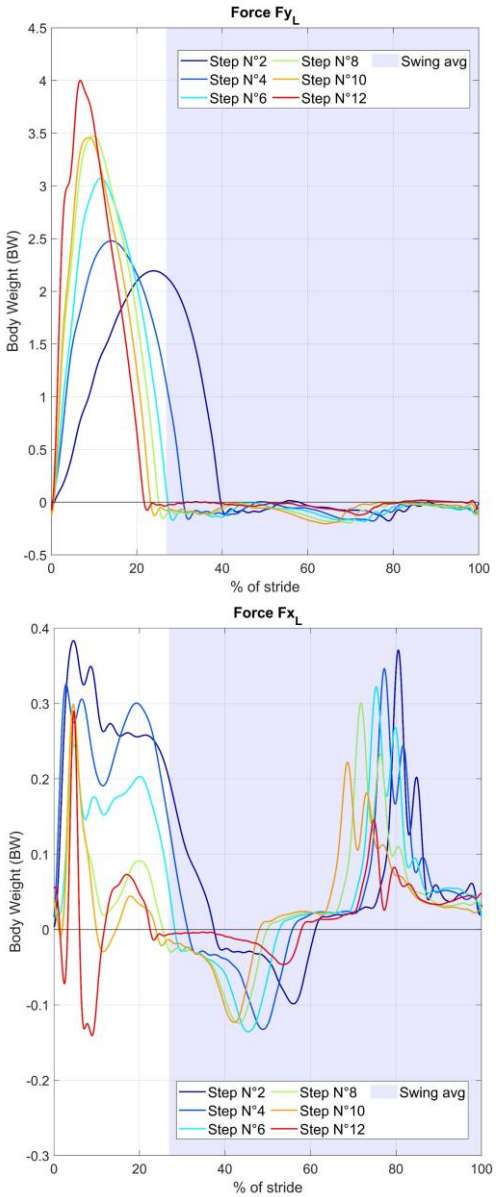

Fig. 3: step progression of the first 6 steps of the affected limb (AL) in a START test, from the reaction forces point of view. Only the AL is presented as the system cannot measure data of the unaffected limb (UL).

In Fig. 3, the step progression during a START trial is displayed in terms of reaction forces in the *LC CS*. Only the steps of the affected limb (AL) are represented, with colours varying from blue to red, as the system is not suitable for measuring loads on the unaffected limb (UL). While the Longitudinal force (F_y) increased progressively in magnitude and decreased in contact time, the Shear force (F_x) decreased both in magnitude and contact time simultaneously. An interesting data was provided by the Shear force measured during the swing phase of a running cycle, where two opposite peaks were detected. The first negative peak, at around 45% of the stride, was consistent with the maximum knee flexion that occur after the take-off event. The second, positive, happened at around 80% of the stride in correspondence with the full knee extension, in preparation to the following touch down event. The Shear force generated at this moment is equivalent in magnitude to the force generated during the stance phase.

The loadcell angle θ_{LC}, achieved through the integration of the angular rate, measured with the inertial sensor, and the error compensation, result of the approximating method in the integral calculation, was compared to the same angle obtained with Vicon. The comparison necessarily regarded the portion of the angle within the Vicon acquisition volume. The RMSE found value of 2.8° validated the angle measurement using the wearable system inertial data. This angle allowed to express the reaction forces from the *LC* into the Ground Coordinate System (*GR*). The GRF behavior at the 4th step (Fig. 4) differed from the literature because, at the present state, there is no evidence of reaction forces measured while the athlete was still accelerating. The literature behaviour, denoted by the change in the horizontal force from braking to propulsive, found agreement with the GRFs measured when running at constant speed (TSSR test in Fig. 5). The analysis of the reaction forces evidenced that the F_y did not show relevant dissimilarities when looking at the same stage of the test, but in different *CS*. Conversely, the magnitude peak was increased and reached faster during the steady state stage, which is consistent with the aforementioned progression. Concerning the F_x force, from

acceleration to steady state stage, the overall magnitude decreased in both *CS*, as the force became less propulsive coherently with the acceleration decrease. Eventually, the horizontal GRF became negative in the first half and positive in the second.

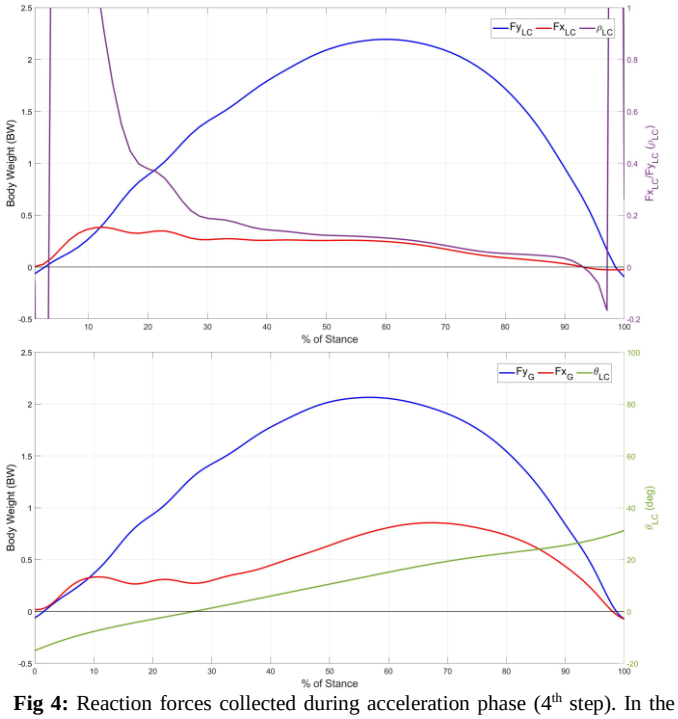

Fig 4: Reaction forces collected during acceleration phase (4th step). In the top graph the forces and the ρ_{LC} are measured in *CS LC*, in the bottom graph the forces and the loadcell angle θ_{LC} are measured in *CS GR*.

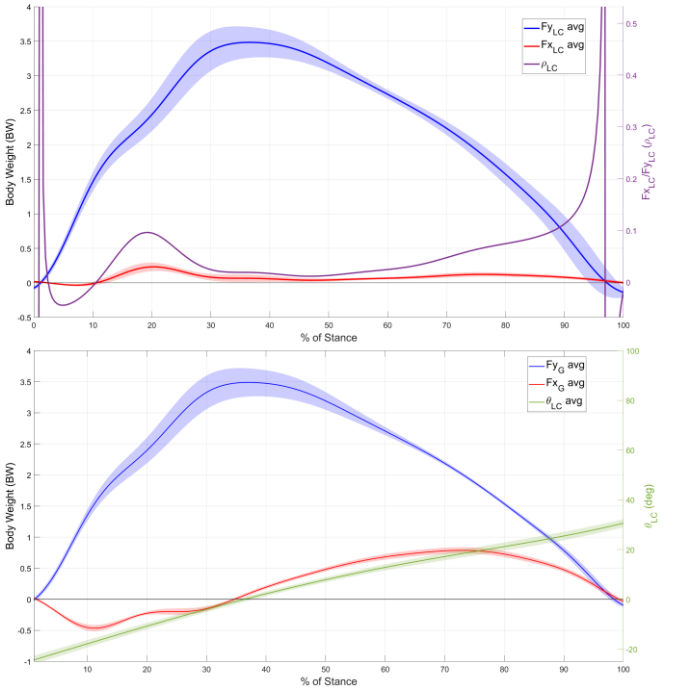

Fig. 5: Average reaction forces in the AL step range 18th – 26th measured both in the *CS LC* and *CS GR*, *in* the top and bottom graph respectively, combined with the ρ_{LC} and the θ_{LC}.

The change of sign in the Shear force can also be noted in the ratio of Fx_{LC} over Fy_{LC}, named ρ_{LC}. This ratio is an indicator of the Shear forward force component with respect to the Longitudinal force. It is a fundamental parameter when replicating the reaction forces on a test bench for RPF characterization. As a matter of fact, several studies [7][9] suggested that the foot stiffness is related to the ρ, and this correlation varies at different inclinations of the foot with respect to the ground [8]. In figures 4 and 5, the initial and final values of ρ are not representative, as the filtering of the foot resonance frequency resulted into negative values of the Longitudinal reaction force at the touch down event, which may seem not realistic. For the same reason, the spikes towards + and – infinity are the result of a non-null Shear force divided by a Longitudinal force equal to 0, which again is not meaningful when considering the instant of contact between the foot and the ground.

IV. CONCLUSIONS

The present work described a wearable system for collection of clamp loads for transfemoral paralympic sprinters. In addition, the inertial sensor allowed to measure the ground reaction forces, proving the system is capable of measuring loads acting from the ground without force platforms implementation. Finally, the Vicon system acted solely as a validation tool, demonstration that the wearable acquisition system can be used independently to measure reaction force and inertial data.

ACKNOWLEDGEMENT

The authors intend to thank the athlete and FISPES for their involvement in the study, INAIL for funding the OLIMPIA project PR19-PAI-P4.

***Abstract*—Spinal muscular atrophy (SMA) is a neurodegenerative genetic disorder affecting motor neurons in the spinal cord. Depending on the different SMA classifications, symptoms can vary significantly among subjects and they usually include progressive muscle atrophy, weakness, and paralysis affecting the whole body. While impairments in trunk and limbs have been widely investigated, there is a paucity of research on oro-facial and bulbar functions. Since face analysis tools are gaining interest in the clinical context this study aims to verify the potential benefits of adopting them to assess symptoms in SMA. In this study, a face mobility index (FMI), previously developed by the authors for applications in Parkinson's disease, is proposed in a modified version adapted to SMA impairments. Fifty subjects affected by SMA at different stages of the disease (types and functions) and twenty healthy controls (HC) were evaluated and compared in different forced and relaxed tasks. A cluster analysis was applied to the obtained FMIs in order to highlight possible biomarkers of SMA. Results showed that FMI was able to better characterize SMA from HC while subjects were performing tight-lipped smile. Furthermore, this task was found to be related to the lip strength clinical variable. This innovative approach could be used by clinicians as a new non-invasive measure of face mobility. However, future analyses are needed to validate the metric and to increase the sample size.**

***Keywords*—Spinal Muscular Atrophy, Face Mobility, Cluster Analysis**

I. INTRODUCTION

Spinal Muscular Atrophy (SMA) is a severe neurodegenerative disease caused by the deletion of the Survival Motor Neuron (SMN1) gene on chromosome 5. The clinical spectrum of SMA is multifarious and individuals affected by this disease are usually classified into different SMA types on the basis of age of onset and maximum motor function achieved (i.e., non sitters, sitters, and walkers). Types 1, 2, and 3 are the most common ones appearing in the infantile $0-6$ months and $6-18$ months, and juvenile ages ($>$ 12 months), respectively. SMA symptoms are mostly related to the motor system causing progressive muscle atrophy, weakness, and paralysis [1]. Motor function assessment in SMA is therefore essential to describe the disease burden, assess motor impairment, and track disease progression. General consensus has been achieved regarding clinical scales to be employed in muscle strength and functional assessment for testing upper and lower limbs' muscles. However, little is known concerning the evaluation of bulbar functions. Some studies investigated the mandibular range of motion, including the maximal mouth opening, bite force, masticatory functions, and swallowing but, especially in adult patients, these metrics have not been validated and standardized yet [2], [3]. Consequently, there is a need for a better definition of outcome measures to improve the clinical assessment of oro-facial and bulbar functions in SMA.

Recently, face analysis software employed as clinical tools is gaining more and more interest in different pathologies affecting the oro-facial district such as endocrine and metabolic diseases, genetic and chromosome abnormalities, and neuromuscular diseases [4]. This type of technology is non-invasive and contact-free, thus offering a substantial advantage for applications in a wide range of pathologies. In the present study, a measure of face mobility previously validated on subjects with Parkinson's Disease will be employed (Face mobility index FMI, [5]). The index will be adjusted in order to be employed with specific facial tasks designed by the clinicians involved in the study. The aim of this work is to investigate SMA orofacial muscle impairments through this specific metric. Firstly, a comparison between SMA with different types and functions and healthy subjects will be performed. Then, an unsupervised classification technique will be employed as a tool to investigate whether any clinical variable is highlighted among the obtained clusters.

II. MATERIALS AND METHODS

A. Participants

Data of 50 subjects affected by SMA and 20 healthy controls (HC) were evaluated. Subjects were enrolled at the NeMO clinical center in Milan. Written informed consent was obtained from all participants and the study protocol was approved by the local ethics committee (number: 290-27052020). The study complied with the Declaration of Helsinki. Demographic and clinical data of the participants can be found in Table I. SMA subjects underwent clinical evaluations of type, function, and bulbar functions, i.e., active maximum mouth opening (AMMO) defined as the distance between the central incisal edges of the upper and lower central incisors plus the overbite [6], and lip strength (LS), and tongue strength (TS) measured using the validated Iowa Oral Performance Instrument (IOPI) [7].

TABLE I: DEMOGRAPHIC DATA

Characteristic	*SMA subjects*	*HC subjects*
Number	50	20
Age (years mean ± SD)	28.48 ± 18.89	19.0 ± 9.62
Gender	29 M, 21 F	12 M, 8 F
SMA Type	6 SMA 1 21 SMA 2 23 SMA 3 18 non sitters	–
SMA function	24 sitters 8 walkers	–
Lip strength (kPa mean ± SD)	14.19 ± 7.08	–
Tongue strength (kPa mean ± SD)	26.48 ± 16.43	–
Active maximum mouth opening (mm mean ± SD)	19 ± 8.9	–

Demographic data of SMA and HC participants.

B. Data acquisition

Frontal face videos (commercial cameras, 30 fps) of participants were recorded while subjects were comfortably seated with a neutral background behind them. They were instructed to perform the following tasks: (1) frowning, (2) eye closure without exertion, (3) eye closure with exertion, (4) tight-lipped smile, (5) smile, (6) kiss, (7) cheeks inflation. A neutral face expression was acquired as reference.

C. Data elaboration

Face mobility index (FMI) [5] was computed per each task and subject. FMI is obtained by tracking a set of landmarks on the designated frames per each expression and the consequent computation of 40 Euclidean distances, related to specific facial muscles, between these points. Normalization between each distance in the specific expression and the corresponding one in the neutral expression is performed in order to obtain an intra-subject measure of mobility. FMI represents a summary metric determined by the sum of all the mobility deviations from the neutral expression in each expression defined as follows:

$$FMI_j = \frac{\sum_{i=1}^{n_{dist}} |1 - ratio_i| \cdot 100\%}{n_{dist}} \quad (1)$$

where $ratio$ represents the normalized distance over the neutral expression, n_{dist} is the number of available distances and j is the specific expression under analysis.

Both a total FMI and three sub-indexes related to different parts of the face (FMI_up for the upper region, FMI_mid for the middle region, and FMI_low for the lower one) were calculated (Figure 1).

Data of FMIs in SMA individuals were divided into groups considering the two most commonly used clinical classifications, i.e., SMA type and SMA function. Wilcoxon rank sum test was used to compare FMIs in SMA subjects and HC.

Then, k-means clustering technique was applied to FMIs of SMA participants in order to verify the potential of this metrics

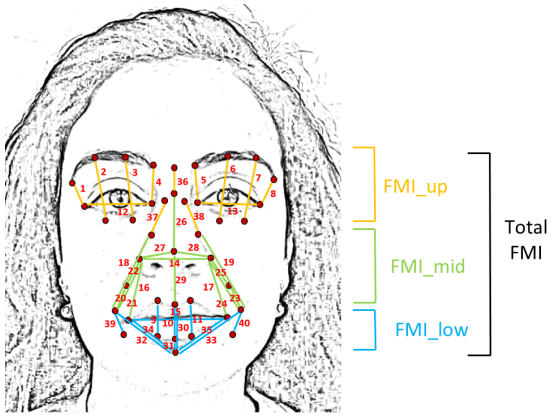

Fig. 1: Distances corresponding to the total FMI, and the FMIs per face regions: FMI_up, FMI_mid, and FMI_low

to characterize SMA impairments. The total FMI and the three subindexes per each task were used as inputs for the cluster analyses. Silhouette score was adopted as the optimum cluster criterion [8]. The results of the clustering were evaluated when they obtained an optimal number of clusters lower than 5. In order to interpret the obtained solutions, Wilkoxon rank sum test was employed to compare the continuous variables (AMMO, LS, TS) across clusters, whereas Fisher's exact test was used for the categorical ones (gender, SMA type, SMA function). A significance level of $p < 0.05$ was adopted for all the statistical analyses.

III. RESULTS

A. SMA type and function analysis

Results of the analysis according to SMA types and functions are reported in Figures 2 and 3, respectively, for only the total FMI per each task (the face region subindexes are not shown for space reasons). Higher values of FMI indicate greater variation from the neutral expression. As regards the SMA type analysis, it can be noted how lower FMI values are present in SMA subjects with more severe impairments, i.e. SMA 1, in some specific tasks. SMA 2 and SMA 3 subjects depict higher values of FMIs in almost all the tasks with respect to HC individuals. Statistically significant differences are found in Task 4 (tight-lipped smile) and Task 7 (cheeks inflation). In particular, Task 4 is able to distinguish both between HC and SMA subjects and within some types of SMA. Whereas, in Task 7 statistically significant differences are present among SMA groups.

The SMA function analysis highlights fewer differences among groups. However, Task 4 and 5 present statistically significant differences between HC subjects and the group of SMA sitters. Additionally, high variability is present in all the obtained data, especially in the SMA population, notwithstanding the clinical classification.

B. Cluster analysis

The cluster analysis considering either the total FMI or the subindexes per face region (FMI_up, FMI_mid, and FMI_low)

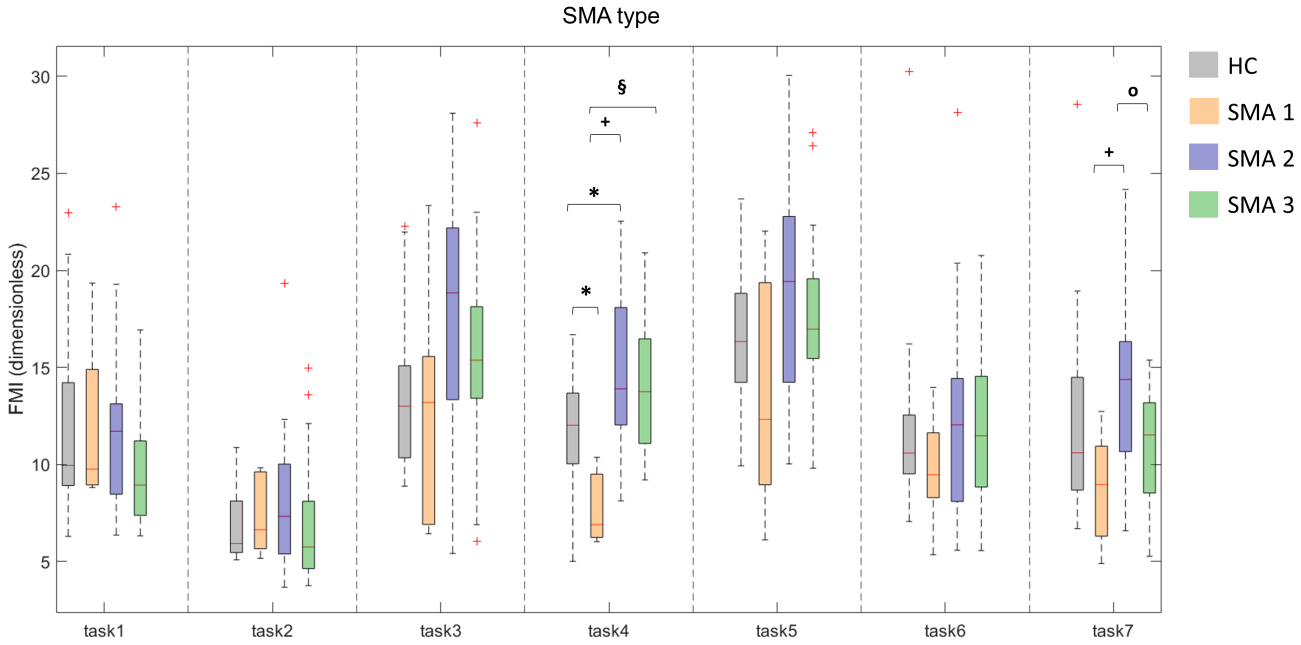

Fig. 2: Boxplot of total FMI per each task in HC and SMA according to their types: SMA 1, SMA 2, and SMA 3. (*) indicates statistically significant differences between HC and SMA subjects. (+), (§), and (o) indicate statistically significant differences between SMA 1 and SMA 2, SMA 1 and SMA 3, and SMA 2 and SMA 3, respectively. All statistically significant differences are considered at the 0.05 confidence level.

led to the definition of a different number of clusters per task. Hereinafter, only clusters that obtained statistically significant differences among clusters are reported. Figure 4 reports the description of the selected ones. FMI_low (Figure 4 (a)) and FMI_mid (Figure 4 (b)) evaluated in Task 4 produced two clusters. In both cases, the clusters include SMA subjects with varying variables. However, they are characterized by LS which is statistically significant between the two clusters in both situations.

IV. DISCUSSION

In this study, a face mobility analysis in SMA subjects was proposed. It represents an innovative approach to assessing oro-facial functions in these individuals. The methodology is easy-to-interpret by physicians and less cumbersome than the commonly used clinical tests (e.g., electromyography, nerve conduction study). Different facial tasks including forced and relaxed movements have been investigated. Generally, except for SMA 1 subjects and non sitters individuals, FMIs are higher than the ones of HC. These findings suggest that in order to perform the same task, compensatory movements recruiting more muscles, are required in these patients with respect to HC ones.

Nevertheless, Task 4 (tight-lipped smile) appears to play a key role in the evaluation of face mobility and it is able to distinguish between HC and SMA subjects and among different classes of SMA types. Moreover, it is the only task that led to a clear distinction of clusters in the FMI_mid and FMI_low with respect to the clinical variable of LS. Higher values of face mobility are related to higher values of LS thus confirming the relationship between impairment in LS and middle and lower face mobility.

The generalizability of these results is subjected to certain limitations. The number of participants is restricted resulting in unbalanced groups of SMA. SMA 1 and walker groups are the less numerous ones with six and eight individuals each. Furthermore, high variability is present in all the analyzed data leading to a need for increasing numerosity in all the considered classes, healthy subjects included. Moreover, the age of participants was not formerly discussed but SMA is known to be partially featured by it. Thereby, age-matched controls should be in included in the study, and classification by age in SMA could be addressed. Finally, formal validation of this approach in SMA subjects should be considered in future developments. Comparison with standardized techniques such as electromyography could be used as a reference tool.

V. CONCLUSION

In conclusion, this contribution proposes a novel potential approach to quantify face mobility in SMA. Results showed that the task that was most revealing was the tight-lipped smile. Clinicians could employ this face analysis tool focusing

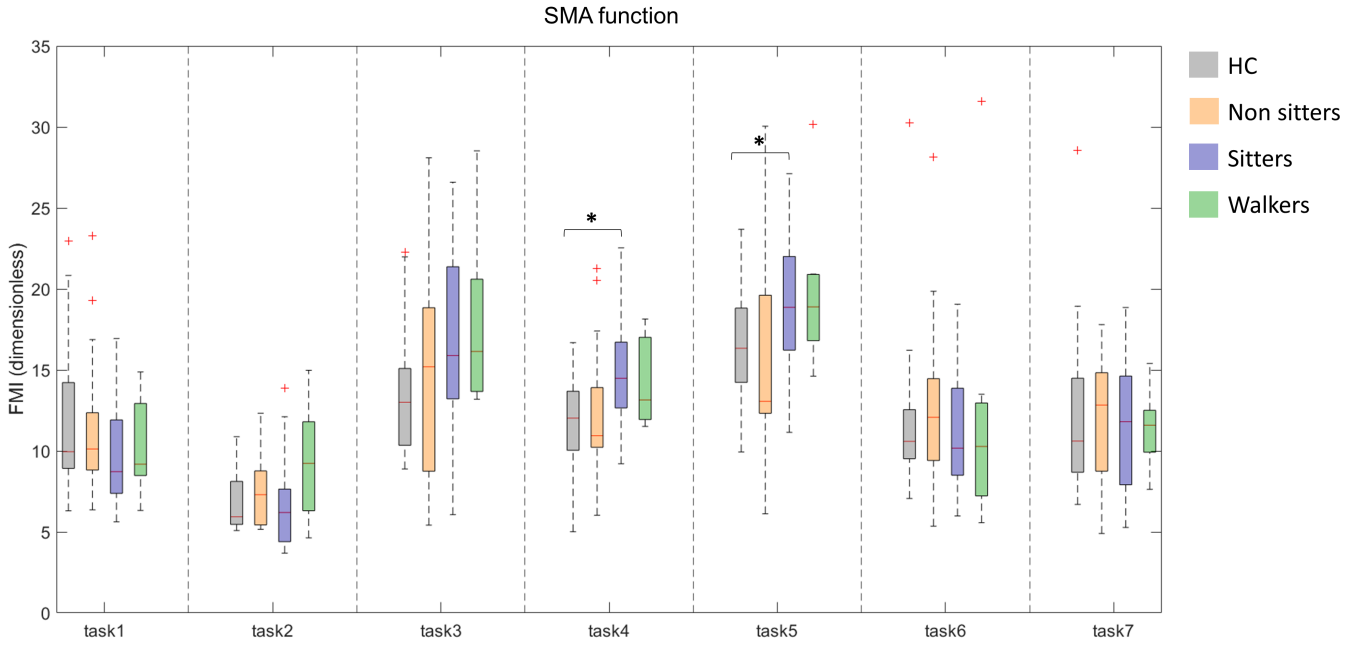

Fig. 3: Boxplot of total FMI per each task in HC and SMA according to their functions: non sitters, sitters, and walkers. (*) indicates statistically significant differences between HC and SMA subjects at the 0.05 confidence level.

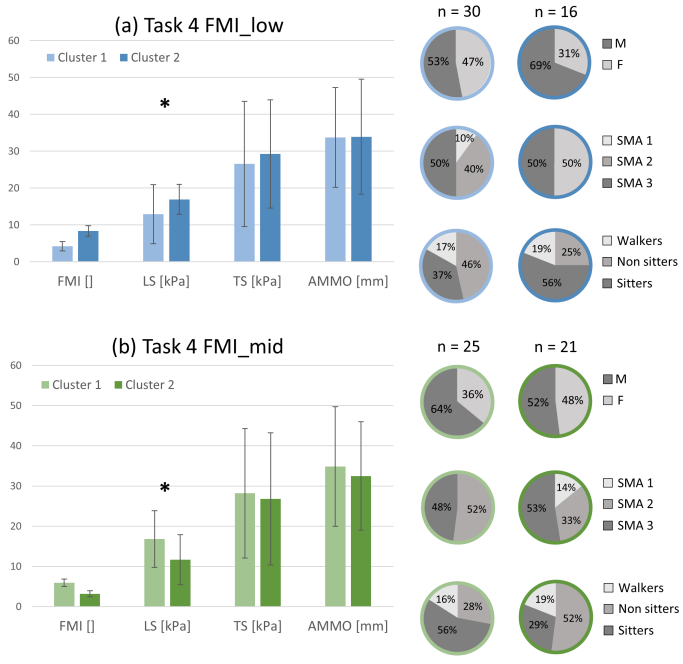

Fig. 4: Results of the cluster analysis in Task 4 FMI_low and FMI_mid in panels (a) and (b) respectively. Numerical variables are depicted as mean ± SD; categorical variables are represented as pie charts. on this expression as an indicator of disease impairment and progression. This easy-to-interpret metric may be employed to track possible alterations in oro-facial muscles mobility associated with the disease and to investigate the impact of different treatments aiming at restoring face mobility.

***Abstract*— The durability of transcatheter heart valves (THV) remains the main disadvantage of transcatheter heart valve implantation (TAVI) for treating aortic valve stenosis. In this study, we assessed the structural mechanics of TAV-in-TAVI using patient-specific modeling. A parametric analysis highlighted that the outcome of TAV-in-TAV depends on the implanted device position and the planned device to be implanted. Contact pressure evinced the impact of different implantation depth and device size on the TAV-in-TAV. This study may bring new insight in the biomechanical performance of TAV to evaluate options for future interventions when the current TAVs experience device failure.**

***Keywords*—finite-element analysis, transcatheter heart valves, redo-TAVI**

I. Introduction

Transcatheter aortic valve implantation (TAVI) is increasingly used to treat patients with severe aortic (AS) stenosis who are deemed inoperable or at high risk for surgical aortic valve repair [1]. After the publication of positive outcomes in inoperable patients with conventional surgery and in operable patients at high surgical risk, TAVI was included for the first time in the 2012 ESC/EACTS (European Society of Cardiology/European Association for Cardio-Thoracic Surgery) guidelines [2]. These guidelines specifically recommend TAVI for inoperable patients with severe symptomatic AS. Ongoing clinal trials are investigating the feasibility and safety of TAVI in low-risk patients and bicuspid aortic valve as these conditions were considered exclusion criteria in past trials [3].

Transcatheter heart valve (TAV) employed in TAVI is typically comprised of a biological valve mounted on a metal stent frame. The balloon-expandable SAPIEN 3 Ultra device (Edwards, Lifescience, Inc., Irvine, CA, USA) is composed of a metal stent in chrome-cobalt alloy, skirt in polyethylene terephthalate, three valve leaflets made of bovine pericardium, while the Evolut (Medtronic, Minneapolis, MN, USA) is made of porcine pericardium, and mounted on a self-expandable nitinol stent frame and sealing skirt [4].

An increasing number of younger patients with longer life-expectancy receive transcatheter aortic valve implantation (TAVI). Thus, even in the absence of concerns about TAV durability, a substantial proportion of contemporary TAVI patients are expected to live sufficiently long to experience the degeneration and failure of TAV. Indeed, the key disadvantage of TAVs is the limited durability as the chemically treated valve leaflets are not immune to structural degeneration from calcification and thrombosis. For instance, thrombosis was occurred within 3-year from TAVI procedure. The therapeutic option for the treatment of structural TAV degeneration are limited to open-heart surgery and redo-TAVI (or TAV-in-TAV) [5]. While the feasibility of TAV-in-TAV was recently demonstrated, the risk of coronary obstruction due to sinus sequestration is high [6].

In this context, computational modelling may allow to determine the biomechanical interaction of redo-TAVI. This study aimed to develop a computational framework to simulate TAV-in-TAV as clinically performed in one patient with early failure of the implanted device. Patient-specific computational modelling was carried out to determine structural metrics of delivered devices while a parametric analysis of the implantation depth of the second TAVI procedure was performed to assess the impact of the relative device position.

II. Materials and Methods

A. Patient Study Case

A 68-years old gentleman with severe AS was initially treated with a 23-mm SAPIEN 3 Ultra TAV at IRCCS ISMETT in 2019. After 3-year from TAVI, the device failure was treated by redo-TAVI with a 29-mm Evolut Pro device. The patient was discharged and is currently monitored with echocardiography. CT imaging was performed prior the first TAVI procedure for annulus size evaluation, after the TAVI and redo-TAVI.

B. 3D Reconstruction

Pre-TAVI CT images were processed in Mimics (v.21, Materialize, Belgium) to reconstruct the aortic root anatomy and calcific plaques using semi-automatic thresholding of the contrast-enhanced images [7]. Once segmented regions were obtained, the aortic wall and calcific plaques were exported as stereolithographic files for meshing. Since native valve leaflet were not clearly visible at CT scan, a parametric modelling approach was adopted generate the leaflet geometry using anatomic measurements and the CAD tool Rhinoceros (Rhinoceros v.7, McNeel & associates, USA). In brief, two 3rd-order NURBS curves interpolating commissures were delineated to model the free edge of valve leaflets, while the belly of each leaflet was considered using one control points. To model the leaflet-to-sinus attachments, a second set of 3rd-order NURBS curves were developed using Rhino software (v.7.1, McNeel & associates, USA). The NURBS curves were constrained to the aortic root surface by curve-to-surface projection, and then native valve leaflets were developed by a

multi-patch network of NURBS surfaces [8, 9].

Using ICEM meshing software (v2021, ANSYS Inc., USA), the aortic root luminal surface was discretized with unstructured triangular shell elements with size of 0.6 mm. Calcifications were meshed with tetrahedral solid elements with size of 0.5 mm. Native valve leaflets were initially discretized with triangular shell elements (element size of 0.6 mm) and then solid elements were obtained by element protrusion with thickness of 0.5 mm and 4 layers. Figure 1 shows the anatomic model parts of the patient model.

For the sake of simplicity, neo-Hookean models were adopted for both the aortic root and native valve leaflets. Specifically, the aortic root had C1=1.05 MPa and D=0.048 MPa^{-1} while the AS valve had C1=2.29 MPa and D=0.022 MPa^{-1}[10]. The neo-Hookean model allows to imitate the characteristics of the native tissue of aortic root in according to literature investigations [11].The calcification had a linear-elastic model with Young modulus of 400 MPa and Poisson coefficient of 0.475 [12]. Tie contact conditions were used to constraint anatomic parts while the proximal and distal ends of the aortic root was fixed in all directions.

C. *TAV Models*

Geometrical models of 23-mm SAPIEN 3 Ultra and 29-mm Evolut PRO device frames were obtained by reverse engineering of micro-CT images as described in a previous study from our group [13]. For the 23-mm SAPIEN 3 device, the metallic frame was meshed with nearly 60,000 structured-hexahedral solid elements with reduced integration (C3D8R). The Cobalt-Chromium alloy of stent frame was modeled with Von Mises plasticity and isotropic hardening [12]. The Evolut Pro device was meshed with 315,653 structured-hexahedral solid elements with reduced integration and hourglass control. The stent frame was modelled with nitinol alloy material properties as proposed by Auricchio et al [11]. In both cases, the sealing skirt is obtained closing the struct cell geometries with several surfaces modelled at mid-thickness of the device frame. For the SAPIEN 3, the sealing skirt was modelled at crimped stage of TAVI and after the redo-TAVI for the Evolut Pro. Skirts were simulated using surfaces with triangular shell elements assuming thickness of 0.1 mm and were then connected to the device frames using tie contact conditions. Elastic-plastic material properties were assumed for sealing skirt materials [13]. To include the SAPIEN 3 valve leaflets after TAVI, we closed all cell-struct frame to mimic the leaflet displaced by the TAV-in-TAV. For the Evolut Pro, the device leaflets were mapped after redo-TAVI. Figure 1 shows the device models.

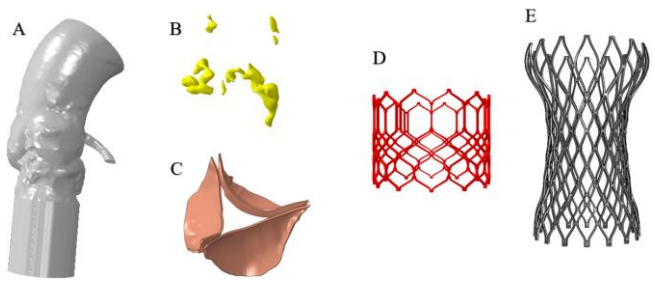

Figure 1: (A) patient model, (B) calcific plaques, (C) native valve leaflets, (D) SAPIEN 3 frame and (E) Evolut Pro frame

D. *Finite-element Analysis*

Numerical analysis of the redo-TAVI procedure was developed in Abaqus/Explicit (v2021hf7, Dassault Systèmes, USA) using a quasi-static approach and thus monitoring energy and ensuring the ratio of kinetic energy to internal energy remained less than 10%. Mass scaling was applied with an element-by-element stable time increment of 10^{-6} every 100 increments to reduce the computational cost.

The SAPIEN 3 stent frame was crimped by a rigid cylindrical surface gradually moved along the radial direction from the initial diameter of S3 (23 mm) to the final diameter of 6 mm. Frictionless contact condition was defined between the crimping surface and the device stent. Using a restart analysis, the crimped device was placed in the human host considering the stress state resulting from the crimping simulation (Fig. 2A). The SAPIEN device was positioned with an implantation depth of 5 mm. Expansion of S3 stent frame was simulated by the radial displacement of a rigid cylindrical surface representing the wall of the expanding balloon. The cylindrical surface is enlarged from the initial diameter of 6 mm to the nominal diameter of 23 mm. Frictionless contact was enabled between the cylindrical expanding surface and the S3 stent frame, which was allowed to be in contact with other anatomic parts. After expansion, an elastic recoil was allowed by the release of the cylindrical surface [5]. After TAVI simulation, the Evolut Pro was crimped using a cylindrical surface gradually moved along the radial direction from the initial device diameter to the final diameter of 6 mm using frictionless contact conditions. Both the stent and sleeve were positioned in the TAVI model with an implantation depth of 9 mm. By pulling the sleeve towards the distal ascending aorta and releasing the stent, because of its residual stresses, the Evolut Pro stent was gradually deployed into the TAV. The pull out of the rigid sleeve was performed by a uniform displacement of 75 mm.

Four different TAV-in-TAV scenarios were simulated varying the implantation depth or device size. The following parametric analysis were therefore performed:

1. 5-mm implantation depth for SAPIEN 3 and 9-mm implantation dept for Evolut Pro (reference configuration)
2. 5-mm implantation depth for SAPIEN 3 and 16-mm implantation dept for Evolut Pro (low redo-TAVI implantation depth)
3. 3-mm implantation depth for SAPIEN 3 and 9-mm implantation dept for Evolut Pro (high TAVI implantation depth)
4. 26-mm Evolut Pro in 23-mm SAPIEN 3 device (redo-TAVI overexpansion).

E. *TAV-in-TAV Analysis*

Eccentricity and expansion indexes were calculated from both TAVI CT and redo-TAVI CT images and then compared to those predicted by computational analysis. For each finite-element simulation the eccentricity index was calculated as follows: [1 − (minimum external THV diameter/maximum external THV diameter)] × 100 while the expansion index was expressed in relation to nominal prosthesis size as follows: (observed THV external area/ device area nominal size) × 100

[5]. Measurements were performed at 4 different anatomic levels (see Figure 6). For each simulation, the contact pressure exerted by the devices on the aortic wall was extracted. Distributions of contact pressure after redo-TAVI were mapped for the different scenarios.

III. RESULTS

Comparison between numerical and CT-based structural indices showed that numerical expansion indices remain lower than CT measurement at different anatomic levels (ie, 120.8 ± 10% for CT-based measured of S3 versus 96.5 ± 14% for numerical-based measured of S3, while 90.6 ± 13% for CT-based measured of Evolut Pro versus 79.2 ± 21% for numerical-based measured of Evolut Pro). In a different way, the eccentricity index shows that numerical simulations slightly underestimate frame-related elliptical deformed shapes.

Figure 2 shows the delivering phases of SAPIEN 3 device and Mises stress distribution at the end of crimping phase. Similarly, Figure 3 displays the deployment of Evolut Pro in the previous SAPIEN 3 TAV as well as the Mises stress distribution for self-expandable device.

Figure 5 shows the Mises stress distribution and deformed shapes of each device.

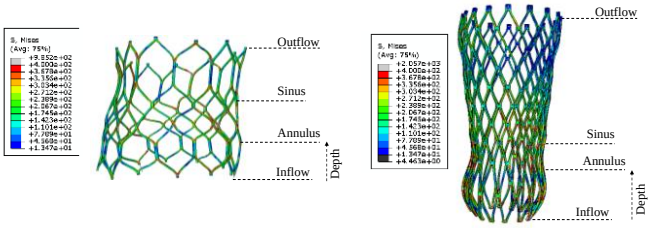

Figure 6: Mises stress distribution of each device for TAV-in-TAV

Figure 7 shows the contact pressure distribution among device frames (SAPIEN 3 and Evolut Pro) and aortic root for each TAV-in-TAV scenario. It is possible to observe a lower contact pressure in the fourth scenario (redo-TAVI overexpansion).

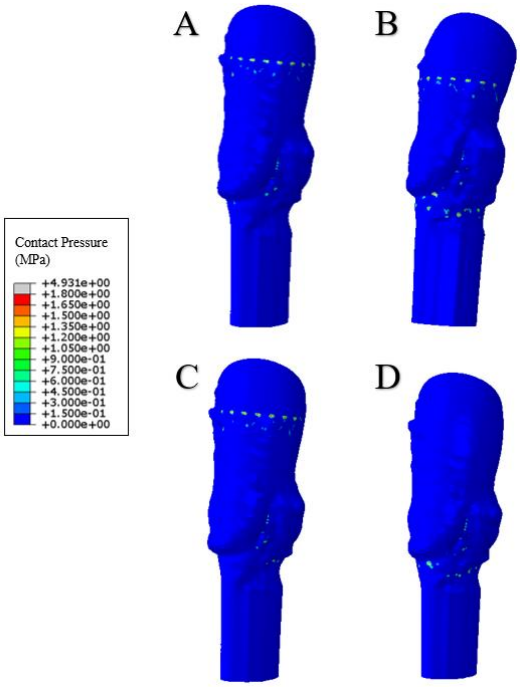

Figure 7: Contact pressure for (A) reference TAV-in-TAV as done clinically, (B) low redo-TAVI, (C) high redo-TAVI and (D) TAV-in-TAV overexpansion

IV. Discussion

To the best of our knowledge, this is the first computational study evaluating the structural mechanics of TAV-in-TAV. We first simulated the TAV-in-TAV according to the implantation depth and device size indicated by the Heart Team, and then carried out a parametric analysis varying these device parameters. The tendency of Evolut Pro devices to expand asymmetrically in the previous SAPIEN 3 device was observed and quantified at several anatomic levels. The utilize of a larger device size than that used by the Heart teams has increased the contact pressure on the aortic wall. We also found that the high implantation depth of Evolut Pro can lead to a final skirt position likely closing the coronary ostia. Future computational flow studies will be undertaken to explore whether the parametrically-derived TAV-in-TAV shapes may lead to coronary flow obstruction and thus adverse events.

Computational analyses of the structural mechanics of TAVI demonstrated that an overexpansion of the implanted device can lead to a high risk of the aortic annulus rupture [9, 13-17]. The impact of aortic root anatomy and tilt angle of the device [18], calcification patterns [19] and native leaflet morphology [20] on the device deployment were also investigated. Fluid-solid interaction was also proposed to simultaneously simulate the structural mechanics and hemodynamics [21]. Moreover, simulations were used to explore the efficacy and safety of TAVI in young and high-risk patients, which are not conventionally treated with THVs. With regards to bicuspid patients, Brouwer et al. [22] carried out computational flow analyses to assess the paravalvular leakage in bicuspid patients, and thus demonstrate the feasibility of TAVI with the newest generation of THVs. Similarly, Pasta et al. [16] investigated stenotic bicuspid patients and found a good agreement between computer and post-TAVI CT-based measurements of the device conformation to the bicuspid anatomy. Recently, the hemodynamic of TAV-in-TAV was investigated using particle image velocimetry by Hatoum and collaborators [23]. They performed a parametric analysis to investigate different device-size combination of TAV-in-TAV with both the SAPIEN 3 and Evolut THVs. They also found more turbulence for the TAV-in-TAV procedure as compared to that of traditional TAVI. In a different way, this study provided more insights on the structural mechanics of TAV-in-TAV to evaluate options for future indications when performing redo-TAVI. The material modeling of vessel wall using a neo-Hookean can be considered a limitation of the current study. However, the study documented by Bosi et al [12] has reported evidence that a linear elastic material model for the vessel is a valid approach to account the stiffen behavior of the diseased vessel.

V. Conclusion

We conclude that computational simulations can reveal important insights into the deployment of THVs when current devices experience structural valve failure. The outcome of TAV-in-TAV depends on both the original implant and the device to be implanted. Future flow studies are needed to assess whether the predicted TAV-in-TAV configurations can lead to coronary flow obstruction.

Abstract—**Atherosclerosis is a systemic pathology that leads to the development of plaques within the walls of vessels. Three types of plaque can be distinguished within the wall structure: soft, calcific and fibrous. The rupture of the plaque could cause thrombo-embolic events; thus, the assessment of plaque vulnerability is fundamental for their prevention. Our goal is to propose a workflow to model the atherosclerotic carotid wall and evaluate the stress distribution in the plaque region through finite element analyses. The segmentation of computed tomography angiography images of a patient was used to derive the geometries of the carotid lumen, calcific and lipid plaque components, while the fibrous component was reconstructed (together with the vessel wall) using purposely developed procedures. The resulting 3D patient-specific model of the vessel, including all plaque components, was used for structural simulations. Pressure load values were instead obtained from an ultrasound modality. The results were used to evaluate how mechanical and geometrical factors affect the stress in the atherosclerotic wall. In the paper, results from the analysis of a heterogeneous plaque with a lipid core surrounded by a thin fibrous cap, which could represent a potentially vulnerable plaque case, will be presented.**

***Keywords*— carotid plaque, image-based modelling, computational analysis.**

I. Introduction

CAROTID artery (CA) represent a common site for the development of atherosclerotic plaques [1]. The presence of the atheromatic plaque in carotid arteries is associated to acute cardiovascular consequences [2] and accounts for a major cause of all ischemic strokes [3]. Indeed, atherosclerosis involves the accumulation of deposits in the inner layer of artery walls (intima), that leads to the formation of an atheromatic plaque, whose development and progress depend on the influence of mechanical forces exerted on vessel walls. The earliest vascular change is the intimate thickening, which consists of layers of smooth muscle cells and extracellular matrix [4]. Some lesions with pathological thickening are characterized by the presence of varying degrees of cholesterol within lipid pools covered by a thick fibrous cap (FC) that begins to thin over time [5]. The FC thickness is critical for the maintenance of the integrity of the lesion and is subject to thinning, prior to rupture. The plaque that is prone to rupture is defined as "vulnerable". A calcified nodule could be present in the advanced stage of a lesion too, however it is the least frequent cause of thrombosis.

The rupture of the plaque is a mechanical event that occurs when the carotid wall loading exceeds the tissue strength and it is regulated by the cellular and molecular composition of plaques [6] [7]. Identifying patients with vulnerable plaques represents an important step to prevent acute and adverse cardiovascular events which could lead to complications [8].

Computational studies provide the three-dimensional (3D) stress/strain distributions in patient-specific diseased arteries with different plaque types and morphologies, so they could have the potential to give valuable information for the plaque vulnerability assessment. By combining clinical imaging methods, like e.g. computed tomography angiography (CTA), with computational analyses, several groups studied the structural stresses of diseased carotid arteries obtained from different modelling strategies. However, usually in CTA scans the fibrous component of the plaque and artery walls are not clearly distinguishable. For this reason, the reconstruction of these structures is challenging. Some works proposed the manual segmentation of clinical images to reconstruct the plaque components and wall structure geometries, such as [9], [10]; other studies performed a semi-automatic segmentation of lipid and calcific plaque components only [11] or modeled these ones as idealized geometries [12], while the fibrous and healthy wall tissues surrounding them were again reconstructed manually.

This work aims at providing a workflow that allows to model a patient-specific atherosclerotic CA and to perform 3D finite element analyses (FEA) in order to evaluate its structural behaviour, considering different plaque compositions (including both calcific, lipid and fibrous components) and biomechanical vessel loads. Concerning the atherosclerotic vessel modelling, we propose an *ad-hoc* developed semi-automatic procedure to reconstruct the carotid walls starting from CTA images. Since fibrous structures, such as the healthy wall and plaque fibrous component, are challenging to highlight in CTA images, we firstly segmented the plaque calcific and lipid components only and subsequently reconstructed the model of the plaque fibrous component and wall by applying the proposed automatic procedure. Indeed, modelling also the plaque fibrous component allows to represent more accurately the composition and morphology of the atherosclerotic vessel. Finally, for what concerns the vessel biomechanical load conditions to be set in FEA, we considered pressure values obtained from a specific ultrasound (US)-based wall-tracking modality, thus also exploiting different imaging techniques to derive patient-specific data.

II. Materials and Methods

A. *Image Acquisition*

Two different image acquisitions were performed on the considered patient before undergoing endarterectomy: 1) neck-head CTA scans, which were used to segment the different vessel structures in the DICOM sequences; 2) US

scans employing a dedicated software package that implements a radiofrequency (RF)-echo-based arterial-wall tracking procedure to derive carotid pressure waveforms. Further details are provided in [13], [14]. The software provided the local CA diastolic and systolic pressure values that were used in FEA analysis. The patient gave written informed consent and the study was approved by the IRCCS Ospedale San Raffaele ethical committee (record number 110/int/2019, 20 June 2019).

B. Proposed CA Modelling Methodology and Biomechanical Simulations

The atherosclerotic CA wall was reconstructed starting from the CTA segmentation (Fig. 1a). The segmentation of the CA lumen, calcific and lipid plaque components was performed using the ITK-Snap software [15]. The segmentation was confirmed by the vascular surgeon (D.M).

Since a semi-automatic segmentation of the CA wall and plaque fibrous component is not possible in CTA images, such structures were generated as computer aided design (CAD) models through a purposely-developed procedure using the Rhinoceros software (McNeel and Associates, Seattle, WA, USA) and the Grasshopper plug-in.

Firstly, the procedure started with the processing of the lumen STL (Fig. 1b) to generate the vessel wall inner surface; then, equally spaced sections were selected from the lumen surface and these latter were enlarged to obtain the vessel wall outer surface, keeping the plaque surface STL enclosed between the inner and outer walls (Fig. 1c). The final CA wall solid geometry was created by Boolean difference of the inner and outer walls.

Secondly, filling the stenotic area of the lumen between the inner and outer surfaces of the wall surrounding the other plaque components provided the plaque fibrous component (Fig. 1d).

3D FEA were then carried out using the commercial finite element package Abaqus CAE (Simulia, Providence, RI, USA). The solid domain was discretized with tetrahedral elements. The mesh was thickened with a local refinement in the plaque region, choosing a local mesh size of 0.3 mm, after a mesh convergence analysis. The global mesh size, out of the plaque region, was set to 0.8 mm.

The materials assigned to both the vessel wall and plaque components were set as incompressible, isotropic, linear elastic, with a 0.49 Poisson's ratio; instead, a different Young's Modulus was considered for each of them. The used material properties were chosen after a literature review [12], [16]–[21].

The load conditions of the CA wall were defined as follows: the distal and the proximal ends of the carotid bifurcation were constrained in the longitudinal and circumferential directions; also, the inner wall was loaded with a constant uniform pressure (i.e., 68.5 mmHg, as this was the patient-specific pressure value obtained from US acquisitions).

III. Results

In this section, results relative to one patient selected to test the developed procedures are presented.

First, the model resulting from the procedure previously described is shown in Fig. 1e. The model represents an heterogeneous plaque within CA walls with all the three plaque components mentioned before.

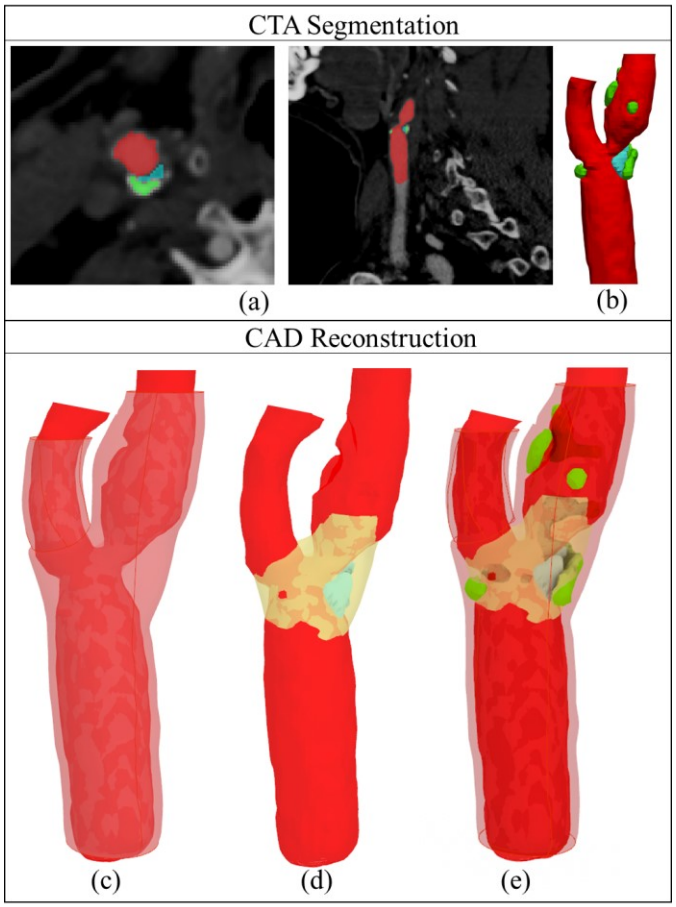

Fig. 1. Atherosclerotic carotid reconstruction workflow. CTA axial and sagittal views with overlapped segmentation (a) and the corresponding STL (b): the lumen is labelled in red, the lipid content of plaque is represented in blue and the calcific content in green. The CAD reconstruction provides: the final atherosclerotic wall geometry (e), obtained through a lumen enlargement procedure used to include the calcific and lipid components of the plaque (c), and the fibrous plaque component (in yellow in (d-e)) filling the stenotic lumen areas.

The obtained von Mises (VM) stresses were then analyzed as the simulation output. From a qualitative point of view, the contour plot of the stress distributions allows to check the localization of the highest stresses. In Fig. 2, the VM stresses distribution in the fibrous plaque and the CA healthy wall elements is provided. High VM stress regions (colored in red in Fig. 2) could appear both in the fibrous plaque and in non-pathological areas. In the plaque region, the highest stresses were located in the region of the FC, at the interface between the lipidic component and the lumen.

To perform a comparative analysis and validate the proposed procedure, the vascular surgeon provided the manual segmentation of the plaque fibrous component from CTA scans. Subsequently, two structural simulations were performed using, in one case, the fibrous plaque CAD model automatically generated using the proposed approach, and in the second one the STL file obtained from the manual segmentation of this component, performed by surgeon. The results of the two simulations are reported in Fig. 3. To analyze the stress distributions, we selected the same cross-sectional

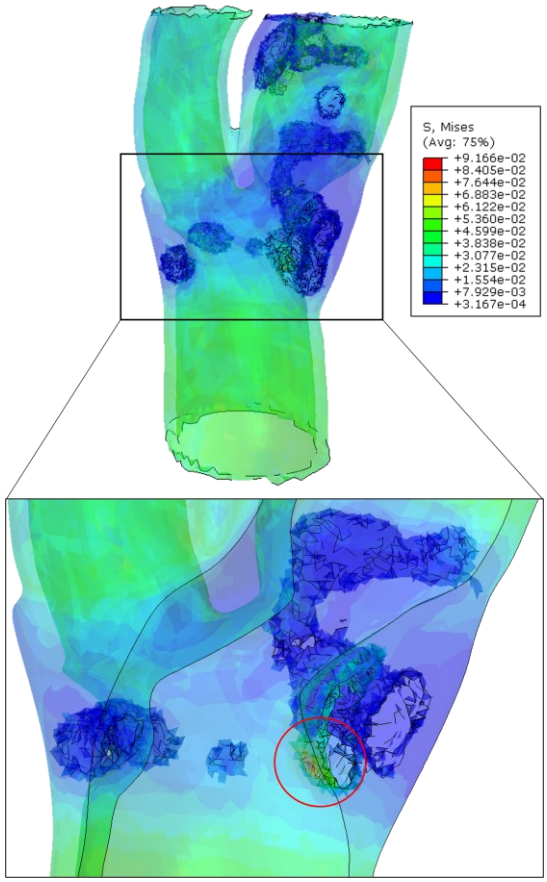

Fig. 2. Contour plots of the VM stress distribution, both in the CA healthy wall ad fibrous plaque regions, in 3D views. The highest stress regions in the fibrous subset are displayed in red (see color scales) and highlighted by the red circle.

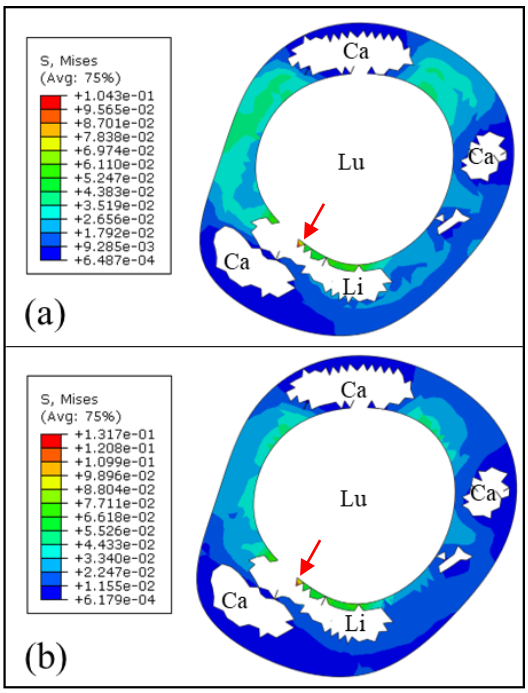

Fig. 3. Results of the comparative analysis. The figure shows the cross-sectional contour plots of VM stress distributions (colour scale in MPa) in the CA healthy wall and fibrous plaque, obtained from simulations with the proposed CAD model (a) and with the manually segmented model of the fibrous component (b). The slice including the maximum VM stress (highlighted by the arrow) has been selected. The lumen is denoted as Lu, while the lipid and calcific subsets are denoted as Li and Ca, respectively.

slice in both simulation outputs. In Fig. 3 a-b, the contour plots of the obtained VM distributions are compared: the simulated VM stress distributions and the location of the highest stress concentration look qualitatively similar in both models.

IV. Discussion and Conclusion

The aim of this work was to propose a new methodology to model an atherosclerotic carotid wall and different plaque components from CTA images, and to perform a computational analysis of stress distributions, including also data derived from an US-based modality. The advantage brought about by this method is that it generates models that are patient-specific and models the fibrous content of the plaque in an automatic way as a further plaque component, differently from other works that did not make any distinction between the fibrous plaque and vessel wall [22], [23] or in which these structures were manually segmented [11]. Modelling the plaque fibrous component allows to have a more accurate representation of the FC in plaques at different stages, that could be prone to rupture. Furthermore, different mechanical properties can be assigned to each region for a more accurate representation of the actual plaque composition.

On the other hand, the workflow here proposed also shows some limitations. First, the modelling procedure is not completely automatized, so the reconstruction is time-consuming because of the complexity of geometries; the settings of simulation are based on some simplifying hypotheses [12], [16], [17] concerning the material properties, even if it is well known that arterial soft tissues are non-linear hyperelastic materials. The simulations did not account for pre-stresses or specific CA loading conditions (i.e. blood pressure, residual stresses and axial pre-stretch) due to missing information on the cardiac cycle phase corresponding to CTA scan acquisitions. Finally, VM stresses were considered in these analyses, since they are suitable to describe the distribution of loads among different subsets of the simulation, and were used also in several other works in the literature [11], [12], [17], [22], [24]. These limitations will be addressed in future works, together with the inclusion of a higher number of cases in the analysis.

***Abstract*— Cornea is a composite tissue that exhibits nonlinear and time-dependent mechanical properties. Ulcers are one of the main pathologies affecting corneal tissue, leading to a structural non-integrity, and worsening the performance due to impaired functions. For this reason, assessing the mechanical behavior of the cornea is crucial not only to reveal the alterations induced by pathologies and lesions that could induce further damages, jeopardizing the mechanical response and performances of cornea, but also to evaluate treatments aimed at contrasting the corneal weakening.**

This study aimed at mechanically characterizing the healthy porcine corneas, as a suitable model to replace the lack of human samples, by performing sub-structural (uniaxial tensile) and structural (saline solution inflation) tests to reveal the mechanical behavior and the deformability of the corneal tissue. In detail, failure, cyclic and stress-relaxation tests were carried out on fresh corneas while structural tests were performed also on frozen corneas, to assess if the storing process alters the mechanical properties. The inflation tests were performed after having designed and printed a corneal support device, conceived to guarantee an adequate grip and a sealing system.

The results of tensile tests revealed that the failure was in average reached at a strain of 0.79 (± 0.14), relative to a mean stress of 1.274 (± 0.368) MPa. In cyclic tests, the two tested velocities seemed not to influence the results, while stress relaxation tests confirmed the viscoelastic behavior of the tissue. The inflation test results showed a non-significant difference in pressure-volume behavior between fresh and frozen corneas.

This work gave an overview of the mechanical properties of the healthy porcine corneas, also for large deformation, that in the past was not analyzed. Once the corneal tissues are proper characterized, a complete and validated computational model can be developed. Computational analysis could be a starting point to evaluate in silico the mechanical behaviour of cornea both in healthy status and simulated pathological conditions, without collecting biological samples.

In future, the same tests will be performed on treated corneas, for example via plasma treatment for cellular proliferation (used to treat wounds) or cross-linking, and on corneas subjected to a simulated lesion, to quantify the induced changes in mechanical proprieties.

***Keywords*—stress relaxation, corneal tissues, failure, cyclic test, inflation test**

I. Introduction

THE cornea is the outermost transparent tissue and the essential refractive component of the eye. Among the most common corneal pathologies, the ulcerative melting keratitis alters the microstructural organization of the tissue, impairing its mechanical and functional behaviour and, in the most severe cases, leading to blindness. Nowadays, considerable research efforts in regenerative medicine are focusing on the development of reliable alternatives to keratoplasty, due to the limited availability of healthy donated corneas. One of the main aspects to identify an adequate treatment is the restoration of the mechanical properties that have been modified due to the pathologies.

The mechanical behaviour of the corneal tissues has been studied largely in the last years and still numerous publications on the subject are emerging. Uniaxial tensile and inflation tests are the most frequent kind of experimental tests performed to evaluate the mechanical response of ex vivo corneas, revealing the nonlinear elastic, anisotropic and quasi-linear viscoelastic mechanical behaviour of the cornea [1]–[8]. Such mechanical response depends on the intricate, multi-scale structures with distinct patterns of fiber organization disposed on different layers [9]. Brillouin microscopy has been also applied for mapping the mechanical properties of the cornea as the elastic modulus in three dimensions with a high spatial resolution [10]. Because the difficulties in collecting human corneal tissues, porcine corneas are frequently used to replace them in assessing the biomechanical properties. However, despite some differences in corneal thickness, porcine cornea is largely accepted as a suitable model because exhibits similar stress-strain behaviour under short- and long-term loading and reacts likewise to sustained loading, although the creep is higher in human than in porcine corneas [3].

A mechanical overview of the corneal tissues could be crucial in the framework of biomechanics. In fact, several studies reported the finite element analyses on the corneal structure that, initially, were used to simulate the corneal mechanical response to refractive surgery. They provided a useful starting point for surgical planning and demonstrated how mechanical modeling could explain the refractive effects achieved by modulating the length and depth of surgical incisions. More recently, models have become more advanced by considering also patient-specific geometry, alignment and distribution of collagen fibrils, the aging and cornea transplant surgery [9].

In this study, several tests on healthy porcine corneas were performed, such as failure, cyclic and stress relaxation uniaxial tensile tests at large deformation that lacked in literature. Moreover, the saline solution inflation test was performed on fresh and frozen healthy corneas, highlighting if significant differences due to the storing process were detectable. Finally, a preliminary computational model simulating the inflation test was implemented with a view to implement in the future a model that has a robust constitutive formulation that can

correctly interpret corneal behavior, useful for simulations of surgical procedures.

II. Materials and Methods

A. Sample collection and preparation

A total number of 38 porcine corneal samples were tested. The samples were wastes of a local slaughterhouse and derived from animals intended for food consumption. All corneas were found to be clear, with no presence of corneal scarring or opacities, and transported under sterile condition to the laboratory inside a container with betadine, an antiseptic solution at 10%. The eyeballs were rinsed with phosphate buffered saline concentration to reduce contamination. The samples were split in two main groups: 20 corneas used for tensile tests and 18 for inflation tests.

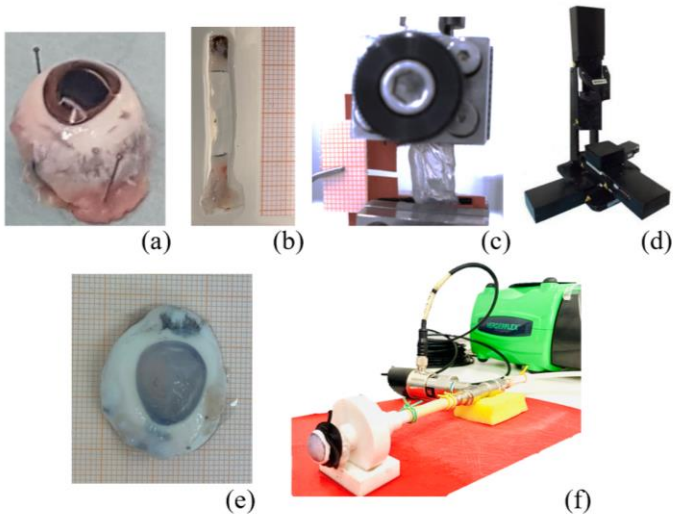

Fig. 1: Healthy eyeball sample (a). Corneal strip (b) and set up of the tensile tests (c). Biomomentum Mach-1 v500csst Machine (d). Whole corneal sample for inflation test (e) and linking of the artificial chamber to the pressure transmitter and peristaltic pump (f).

B. Experimental Set up – Tensile test

All the measurements were performed at the Biomomentum Mach-1 v500csst Machine (linear motion resolution 0.5 um, max acceleration 500 mm/s², single-axis load cell up to 250 N, resolution 12.5 mN) (Fig. 1d).

20 samples were used tensile tests and divided as follows: 7 samples for failure, 5 for cyclic and 8 samples for stress-relaxation tests. The corneal samples were cut into strips (Fig. 1b), ancored to the grips (Fig. 1c) and then preconditioned by the application of 10 loading-unloading cycles imposing a sinusoidal displacement to the tensile machine. The strain reached a maximum of 8%, the frequency was fixed at 0.5 Hz. Then, the samples were submitted to failure tensile tests by applying a progressive strain at a constant strain rate of 1%/s or 0.1 %/s and stopped when a null force was visualized at user interface.

The cyclic test consisted of two sets of three consecutive loading-unloading cycles with different strain rates, 1%/s and 10%/s. Between the sets, a pause of 360 s was imposed.

Also, stress relaxation test was performed and the protocol was composed by four steps of 8% of axial deformation (up to 32%), and a relaxation time of 400 s was waited at the end of each step to permitt the almost complete development of the relaxation phenomena. During tests, saline solution hydrated the surface's sample to prevent tissue dryness.

C. Experimental Set-up – Inflation test

The experimental equipment consisted of a peristaltic pump (VerderFlex Vantage 5000, Verder Ltd, UK), a Verdeprene 3.8mm-diameter tube, a pressure transmitter (range 0-200 mbar, current output, 0.5% precision, Trafag), a National Instruments chassis (NI cDAQ-9189 CompactDAQ), a current input NI module (NI-9253, 8-Ch, +/- 20 mA, 50kS/s/ch, 24-Bit filtered C Series), a laptop pc with installed LabView 2022. A specific LabView code was designed to collect the pressure data and control the pump. 18 corneas were used for inflation test and were split in two groups: 9 tested fresh and 9 stored in the freezer and tested the day after. The lens and iris were removed, while a part of sclera was retained to fix the specimen during the test (Fig. 1e). An *ad hoc* anterior artificial chamber was designed and printed in PA-GF blends polyamide powder and glass beads by Materialize to avoid the pressure leakages that were verified with standard anterior artificial chamber due to a bad grip. The cornea was gripped to the anterior chamber thanks to a gasket and a rubber band and connected both to the pressure transmitter and to the tube of the pump (Fig. 1f).

The protocol on the inflation test consisted in inflating three or four doses in order not to damage the pressure transmitter. Between doses, a relaxation time of 10 minutes was waited to permit the almost complete achievement of the equilibrium.

The equilibrium points after each dose were considered to obtain the pressure-volume curve at the equilibrium, while the relaxation parts of the curve were normalized and processed with a two-branches Prony model to get the viscous parameters (Tab. I).

TABLE I:
MEAN VISCOUS PARAMETERS

Test	*First Viscous Branch*	*Second Viscous Branch*
Inflation relaxation test	$p^{norm} = 1 - \sum_{i=1}^{2} \gamma^i \left(1 - \exp\left[-\frac{t}{\tau^i}\right]\right)$	
Frozen corneas	$\gamma_1 = 0.1555$ $\tau_1 = 28.31$ s	$\gamma_2 = 0.39$ $\tau_2 = 344.90$ s
Fresh corneas	$\gamma_1 = 0.12$ $\tau_1 = 20.12$ s	$\gamma_2 = 0.43$ $\tau_2 = 287.25$ s

D. Computational Analysis

A first preliminary computational model of the cornea was developed in Abaqus/CAE 2022 (Dassault Systémes Simulia Corp., Providence, RI) to simulate the inflation test and validate the constitutive models. The geometry comprehended a hollow spherical cap considering the application of 40° inclined supports at the marginal nodes of the cornea [11]. The thickness was not uniform: the central thickness of 0.833 mm, the side thickness of 1.033 mm, the front and rear base diameters of 13.81 mm and 12.228 mm respectively, the total

height of 2.4 mm [12]. A first-degree hyperelastic Ogden model was chosen for the corneal tissues and defined by inserting the stress relaxation data at equilibrium as Test Data. The evaluation of the material resulted stable for all strains. A fluid cavity pressure was defined, and a pressure ramp imposed.

III. Results

Results showed the nonlinear and time-dependent behavior of the cornea.

A. *Failure test*

In the failure test, no statistical difference was recorded by considering the two strain rates, hence for the elaboration of the results the data were considered as a single dataset. The slope of the curve changes for almost all specimens after a strain of 40 %, before the effective failure. Two Young's moduli were calculated to quantify the stiffness of the corneal tissues, at the initial portion of the curve, approximately up to a strain of 5 %, and at the central linear portion of the curve, ranging from 15 and 40 % of strain. The median moduli were 0.33 (±0.074) and 2.15 (±0.587) MPa. The failure was in average reached at a strain of 0.79 (± 0.14) %, relative to a stress of 1.274 (± 0.368) MPa.

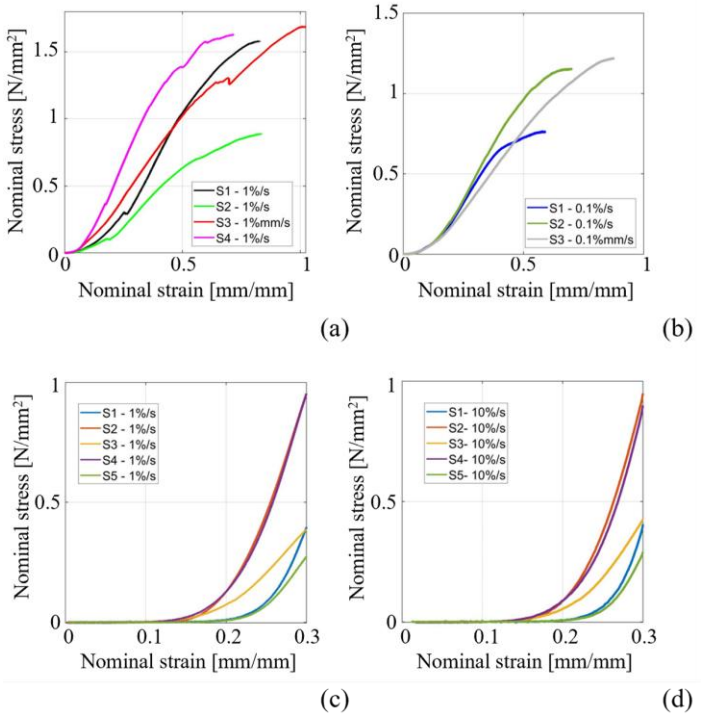

Fig. 2: Results of the failure test performed on 7 samples at 1%/s (a) and 0.1%/s strain rates (b). Results of the third loading ramp of the cyclic test for the 5 samples, at 1%/s (d) and 10%/s (e) strain rates.

B. *Cyclic test*

In the cyclic tests, the first cycle showed the highest hysteresis, while the others almost overlapped. To compare the action of the velocities, only the loading curve of the last cycle was considered in Figure 2 (c and d).

C. *Stress- and pressure- relaxation*

The results related to the stress- and pressure relaxation test for tensile and inflation test are proposed in Figure 3. The data are proposed in terms of equilibrium behavior, normalized stress and pressure over time.

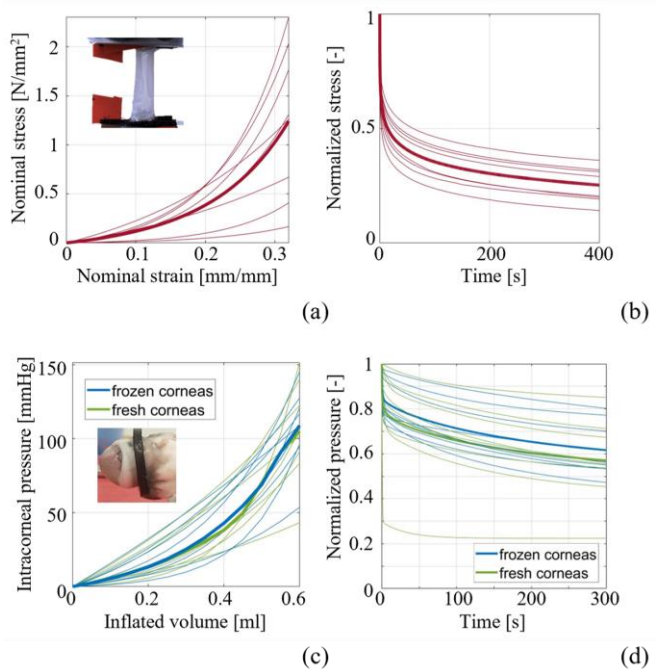

Fig. 3: Results of stress (a and b) and pressure- (c and d) relaxation after tensile and inflation test, in terms of equilibrium behaviour (a and c) and normalized relaxation over time (b and d). The ticker lines are the means, while the others the results of each sample.

IV. Discussion

The values resulting from the failure tests differed from those reported in the literature by Boschetti et al., which presented a significantly lower average failure strain (0.192 compared to 0.794) and a higher average failure stress (4.763 MPa compared to 1.274 MPa) [13], while much agreement was found by comparing the results to Tonsomboon's ones [14]. These failure tests assured the application of the stress relaxation protocol adopted in this work, ensuring that the tissue behaved smoothly at a strain of 32%.

The cyclic test results revealed the almost independence in the mechanical response from the strain velocity, confirmed by studies in literature [14], [15]. In fact, only a significant increase in stiffness at low strain rates, specifically going from 0.01 to 0.42 %/s, was recorded, while the effects of successive increases in strain rate were found to be statistically insignificant.

Figure 3 reported all the curves of the tested samples (thin lines) and the mean curves (thick lines). The results showed the high variability that characterized biological tissues, especially in relaxation over time graph. The results obtained from the computational model are reported in Figure 4. The good agreement between experimental and computational results revealed the reliability of the model in describing the inflation test.

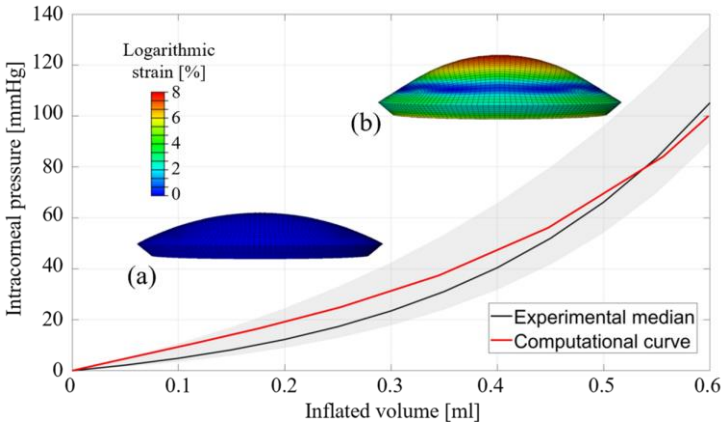

Fig. 4: Comparison between experimental (grey band) and computational (red curve) pressure-volume response for inflation test. The results must be intended at the equilibrium, after the almost complete relaxation of the tissue. Contours of the distribution of the logarithmic strain of the cornea at the beginning of the simulation (a) and 0.6ml of inflated volume (b).

V. Conclusions

The use of porcine corneas in mechanical property studies as an approximate model of human corneas is mainly due to the difficulty of obtaining in large quantities of corneas from human donors [16]. Both porcine and human corneas are characterized by a marked anisotropy and a nonlinear stress-strain relationship, and they exhibit a similar mechanical response to both short and prolonged loads. However, uniaxial tensile and inflation tests have shown a more pronounced viscoelasticity in the case of porcine corneas, putting more emphasis on the bilinear behavior of the tissue, and a lower overall stiffness than in human corneal samples [13]. The anisotropy of the tissues is, in this case, neglected because the low number of samples, preferring to propose different and independent mechanical tests.

The results presented in this work highlighted the time-dependency of the mechanical response of the corneal tissues, delineating the behavior of healthy porcine samples, at a sub-structural (uniaxial tensile test) and structural level (inflation test), at high level of deformation, which lacked in literature.

In future, further tests will be carried out to populate the limited number of samples and to analyze the corneal anisotropy. Furthermore, tests on corneas preserved in culture, treated with plasma or cross-linking and alkali-lesioned corneas will be included to analyze the influence of corneal modification on the tissue mechanical behavior.

***Abstract*— Tricuspid regurgitation (TR), also called tricuspid insufficiency, is a relatively common valvular diseases that can result from structural abnormalities of any anatomic part of the tricuspid valve apparatus. While trivial and moderate TR are compensated by the right atrial compliance, severe regurgitation conditions can result in congestive heart failure and hemodynamic impairment. We aim to model the non-invasive caval implantation treatment of TR seen in one patient using the novel bicaval transcatheter system (TricValve). Geometric models of TricValve devices were obtained from manufacturing guidelines and photography of devices. Then, the TricValve was simulated in a patient-specific model to assess the device structural performance. Computational fluid dynamics was also used to evaluate the pre- and post-TricValve haemodynamic. Ultimately, this study has the potential to better understanding the biomechanical performance of the novel TricValve system and may improve the way we design the next-generation of transcatheter therapies for severe TR.**

***Keywords*—finite-element analysis, computational fluid dynamic, transcatheter bicaval valves, tricuspid valve**

I. Introduction

Tricuspid regurgitation (TR) is a type of heart valve disease in which the valve between right ventricle and right atrium does not close properly [1]. As a result, blood leaks backward into the right atrium, ultimately increasing atrial pressure and leading to heart dilatation. Blood flowing back into the right atrium increases blood volume within the right atrium and results in a decrease in the proportion of blood pumped into the heart and to the body. Consequentially, the right atrium thickness and blood pressure increases in the right atrium and the large veins that flow into it. If the atrium is extremely dilated, the heartbeat becomes accelerated and irregular (resulting in what is known as atrial fibrillation), leading to a reduction in the heart's ability to pump, as the atrium in fibrillation trembles instead of pumping [2].

No major hemodynamic disturbances occur for trivial and moderate TR since the increase in blood pressure is compensated by the compliant nature of the right atrium. In case of severe TR, the haemodynamic impairment can lead to in right-sided congestive heart failure and thus fatal events. The incidence of TR is to be 0.9% in United States [3]. However, the medical management of patients with severe TR lead to a 5-year mortality rate as high as 50% [3]. The optimal timing of surgical repair or replacement of the TV still remains an open challenge.

II. Transcatheter Bicaval Valves

The development of non-invasive therapeutic strategies of the replacement of the TR has gained a remarkable attention.

Edge-to-edge tricuspid valve repair with the TriClip device (Abbott Cardiovascular, Plymouth, MN, USA), the PASCAL Repair system (Edwards Lifesciences, Irvine, CA, USA) have been developed to repair the regurgitant tricuspid valve [4]. Among tricuspid valve replacement, the first clinical applications were based on the utilize of devices not specifically designed for the tricuspid valve anatomy. For the first time, in 2011, transcatheter valve-in-valve was carried out to replace the tricuspid valve as an “off-label” application of the SAPIEN 3 devices (Edwards Lifesciences, Irvine, CA, USA) [5]. Later, a clinical study demonstrated the feasibility of this procedure [6]. The first use of a device specifically designed for the tricuspid valve anatomy was reported in 2020 using the self-expanding EVOQUE tricuspid valve replacement system [7].

Outside the implantation of devices in the diseased tricuspid valve, the TR can be indirectly treated by caval valve implantation using device implanted in the caval anatomy to alleviate congestive signs of heart failure and the hemodynamic impairment [8]. To perform caval valve implantation, the transcatheter bicaval system (TricValve) is the first type clinically-used device to treat TR by reducing caval pressure and improve the functional status at the 8-week follow-up [9, 10]. The TricValve does not substitute the tricuspid valve but it is composed of two valves, one implanted in the superior vena cava (SVC) and the other one in the inferior vena cava (IVC). The TricValve system is composed of self-expanding devices made of bovine pericardial tissue mounted on nitinol stents. The SVC valve has a long skirt designed to minimize paravalvular leakage, while the IVC valve has a short skirt to prevent occlusion of the hepatic vein flow. Device placement prevents regurgitant flow in the IVC and SVC, reducing liver congestion, increasing right ventricle stroke volume into the pulmonary system and improving cardiac output. Since the system does not alter the native tricuspid valve anatomy, the procedure allows for all future tricuspid valve surgical and procedural options, including transcatheter edge-to-edge repair, transcatheter tricuspid valve repair and transseptal puncture. Currently, the TricValve is the only caval implantation device with CE mark approval

obtained in May 2021.

The aim of the study is to carry out a computational analysis of the structural and hemodynamic performance of the TricValve system in patient-specific model. After developing the geometrical models of TricValve, the deployment was simulated to quantify the contact pressure exerted on the caval wall. A computational fluid dynamic study of the pre-TricValve scenario and the short-term follow-up period was also carried out.

III. Materials and Methods

A. Patient Study Case

The case of a 72-yrs old gentlemen with severe TR and sings of heart failure was investigated. The patient had a past history of both aortic and mitral valve repairs as well as pacemaker implantation in the right heart side. Conventional surgery was highly contraindicated.

Using the Materialise Mimics (v21.0; Materialise, Leuven, Belgium) and Rhinoceros 7 (McNeel & Associates, Seattle, WA, USA) software, a 3D model was created from the patient's computed tomography (CT) images [11]. The patient IVC and SVC and right atrium were segmented using semi-automatic segmentation followed by manual editing and smoothing of the anatomic mask. Using the Ansys ICEM program (v2021 Ansys Inc, Canonsburg, PA, USA), the patient geometry was then meshed with triangular shell element (S3) and uniform thickness of 1.5 mm. Given the lack of material parameters, we used an incompressible Neo-Hookean model with C1=0.6 MPa and D=0.074 MPa^{-1} for the vena cava wall [12].

B. TricValve Models

TricValve system are made of nitinol structure with leaflets made of the bovine pericardium. In the absence of device demo, the device geometries were obtained using photographic images acquired prior the clinical procedure. Dimensions from manufacturer manual were integrated for device modeling.

Using Grasshopper application, the model of the two valves was developed from a single wire replicated in polar series and then wrapped on a primitive surface. Specifically, the stent wire was generated from a spline curves interpolating several point representing the stent wire curvature. A rectangular cross section (0.300 x 0.135 mm) was used and then the stent wire was modeled with a surface in the unfolded configuration. After replicas and polar series, the IVC-related device was composed of six cells in the longitudinal direction and sixteen cells in the circumferential direction. The SVC-related device was modeled with seven cells in the longitudinal direction and eighteen cells in the circumferential direction. The unfolded device geometry was then wrapped on the primitive surface shape with varying diameter along the device axis to obtain the final TricValve geometry. The devices were then positioned in the patient vena cava anatomy with the support of CT images.

Both SVC and IVC devices were meshed with size 0.5 mm resulting in 149939 and 167729 hexahedral-structured elements, respectively (C3D8). The constitutive model proposed by Auricchio et al. [13] was used to simulate the biomechanical response of TricValve nitinol material. A Rayleigh damping of 200 was adopted to regulate the dynamic material response while a density of 6590 kg/m^3 was adopted.

C. Finite-Element Analysis

The simulation consisted of a) delivering both the IVC and SVC devices in the human host, followed by an elastic recoil, b) computational fluid dynamic analysis of post-TricValve deployment.

The crimping phase (0.5 s) was carried out using a cylindrical surface gradually moved along the radial direction (displacement of 18 mm) as done previously in similar studies. Frictionless contact conditions were used to model contact between devices and crimper. Once the device are crimped, a sleeve is moved along the device longitudinal axis to gradually deploy the device in the human host. A penalty formulation with factor of 0.1 and tangential behavior conditions were defined among parts in contact during the deployment phase (0.5 s). For boundary conditions, the distal ends of the patient model were fixed in all directions. After elastic recoil (0.1 s), the skirt and device leaflets were mapped in the deformed TricValve frame.

D. Computational Fluid Dynamic

The pre- and post-TricValve hemodynamic were investigated using Ansys Fluent code (v2021 Ansys Inc, Canonsburg, PA, USA). The fluid domain was meshed with unstructured tetrahedral elements with size of 0.5 mm. Laminar flow condition and non-Newtonian viscosity as modeled with the Carreau model were adopted as done in previous studies [14]. As boundary conditions, we imposed flow velocity profile at hepatic veins, IVC and SVC using literature data [15]. Specifically, the total inflow of 6 L/min was split among inlets with division proportional to each inlet area [16, 17]. For the outlet, the pressure waveform was obtained transforming and scaling the velocity profile to match the Cath-lab pressure of 27 mmHg. The so-obtained pressure waveform was imposed at tricuspid valve. As the leaflets of TricValve system are closed during systole, for the, the flow velocity and pressure were set to null values to mimic the systolic phase of post-TricValve hemodynamic.

IV. Results

Fig. 1 shows several steps of the crimping and deployment of the SVC device in the human host. The device is implanted in position in the IVC wall with device belly at the level of the innominate vein and without obstruction of the branch ostium. This reduces the risk of device migration induced by the oscillatory flow forces exerted on the device stent frame during the cardiac cycle.

Figure 2 shows the comparison of deformed shape of SVC device with the post-TricValve CT image. A good qualitative agreement between predicted and CT images can be observed.

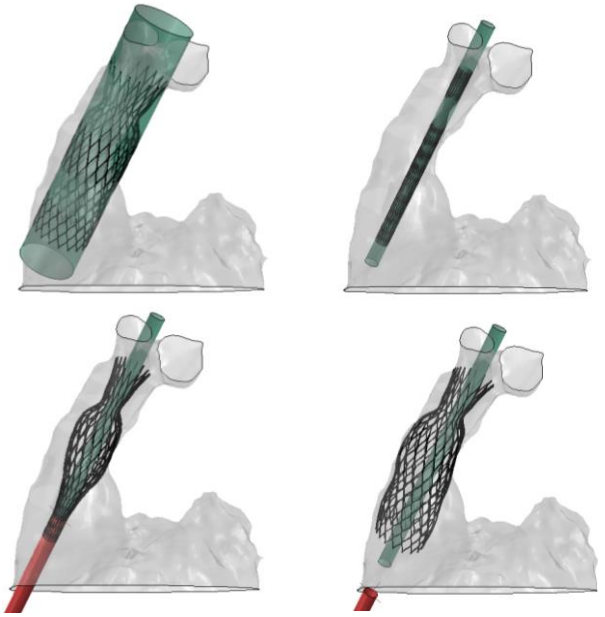

Figure 1. SVC simulation of crimping and release phases

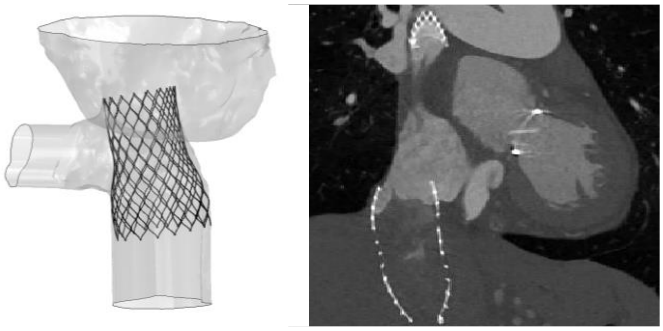

Figure 2. Comparison between the SVC-related TricValve and post-TricValve CT imaging.

Figure 3 shows the map of contact pressure for both the IVC and SVC part.

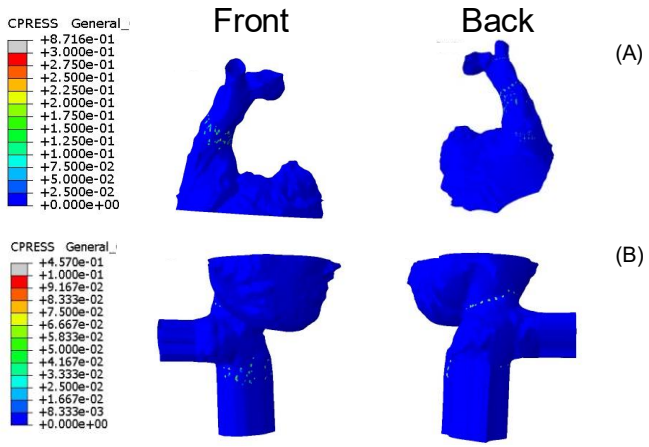

Figure 3. Map of contact pressure for both (A) SVC and (B) IVC devices.

Figure 4 shows the velocity distribution at a crosse section of patient model for both pre- and post-TricValve flow analysis. We found high velocities magnitude at the two systolic peaks rather than the diastole. During diastole (0.44 s), when the valve leaflets of both SVC and IVC devices are closed, the velocity drastically reduces as compared to that of pre-procedural scenario.

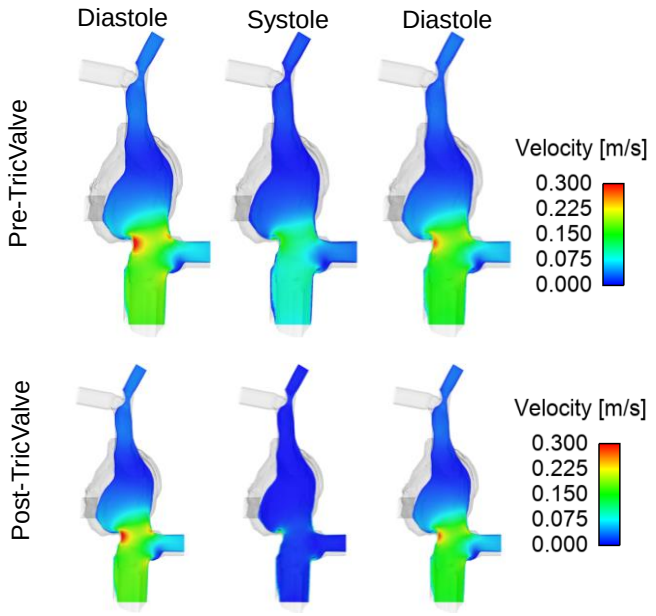

Fig. 4 Velocity map distribution for both pre- and post-TricValve during first diastolic peak, trough systole and then second diastolic peak

V. Discussion

To the best of our knowledge, this is first study describing the biomechanical performance of the new TricValve system to treat severe TR. The TricValve system deployment in the patient-specific anatomy was analyzed using both structural and flow simulation. The most striking findings are the contact pressure as indicator of the risk of stent frame migration and the low flow velocity alleviating the hemodynamic impairment during diastole. This study may provide new insight in the pre-procedural planning of TricValve implantation in the context of a complex clinical conditions.

In transcatheter aortic valve implantation, structural simulations of transcatheter heart valves have been proposed to understand the optimal device size, implantation depth and risk of annulus rupture [18-24]. Analysis of intramural stress at annulus may be used to assess the risk of aortic valve rupture [25]. Different studies have reported the distribution of contact pressure between the device and aortic wall as indicator of device anchorage [25, 26]. Using contact pressure, in the superior vena cava, the resulting device forces were found high in the region in contact between the wall vein and the device belly. The SVC device of TricValve system is designed with a belly in the upper frame region to reduce the risk of obstruction of flow circulating in the innominate vein. The device skirt is below the ostia of innominate vein so that migration into the right atrium may occur if not enough contact pressure are generated. On the other hand, in the inferior vena cava, the contact pressure was found high in the bottom region of the IVC device because of the pronounced area of the device in contact with the vena caval wall. This is because the inferior region of the prosthesis has highest radial force and larger

diameter than the upper region. The upper portion of the IVC-device is implanted in the right atrium as the bird-beak seen in thoracic endograft [27].

The computational flow analysis has allowed us to quantify the flow velocity during the cardiac beating. It should be however noted that the TricValve system ameliorates the right atrial blood pressure after 8-week from the implant. Therefore, the beneficial effect of the device deployment cannot be seen in our computational studies. We speculate that the low flow velocity seen in diastole may allow to outflow the cardiac flow in a larger time period with respect to the pre-TricValve hemodynamic conditions. This may reduce the hemodynamic impairment with the left heart and then the pressure into the right atrium, thereby portending remodeling of the right atrial chamber.

There are several limitations in this study. The material properties of the inferior and superior vena cava were from *ex-vivo* data on animal model because of the lack in human material characterization. In the post-TricValve flow analysis, the motion of the device leaflets was not considered. Fluid-solid interaction analysis are therefore recommended.

VI. Conclusion

This study can bring new insights on the biomechanics of the TricValve system to better understand device positioning and flow hemodynamic. Findings may also used to improve the design of novel transcatheter heart valve for the treatment of severe TR in the context of complex clinical conditions

***Abstract*— *In silico* digital twins of spine segments are a valuable technology with the potential to generate biomechanically relevant information, not always obtainable with expensive *in vitro* measurements and invasive *in vivo* techniques. The present study introduces a novel strategy to generate a parametric CAD model of the thoraco-lumbar spine representative of the healthy adult population in standing posture. The CAD model requires few independent input parameters (VBHP, TK, LL, SS) to be completely defined. Regression equations obtained by fitting anatomical literature data were generate and implemented. The model was furtherly refined with the addition of the rib cage, modelled on the base of mean anatomical data inserted as inputs. To demonstrate the capability of the CAD model to be used for relevant biomechanical analyses, a representative thoracic functional spinal unit T6-T7-R7 functional unit was isolated and the material properties of each sub-structure (annulus fibrosus, nucleus pulposus, neural arch, facet joints, ligaments, ribs and sternum) were calibrated following a step-by-step backward stepwise reduction procedure.**

***Keywords*— Spine, biomechanics, finite element model, digital twin, calibration.**

I. Introduction

The human spine is a complex structure made up of interconnected hard and soft tissues, which contribute in supporting external loadings and maintaining the upright posture and sagittal human balance.

Spine pathophysiology is often studied using detailed patient-specific finite element models (FEMs) built using clinical diagnostic data (e.g. CTs, MRIs), which can be hardly generalized. Parametric spine models could be a more efficient strategy to generate whole cohorts of digital twins of patients with desired features and to virtually test *in silico* the biomechanical effects of a variety of treatment options.

Moreover, the potential of using digital twin technology to study any patient, to explore literally any clinical or virtual scenario and the potential for obtaining intrinsic quantities (stress and strain fields), which could never be assessed with traditional testing methods *in vitro* and *in vivo*, would be of fundamental aid in surgical planning and in basic spine biomechanics.

The goals of the present study were:

i) the development of a thoraco-lumbar parametric CAD model, comprehensive of ribs and sternum, based on regression equations allowing to predict a number of relevant morphometrical measurements starting from few input parameters only;

ii) the calibration of the mechanical properties of different soft and hard tissues materials of a representative thoracic functional spinal unit (T6-T7-R7) by comparison with published in vitro kinematic data (range of motion).

II. Materials and Methods

A. Regression equations + Parametric CAD model

Regression equations were built in order to compute 38 morphological quantities needed to describe the vertebral body (VB) and vertebral arch (VA) using the posterior height of the vertebral bodies (VBHP) as a single independent parameter. Mean anatomical data describing different dependent parameters were taken from Panjabi et al. [1, 2], plotted as a function of VBHP and then best-fitted with a third order polynomial regression functions [3]. The validity of these equations in predicting the 38 dependent parameters the coefficient of determination (R^2) and the Root Mean Square Error (RMSE) were quantified.

The parametric model of the thoraco-lumbar spine was created in Solidworks 2020 (SolidWorks Corporation, Waltham, MA, USA), where all parameters were defined as global variables and the regression equations were implemented.

Single parts representing each vertebra and the intervertebral disc (IVD) above, were drawn reducing each component in elementary geometrical parts. The vertebral body and the cranial disc, divided into annulus fibrosus and nucleus pulposus, were represented as cylindroids with elliptical section. The vertebral arch, the pedicles, the transverse processes and the articular processes were drawn as cylindroids with elliptical section; the spinous process was represented as a solid with rectangular section, whereas the laminae had rectangular section in the thoracic region and trapezoidal section in the lumbar one. The T1-T12 thoracic kyphosis (TK) and the L1-L5 lumbar lordosis (LL) were added as additional independent parameters describing the sagittal profile. At each level, a specific percentage of these angles, which defined the physiological curvatures, was assigned based on literature data. The single parts were then added to the same assembly and the sacral slope (SS) was used as an additional independent parameter to tilt the L5-S1 disc. The ribs and the sternum were modelled and all the needed geometrical quantities were set as global variables where the mean literature values were inserted. The ribs were represented as cylindroids with elliptical section, whereas the sternum was T-shaped and had a quadrilateral section (Fig. 1).

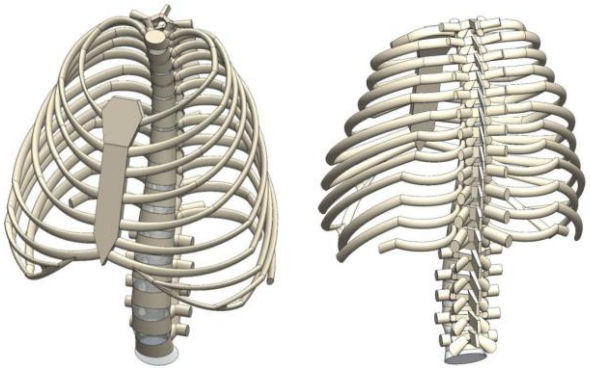

Fig. 1: Assembled thoraco-lumbar spine model: anterior (left) and posterior (right) views.

B. T6-T7-R7 FEM calibration

To demonstrate the feasibility of the presented approach to generate an average model ready to be used for FE analysis, average anatomical measurements were implemented for VBHP, TK, LL and SS, generating one representative average CAD model of a thoracic functional spinal unit.

The CAD model of T6-T7-R7, as a representative thoracic functional spinal unit (FSU) consisting of two vertebrae, the intermediate IVD and the rib, was imported from SolidWorks and assembled in Abaqus 2021 (Dassault Systemes, Simulia, Johnston, RI, USA). In particular, the cortical and the trabecular bone in the vertebral body were modelled using a transversally isotropic elastic constitutive model. The cartilage and the bone of the arch and of the rib, instead, were represented by an isotropic elastic model. For the annulus, the hyperelastic anisotropic formulation for the strain energy potential introduced by Holzapfel-Gasser-Ogden was used. The nucleus pulposus was considered hyperelastic isotropic following the Mooney-Rivlin model. Lastly, all the ligaments were represented as springs defined by their Stiffness (K). The parameters used for the calibration were taken from literature ranges, except for the costovertebral joint ligaments' stiffness where a single value, which was slightly arbitrarily modified to obtain a range, was found. The material parameters needed to define the constitutive equations of each hard and soft tissue were selected using a backward stepwise reduction strategy (Table I).

While the *in vitro* range of motion (RoM) of the FSU was evaluated following gradual resections of all the different structures of the FSU (ligaments, arch and nucleus), in the present study the *in silico* RoM was evaluated in a backward fashion quantifying at each step the biomechanical contribution that the addition of each spinal structure had on the kinematics of the FSU. The predicted *in silico* results, obtained under the same loading and reduction steps, were compared with the corresponding *in vitro* data. For the analysis on the FSU without ribs, the work by Wilke et al. [4] was considered, for the costovertebral joint the results by Lemosse et al. [5] was used, whereas for the intact T6-T7-R7 FSU including the sternum the data by Liebsch et al. [6] were used.

The CAD model was discretized assuming an average mesh size of1 mm (Fig. 2). Linear hexaedral elements were used for the vertebral bodies, the intervertebral disc, the endplates and the facet cartilage, while linear tetrahedral elements were used for the vertebral arch and the ribs, ligaments were modelled with non-linear spring elements.

TABLE I: Calibrated material constitutive parameters and mean error vs. kinematic *in vitro* data.

Material	*Constitutive parameters*	*Mean error (vs. experimental dispersion)*
Cortical bone	E_3=22 GPa, E_1=E_2= 11.3 GPa, G_{12}=3.8 GPa, G_{13}=G_{23}=5.4 GPa, ν_{12}=0.48, ν_{23}=ν_{13}=0.2	-
Trabecular bone	E_3=200 MPa, E_1=E_2= 140 MPa, G_{12}=48.3 MPa, G_{13}=G_{23}=48.3 MPa, ν_{12}=0.45, ν_{23}=ν_{13}=0.32	-
Endplates	E=26 MPa, ν_{13}=0.4	-
Annulus fibrosus (AF)	C_{10}=0.43MPa D=0.3MPa-1 k_1=1.08MPa k_2=11, k=0	20% (vs. 46%)
Nucleus (NUC)	C_{10}=0.64MPa C_{01}=0.09MPa D=0.022MPa-1	20% (vs. 62%)
Anterior longitudinal ligament (ALL)	K=61 N/mm	17% (vs. 58%)
Posterior longitudinal ligament (PLL)	K=25 N/mm	18% (vs. 70%)
Vertebral arch (VA)	E=6 GPa ν=0.25	19% (vs. 83%)
Facet joint capsules (FC)	E=4 GPa ν=0.25 K=45 N/mm	14% (vs. 81%)
Flaval ligament (FL)	K=25 N/mm	16% (vs. 84%)
Interspinous ligament (ISL)	K=8 N/mm	15% (vs. 87%)
Supraspinous ligament (SSL)	K=77 N/mm	12% (vs. 90%)
Rib (left)	E=6 GPa, ν =0.25	-
Costovertebral ligament (CVL)	K= 50 N/mm	41 % (vs. 60%)
Interosseous costotransverse ligament (ICT)	K= 60 N/mm	30% (vs. 51%)
Lateral costotransverse ligament (LCT)	K= 60 N/mm	26% (vs. 50%)
Superior costotransverse ligament (SCT)	K=40 N/mm	31% (vs. 40%)

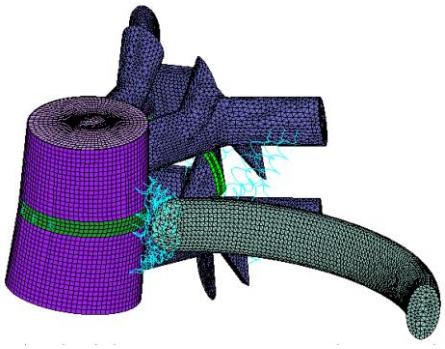

Fig. 2: Meshed T6-T7-R7 FSU including the first part of the left rib.

For the calibration of the FSU, the assembled unit, at each step comprehensive of the structures that were not resected in vitro only, was fixed in space by blocking all degrees of freedom on the bottom surface of the T7 vertebra. A bending moment of 1 Nm and 2.5 Nm was applied in flexion, extension, right lateral bending and left axial rotation on a reference point that was coupled with the upper surface of the T6 vertebra.

For the costovertebral joint calibration, instead, the boundary conditions limiting all the degrees of freedom were extended to the lower articular facets surfaces and to the previously described reference point. A local coordinate system was defined along or about which the loads were applied and the rotational displacements were evaluated in torsion, cranial/caudal and ventral/dorsal flexion. Two new reference points, which were coupled to a 10mm wide rib segment, were created for the loads' application according to Lemosse et al. [5]. Each of these loading conditions, replicating the ones implemented in the experimental set-ups, were simulated and the resulting rotational displacements were computed and compared with the expected values. The combination of parameters that provided the lowest mean total error, with respect to the in vitro data, was assigned to the material under analysis.

III. Results

A. *Regression equations + Parametric CAD model*

The relative error of the predicted values with respect to the anatomical measures (mean RMSE value: 8%) resulted always lower than the mean experimental dispersion (mean value: 20%). Fig.3 summarizes the predition error for all morphological parameters, by comparison with the average measurement error by Panjabi et al. [1, 2].

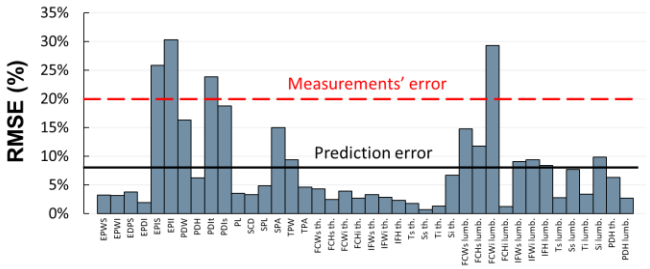

Fig. 4: RMSE of the prediction error for each anatomical parameters. The dashed line indicate the average measurements error on experimental data [1,2] .

B. *T6-T7-R7 FEM calibration*

At each calibration setp, the combination of material parameters minimizing the error or the difference vs. the experimental *in vitro* data was kept for each subsequent calibration step. Table I collects all the calibrated constitutive parameters and the mean final error obtained in all the performed calibration steps.

Each loading condition implemented in the referenced experimental set-ups [4, 5, 6] was replicated and the predicted RoM values were compared with the experimental data (Fig. 4, 5, 6).

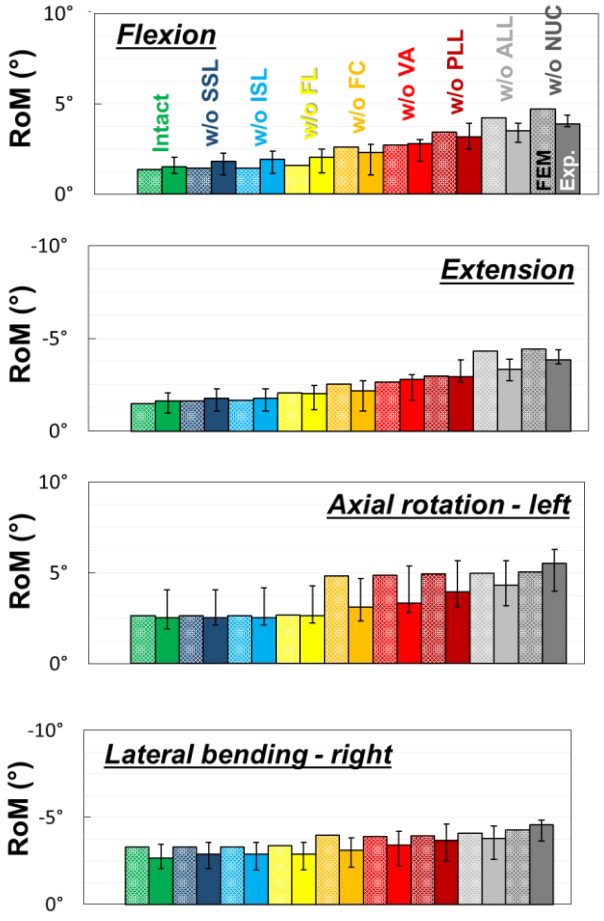

Fig. 4: RoMs comparison for the T6-T7 FSU during subsequent simulations (applied bending moment 2.5 Nm). For each colour, the left bar represents the *in silico* results (FEM), the right one the *in vitro* data (Exp.) [4].

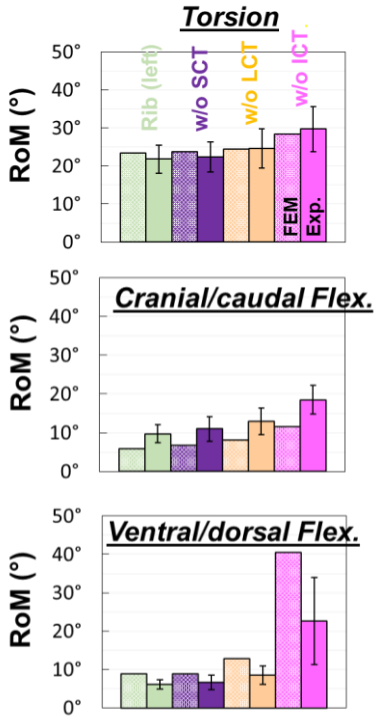

Fig. 5: RoMs comparison for the costovertebral joint (T6-T7-R7left) during subsequent simulations (applied bending moment 0.6 Nm). For each colour, the left bar represents the in silico results, the right one the in vitro data [5].

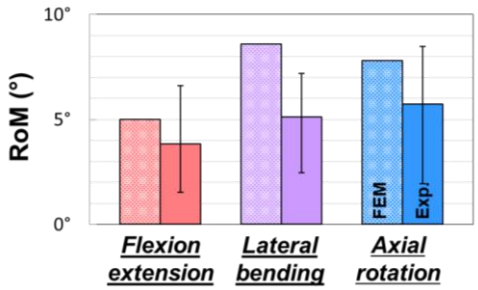

Fig. 6: RoMs comparison for the intact T6-T7-R7 FSU (applied bending moment 5 Nm). For each colour, the left bar represents the in silico results, the right one the in vitro data [6].

IV. Discussion

Several parametric models of the spine are already present in the literature, but the majority focus only on the lumbar segment. Models including the whole thoraco-lumbar spine, maybe including the rib cage, are mainly patient-specific or built based on CT or MRI diagnostic images.

The strength of the presented approach resides in the fact that by changing few independent parameters (1 per vertebra), like the posterior height of the vertebral bodies and the sagittal spinal curvatures (SS, LL and TK), the thoraco-lumbar CAD model can be easily updated to generate a variety of patients cohort. These parameters are easy to measure on traditional clinical images, therefore even an unexperienced user may generate patient-specific models within just few seconds. In the future, this model could be extended by including also the cervical region as well, by simply implementing regression equations specific for this spinal region.

During the calibration procedure it was observed that the model provided a good representation of the T6-T7 FSU kinematic behavior. During subsequent calibration steps, the mean error ranged from 12% to 20%, whereas the mean experimental dispersion ranged from 46% to 90%.

When calibrating the ribs, instead, the results were not as good, probably because no literature data on the ligaments' attachment points or stiffness ranges were found. Indeed, the mean error ranged from 26% to 41%, whereas the mean experimental dispersion ranged from 40% to 60%. When adding also both ribs nad the sternum the kinematic behavior of the intact T6-T7-R7 model was overall satisfactory, as it was always within one standard deviation of the experimental *in vitro* data. Therefore, besides capturing the general anatomical features of the spine, the model well replicated the kinematic behaviour of the FSU following different resection steps.

In the future, the whole thoraco-lumbar spine model could be fully calibrated also monitoring other relevant biomechanical data in more relevant functional loading conditions.

V. Conclusion

The developed parametric CAD model accurately describes the overall morphometric characteristics of an average healthy adult thoraco-lumbar spine. Furthermore, the material properties assigned to the representative thoracic FSU provide reliable kinematics data. Continuing with the calibration process, it could become useful for computing additional relevant biomechanical outputs and clinical values, such as intradiscal pressures, stress and strain fields on different FSU components with specific loading conditions.

***Abstract*—Plantar fascia is a complex structure, which stands between the calcaneus and the forefoot region of the foot. It plays a key role in foot biomechanics and its functionality can be compromised by different pathologies (*e.g.* plantar fasciitis). For these reasons, the aim of this study is the investigation of the plantar fascia's mechanical properties through experimental tensile tests.**

Mechanical tests have been performed on samples obtained from human plantar fascia considering different regions and directions. From failure tests, the ultimate tensile stress and the corresponding failure strain were obtained, while stress-relaxation tests were performed to compute the viscoelastic tissue parameters. Initial and final Young's moduli were determined for stress-strain curves from both failure and stress-relaxation tests. Experimental results showed a similar behaviour between proximal and distal plantar fascia regions, while it was different considering the proximal-distal and lateral-medial directions. Furthermore, the results highlighted the non-linear time-dependent behaviour and the anisotropy of the plantar fascia.

As further steps, these results could be implemented in a computational model of the entire foot region to investigate the mechanical response of tissues in both healthy and pathological conditions.

***Keywords*— Plantar fascia, tensile tests, biomechanics, anisotropy.**

I. Introduction

THE foot plantar fascia, also called plantar aponeurosis, is a connective tissue which spans between the calcaneal tuberosity and the forefoot. It is mainly composed of type I collagen fibres, elastic fibres and an extracellular matrix rich in hyaluronan [1]. Collagen fibres show a variable thickness, and are arranged along the proximal-distal direction but also along the transversal and oblique directions [2]. Plantar fascia plays a key role during propulsion in the gait cycle, it supports the medial and longitudinal arch of the foot [3], and permits the transmission of forces from the rear to the forefoot region and vice-versa.

Its mechanical functionality can be compromised by different pathologies such as plantar fasciitis, plantar fibromatosis (also called Ledderhose disease), and systemic pathologies such as type I diabetes. Plantar fasciitis is one of the most common diseases and usually affects runners or workers, whose activities require walking for a long time on hard surfaces [4]. Therefore, a better understanding of the plantar fascia's mechanical properties is of great interest in order to facilitate the treatment of its diseases.

Over the years, some studies analysed and tested plantar fascia's biomechanical behaviour, both in healthy and pathological conditions [5], [6], [7], reporting its visco-hyperelastic behaviour. However, tissue samples tested in these studies were taken only from the proximal-distal direction of a limited number of patients [5], [8]. Moreover, plantar fascia's behaviour was considered to be isotropic [9], [10], even if its collagen fibres are not only arranged in the proximal-distal direction.

In this context, the aim of this work is to fully describe the mechanical behaviour of the plantar fascia, in relation to its microstructure, by performing multiple experimental tests on samples taken from different fascia regions and orientations, with the future purpose to develop a computational model able to mimic its real mechanical behaviour.

II. Materials and Methods

A. Sample collection and dissection

Experimental tests were performed on plantar fascia collected from four human donors (male; age 56±18 years; BMI: 26.1±2.1) undergoing amputation due to cancer in other regions of the leg, at the Orthopedics and Orthopedic Oncology Unit, University Hospital of Padova (CESC Code: AOP2649). Plantar fasciae were not affected by musculoskeletal degeneration or pathology. After the dissection, the samples were frozen without additional treatments and kept at -20°C until the day of testing.

Each plantar fascia was cut into strips of approximately 13.2 (±3.2) mm in length, 8.6 (±2.7) mm in width, with 1.8 (±0.6) mm thickness, this latter measured with a manual calliper. Samples were obtained from all plantar fascia regions, *i.e.* distal, central and proximal, and they were cut according to longitudinal (proximal-distal, PD) and transversal (lateral-medial, LM) directions (Fig. 1 a-c). More precisely, samples collected from the central region were cut according to the LM direction, while those from distal and proximal regions were cut along the PD one. For simplicity, samples were named proximal-PD and distal-PD for specimens harvested according to the PD directions from the proximal and distal region respectively, and all-PD and all-LM for samples collected from different plantar fascia regions but cut along the PD and LM directions, respectively.

B. Mechanical tests

Uniaxial tensile tests were performed with the

Biomomentum testing machine (Model Mach-1 v500c, ©Biomomentum Inc.) using the uniaxial load cell with a capacity of 250 N and resolution of 0.0125 N. Specimens were tested at room temperature adopting two testing protocol types: (i) application of a constant strain rate until failure, and (ii) stress relaxation ramps. Samples were glued using cyanoacrylate to c-shaped specimen holders made of cardboard and Velcro to prevent sample slip from grips during testing.

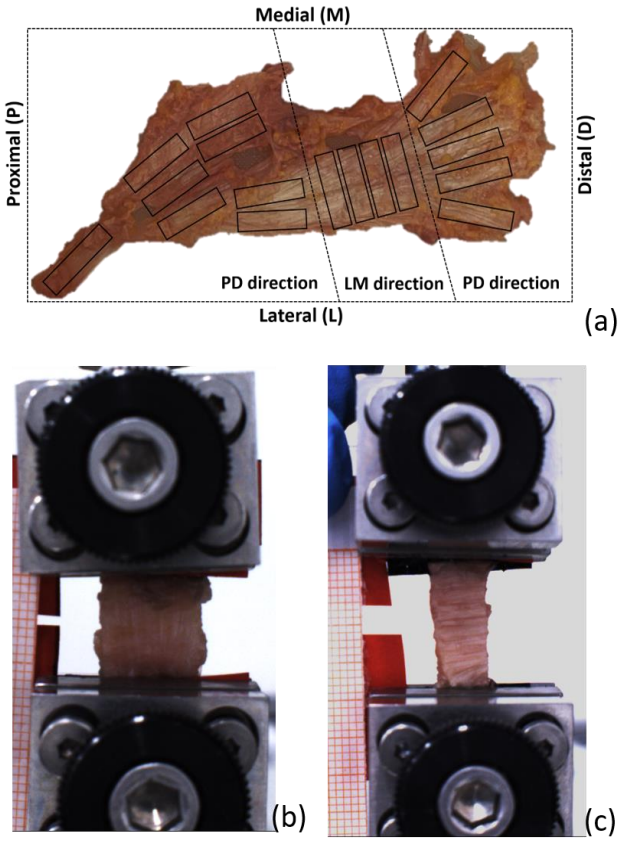

Fig. 1: Plantar fascia samples subdivision according to direction (a): PD and LM; an example of a tensile test on a sample cut according to PD (b) and LM directions (c).

Each sample was preconditioned by applying 10 loading-unloading cycles at 0.25 Hz with a maximum tensile strain equal to 4%. Sample preconditioning was applied to both types of tests as it allows repeatable and comparable results when investigating biological tissue properties [9]. In failure tests, samples were tightened at a 1%/s strain rate until rupture. Regarding stress relaxation protocol, five ramps composed of 2.5% strain at 100%/s strain rate and a subsequent 300s of resting, to allow the almost complete development of relaxation phenomena, were performed.

The experimental results were analyzed with Matlab 2021b (The MathWorks, Inc., MATLAB and Statistics Toolbox Release 2021b, Natick, Massachusetts, United States).

C. *Statistical Analysis*

The results of experimental tests were reported as mean ± standard deviation. Comparisons between groups (proximal-PD vs distal-PD and all-LM vs all-PD) were evaluated using a 2-sample T-test. All analyses were conducted with the statistical software Minitab 20 (Minitab, 2020). Significance was set at $p<0.05$.

Initial (E_i) and final (E_f) moduli of equilibrium stress-strain and viscous parameters for the two different regions (proximal-PD and distal-PD) and the two different directions (all-PD and all- LM). Mean value ± SD (*p-value < 0.05).

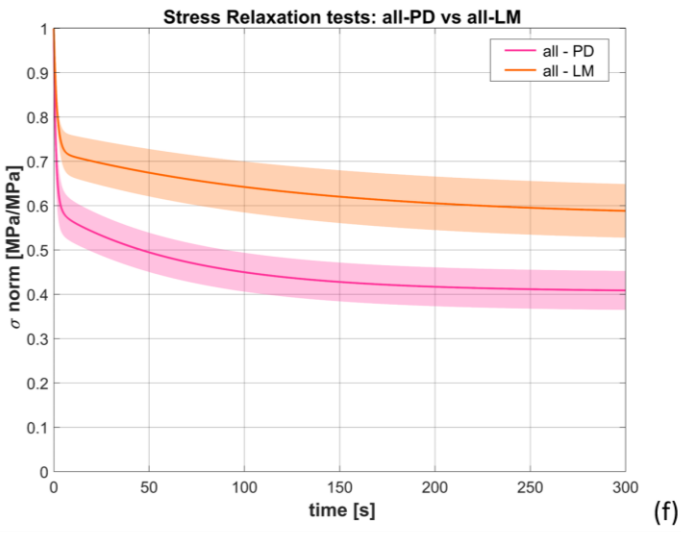

Fig. 2 A representative stress-strain curve obtained during failure tests for Subject 1 (a), initial and final Young's moduli obtained by failure curves (b) (* p-value = 0.371, ** p-value = 0.201, x p-value = 0.042, xx p-value = 0.001), stress-strain equilibrium curves (c) and normalized stress-time results (d) from tests performed on proximal-PD and distal-PD samples, stress-strain equilibrium curves (e) and normalized stress-time results (f) from tests performed on all-PD and all-LM samples. Mean value ± SD.

III. Results

Stress-strain curves obtained from failure tests are reported in Fig. 2 a. The mean value of ultimate tensile stress (UTS) and the corresponding failure strain, were computed for each region, proximal-PD and distal-PD, and for both directions, all-PD and all-LM (Table I). The initial and final Young's moduli of the failure curves were calculated (Fig. 2 b), *i.e.* the slope of the stress-strain curve in the toe region and in the quasi-linear region, respectively. UTS resulted statistically significant different ($p = 0.001$) when comparing PD and LM directions (all-PD: 3.91 MPa vs all-LM: 0.79 MPa), while failure strain was almost the same in all the plantar fascia (between 47.29% and 51.12%). Regarding the initial and final Young's moduli, distal and proximal regions showed similar values, while they were statistically different ($p = 0.042$ for E_i and $p = 0.001$ for E*f*) considering the orientation of the fibres (the all-PD final Young modulus is 15.42 MPa, seven times higher than the all-LM Young modulus, which is 1.93 MPa). These results demonstrate the plantar fascia anisotropic behaviour, which was also observed in the stress-strain equilibrium curves obtained from the stress-relaxation tests (Fig. 2 c, e). These curves were achieved by interpolating the stress and strain data obtained at the end of the holding phase of each ramp with an exponential formulation. A statistically significant difference was found for the initial ($p = 0.010$) and final elastic moduli ($p = 0.003$) between PD and LM directions, whose values are reported in Table II. The normalized stress-time curves (Fig. 2 d, f) highlighted the time-dependent behaviour of the tissue and the viscoelastic parameters (Table II), obtained by interpolating these curves with a typical exponential formulation using Matlab curve fitting tools [11], showed similar values for all regions except for the samples taken according to the LM direction.

IV. Conclusion

The results of the experimental tests highlighted a similar behaviour among the different plantar regions (proximal and distal), while a different one was observed considering longitudinal and transversal directions, supporting that the anisotropic behaviour of plantar fascia is due to its high component in collagen fibres. To the best of the authors' knowledge, this is the first study in which the plantar fascia anisotropy was analyzed and observed in detail. Indeed, in the literature, different studies assessed the viscoelastic and visco-hyperelastic plantar fascia behaviour till now [6], [7], [12], but none of them has considered the tissue anisotropy, due to the lack of mechanical tests on samples along the transversal direction.

Regarding the viscoelastic behaviour, slightly different results were observed comparing our fitted viscous parameters values with those of previous studies. For instance, the reduced percentage of stress at the end of the stress relaxation phenomena in both proximal and distal regions was 59% after 300 s in this study, while Pavan et al. [6] reported a stress decay of 35-40% in a time interval of 120 s. Results are comparable considering that, in the present study, samples were let to develop the relaxation phenomena for a higher time interval. Regarding the viscous parameters (γ_1, γ_2, τ_1 and τ_2), their values were confirmed by other studies except for the τ_1, which corresponds to double that of another work [12].

The data of this study suggest that human plantar fascia can be characterized as a non-linear anisotropic and viscoelastic material. The achieved experimental results will be therefore used, to define and develop a complete constitutive model able to describe the real mechanical behaviour of the plantar fascia.

The future goal is to introduce the complete plantar fascia mechanical characterization in the computational model of the foot, in order to investigate and compare the mechanical response of tissues in both healthy and pathological conditions. The numerical model of the foot could be a valuable tool to gain information on the mechanical behaviour of tissues that cannot be obtained through experimental tests. Furthermore, it could also be useful for clinicians in planning and simulating surgery, *e.g.* to repair pathological plantar fascia.

Synergy-dependent patterns of reaction forces in sit-to-stand movements

***Abstract*—Sit-to-stand is a widely studied clinical test; however, despite its importance in the characterization of motor performance, the neuromechanical processes underlying its control are rarely characterized. One of the most used tools for neuromechanical characterization is the analysis of the ground reaction forces; moreover, muscle activations are often characterized in terms of coactivation structures, or muscle synergies. In this work, we analysed the reaction forces, both on the chair and on the ground, in a group of healthy subjects during sit-to-stand movement. Using an information-based model selection criterion, we divided participants based on the number of muscle synergies underlying movement generation, and analysed the inter-group differences in terms of the aforementioned reaction forces. Results show how it is indeed possible to isolate force characteristics that are dependent on the number of muscle synergies, especially in the management of body inertia and symmetry.**

***Keywords*—sit-to-stand, muscle synergies, reaction forces, neuromechanics**

I. INTRODUCTION

Sit-to-stand test is a widespread clinical test for assessing the alterations of human movement due to aging or neurological pathologies, and it has been shown to unveil an important relationship between the speed of repeated movements and the subjects' independence during activities of daily living [1]. This test is typically administered to obtain semi-quantitative information, such as the time needed for executing 5 times the movement (5 times sit to stand) or the number of sit-to-stand cycles completed in a 30 seconds time frame (30 seconds sit to stand); more recently, some instrumented versions of the sit-to-stand test have been proposed in the literature [2], aiming at increasing the amount of extracted clinically relevant information. To ensure a fast and simple execution of the test in clinical scenarios, these implementations typically foresee the use of wearable sensors or conventional cameras coupled with algorithms for extracting information from a short test. These implementations typically aim at adding insights on the motor control strategies adopted by the subjects during the task. Other approaches rely on a more complex setup, such as motion capture systems, to measure more detailed kinematic or muscle activity quantities. Regarding the latter, studying how muscles coordinate during sit-to-stand has gained the attention of the scientific community during the last few years [3]; these studies exploit the muscle synergy model [4] to identify muscle coordination patterns that are related to specific biomechanical functions, shifting the focus onto a neuromechanical characterization of sit-to-stand in healthy and pathological conditions [3], [5]–[7]. In all these applications, the correct identification of the underlying synergistic structure is of key importance. The accurate and thorough extraction of muscle synergies from multi-muscle surface electromyography (sEMG) requires a precise tuning of the methodologies that process and factorize the raw signals [8]–[10], to have a reliable and ecological neuromechanical assessment of sit-to-stand in clinical settings. It is thus important to understand how using relatively short signals coming from sit-to-stand standard clinical trials can yield relevant neuromechanical information. In this study, we use a dataset of sEMG and kinetic data recorded from a population of healthy subjects for studying the feasibility of standard sit-to-stand tests to characterize the adopted motor control strategies through an optimized muscle synergy analysis. The data have been recorded on the BENCH device, an instrumented chair for the biomechanical assessment of sit-to-stand maneuvers.

II. METHODS

A. Experimental protocol

The experimental protocol has been carried out using the BENCH instrumented chair [11] (Figure 1). This chair is equipped with two force platforms (*BTS P6000, BTS Bioengineering, Milan, Italy*, sampling frequency: 1 kHz), placed one at ground level and one on the seating plane. These two platforms have been used for the recording of the ground reaction forces during movement, in a synchronous fashion with respect to an 8-channels surface electromyography system (*BTS FreeEMG, BTS Bioengineering, Milan, Italy*, sampling frequency: 1 kHz) and a stereophotogrammetric system (*BTS SMARTDX, BTS Bioengineering, Milan, Italy*, sampling frequency: 250 Hz). EMG signals were acquired from the following muscles of the dominant leg: *soleus*, *gastrocnemius medialis*, *peroneus longus*, *tibialis anterior*, *biceps femoris long head*, *vastus lateralis*, *rectus femoris* and *gluteus maximus*, electrode positioning has been selected according to the SENIAM protocol. A reflective marker, placed in correspondence of the *sacrum* has been used as a kinematic reference for segmenting the sit-to-stand cycle; each cycle is

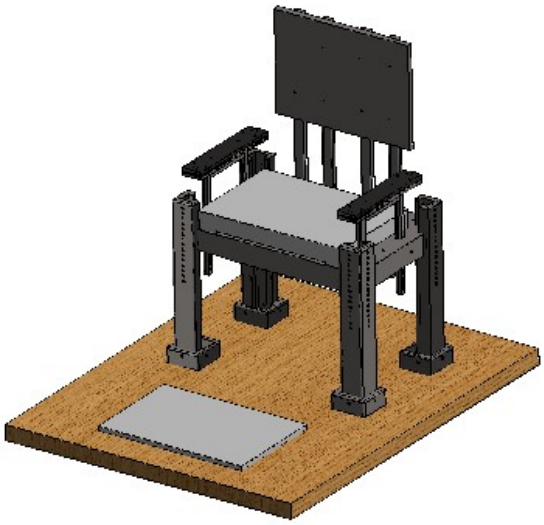

Fig. 1: A representation of the BENCH apparatus

defined as the portion of the signal between two subsequent maxima of the antero-posterior component of the 3D trajectory of this aforementioned marker.

In total, 12 healthy subjects (37 ± 10 years old, range 24-55 years old, 177.2 ± 6.6cm, 79 ± 11.7kg) participated to the experiment. The experimental protocol was approved by the ethics committee of the Roma Tre University, and was carried out according to the principles of the Declaration of Helsinki. The subjects were asked to perform a *30 seconds sit-to-stand* trial with their arms folded across the chest, and without moving the feet. The trial started in a seated position. At the *go* signal, the subject seamlessly performed sit-to-stand and stand-to-sit movements until the *stop* signal. The subjects were instructed to execute the test in a fast yet comfortable and clean way, reaching the full standing position at the end of every sit-to-stand movement.

B. Synergy Extraction

For synergy extraction, the envelope of the sEMG signal has been extracted through rectification and low-pass filtering at 10Hz. Prior to envelope extraction, sEMG signals have been filtered with a band pass filter between 30 and 450 Hz. Factorization of the multi-muscle signals has been realized through Non-negative Matrix Factorization [12] and the optimal number of synergies has then been selected using the adjusted Akaike Information Criterion presented in [9].

The analysis of the synergistic control strategies has been carried out by focusing on the temporal components alone, during the whole sit-to-stand-to-sit cycle. In order to do so, the H profiles coming from each cycle have been time-normalized on 100 samples, and an average cycle profile has been defined for each subject. Subsequently, subjects were categorized with respect to their number of synergies, and an inter-subject average profile has been defined for each N_{syn}.

In addition, all the average H profiles have been fed to a K-Means clustering algorithm ($K = 4$) to extract the four main waveform that can describe the coordination structure of all the subjects. Before the K-Means algorithm, some basic features describing the waveform have been extracted, namely the position of the first peak, the area under the waveform, the peak value, the time spent at a level higher than the 50% of the maximum and the centre of activity.

C. Force computation

Forces have been analysed in the vertical (z) and antero-posterior (x) directions for the platform on the chair, and for all direction for the ground sensors.

Force profiles have then been time-normalized following the same procedure described for the synergy activations, and an average behaviour for subjects characterized by each of the identified N_{syn} has been computed from the subject-specific average force profiles.

III. Results

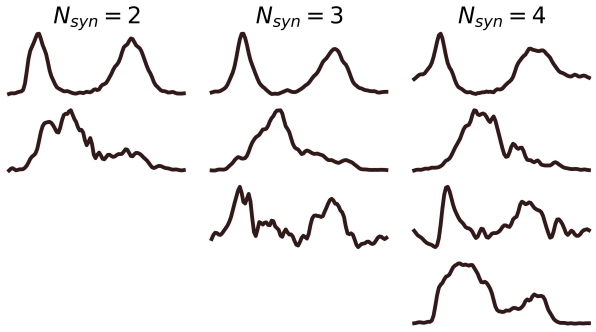

Fig. 2: Average profiles coming from the subjects exhibiting different N_{syn} values

The study population completed the *30 seconds sit-to-stand* trial executing 13.1 ± 1.66 cycles across subjects, with a complete sit-to-stand-to-sit cycle duration of 2.42 ± 0.32s across subjects.

A. Synergy results

The optimal number of synergies selection criterion resulted in the 25% of the subjects requiring two synergies for reconstructing the movement, while the 42 % and 33 % of the participants required three or four modules, respectively.

The average synergy activation profiles for the different N_{syn} are shown in Figure 2. The first biphasic shape (*cluster1*) appears to be consistent across all the identified groups; moreover, all the sets of waveform are characterized by only one mono-phasic activity (*cluster2*), while additional two-bursts activations are present for N_{syn} higher than two.

In Figure 3, the centroids coming from the K-Means procedure are presented, together with the waveforms composing the clusters. Cluster 1 is identified in the 83% of the subjects, while cluster 2, 3 and 4 in the 67, 25 and 50 %, respectively. The shapes identified in this procedure are coherent with the ones presented in Figure 2.

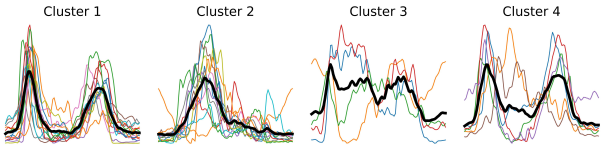

Fig. 3: Clustering results from the subject-specific H profiles

B. Force profiles

The force profiles related to the subject requiring different N_{syn} for movement generation are shown in Figure 4. The waveforms qualitatively show how subjects requiring different synergy sets are characterized also by different force profiles, especially in the management of the contact with the ground after standing and before seating. Differences are more evident for the subjects requiring 4 synergies, especially in the transverse plane.

IV. Discussions

The results presented here show how, in a population of healthy people performing a standard sit-to-stand test, the complexity of the motor control strategies may substantially differ. In this work, the number of muscle synergies required for the control of the sit-to-stand movement has been used as a key feature of motor control, investigating how people that differ in this parameter also differ in their biomechanical output (*i.e.* the reaction forces). At the same time, the biomechanical correlate that has been qualitatively identified here can be seen as the proof that optimal synergy analysis methods might pave the way for new interpretation of their outcomes, improving the ability of such analyses to identify neuromechanical relationship from multimodal measurements.

The activation profiles that have been presented here show that a complete sit-to-stand-to-sit cycle is composed at least of two alternating modules, one working in both the standing and sitting phase, and one stabilizing the movement when approaching the full standing posture. Additional modules are required by some subjects; these modules typically work in the same phases as the first module, while being characterized by generally longer activations. These features suggest that those synergies may act as stabilizing mechanisms that are functional to the activity of the two main modules. Clusters shown in Figure 3 support this hypothesis of two main modules (that are identified in a very stable way) and two support modules (that present higher variability).

The force profiles shown in Figure 4 are coherent with this hypothesis, showing that there is an increasing trend on the ground forces when the number of synergies is higher. This might indicate that people that tend to relate more to the inertia of the body (thus generating higher reaction forces during standing and sitting) require additional modules for managing the acceleration and deceleration of the body weight. Moreover, both small (*i.e.* 2) and large (*i.e.* 4) numbers of synergies correspond to an asymmetrical pattern in the medio-lateral ground reaction force around the full standing position, while the solution with three modules seems to represent a smoother and more symmetrical strategy; this latter characteristic might indicate that the presence of a third module stabilizes the body in the ML direction, with any additional module (on the dominant side) shifting the symmetry with respect to the 2 synergies solution, thus generating the out-of-phase pattern in the ML ground reaction force around the full standing phase (Figure 4).

These results are presented here in a qualitative way, but still they highlight a dependence of the biomechanical characteristics of the sit-to-stand movement on the number of motor modules required for the execution of the task. While the causal relationship between these two quantities is still to be unraveled, as well as the complete quantification of the mathematical relationship between those two characteristics, the presence of optimal methods for the investigation of modular motor control strategies yields fine information that typically remains hidden when common patterns (*e.g.* a common number of synergies for all the subjects) are imposed during the analyses.

***Abstract*—Despite the central role that a prosthetic socket plays as the link between the patient and their prosthesis, yet no common guidelines or standardized methods exist to test their mechanical strength. Consequently, the socket structural properties remain largely unknown. The absence of a method to quantify socket structural strength has negative consequences, such as: the tendency to over-fabricate the socket, a general limitation in the introduction of innovative materials and techniques, and a challenge in complying with the current European regulatory requirements. To overcome these limitations, the authors defined a five-step plan intended to serve as a groundwork in the prosthetic field for the definition of a standardized testing method for prosthetic sockets. This plan includes the systematic analysis and organization of the available literature into key domains, the proposal of recommendations to address the current gaps in knowledge, the design, implementation and application of a test bench system based on the available evidence and on a worst-case approach and, finally, the definition of manufacturing guidelines based on quantitative data to be included in the production process of the INAIL Prosthetic Center. The activities described in this manuscript should guide other researchers of the prosthetic community to take coordinate action in the definition of a standardized method for socket testing.**

***Keywords*—Prosthetic sockets, structural testing, ISO 10328, lower-limb.**

I. Introduction

A PROSTHETIC socket is the custom element that serves as interface between the residual limb of a person with lower-limb amputation and the off-the-shelf mass-produced components of the prosthesis (e.g. prosthetic foot and possibly knee). The socket transfers load between the person and the rest of the prosthesis and allows control of the prosthetic limb. For this reason, it has to conform to the anatomy and clinical presentation of each unique limb, ensuring comfort and safeguarding its soft tissues.

Despite the central role of the socket in the prosthesis, no standards or common guidelines exist to test its structural strength, which therefore remains unknown. The current standard for structural testing of prosthetic components (ISO 10328 [1]) does not encompass custom-made devices, such as the socket, but only off-the-shelf mass-produced components (e.g. foot, knee). The traditional manufacturing techniques for sockets, such as lamination with composite materials and vacuum-bagging, are based on manual and highly operator-dependant processes that, to make up for the absence of quantitative data, tend to rely on over-fabrication to ensure safety. Despite having several downsides in terms of increased weight, rigidity and ultimately patient discomfort, this approach has higher risk of failure when experimenting with new materials and fabrication methods, for which training and clinical rules of thumb are not yet established. Finally, the absence of standardized test methods challenge the compliance with the current European Medical Device Regulation (MDR 745/2017) that requires documenting the expected performance of custom-made medical devices, such as sockets [2].

To overcome the current limitations associated to the absence of a standardized test method, meet the current regulatory requirements and improve the present manufacturing procedure of the INAIL Prosthetic Center, the authors have laid the foundation for the definition of a unified testing method based on the available evidence by drafting the following five-step plan:

A. Analyse and compare the current methods for socket testing available in literature;
B. Initiate a collaboration with other international scientists to take action in a coordinate manner;
C. Design and implement a test bench for socket testing based on literature findings;
D. Perform a socket testing campaign to analyse the mechanical strength of prosthetic sockets manufactured at the INAIL Prosthetic Center (Vigorso di Budrio, BO, Italy);
E. Draft internal guidelines for socket manufacturing based on quantitative data.

II. Methods

A. Review of the literature

A systematic review of the literature was conducted in 2021 to collect information about available socket mechanical testing methods. The review had the objective of analyzing the methods used for structural testing of lower-limb prosthetic sockets and among them identifying and analyzing the ones based on ISO 10328:2016 [3]. The review was conducted using the PRIMA process [4] and the findings were organized in key categories, such as socket information (amputation level, shape, fabrication technique and material), test characteristics (reference used, test setup, test sample, mock residual limb, alignment between sample components) and load characteristics (alignment of load line, type of loading, passing condition) [3].

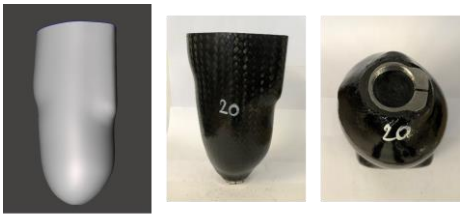
B. Collaboration with the AOPA Socket Guidance Workgroup

In 2020 an international and multidisciplinary group of experts hosted by the American Orthotic & Prosthetic

Association (AOPA Socket Guidance Workgroup) was formed to provide the prosthetic community with evidence-based recommendations regarding socket structural testing methods to meet the emerging regulatory requirements. Using a systematic approach similar to the Delphi process, the first activity of the workgroup was the drafting of a discussion paper meant to highlight the problem of socket testing and call the stakeholders to action.

Starting from the findings of the systematic review [3], the aim of the paper was to describe the current state of knowledge available in literature regarding structural testing of transtibial prosthetic sockets, identify the knowledge gaps in this field and provide recommendations for how to address them. The possible recommendations were chosen from a pool of three options: 1) application of the exiting evidence from the literature, 2) group consensus, motivated by evidence in literature and/or knowledge of experts, 3) formation of a study group to assess the problem and find a way to address it. The paper was submitted and accepted for publication in *Prosthetics & Orthotics International* and is currently in the process of publication.

C. Design and implementation of a test bench for sockets



Based on the evidence collected from the Systematic Review and on the discussions in the workgroup technical meetings, a test bench system for lower-limb prosthetic sockets was designed and implemented at the Laboratory of Machine Design of the University of Padua (Padua, Italy) [5]. The test bench was designed to adapt the testing methods of ISO 10328:2016 to socket testing. Decisions about the modes of adaptations were made using a worst-case approach.

D. Socket testing

Thanks to the design and implementation of a test bench, an exploratory study was conducted at the University of Padua, aimed to analyse the effect of fiber layup, matrix and distal adapter on socket strength [6]. Twenty-three sockets were manufactured at the INAIL Prosthetic Center (Vigorso di Budrio, BO, Italy) from the same identical plaster model, using the traditional lamination technique with composite materials and resin infusion under vacuum-bagging. Each socket had a different combination of stratigraphy, distal adapter and resin. The shape of the limb represented the 98th percentile American male model of transtibial amputees, with a circumference at the patellar tendon bar of 52.4 cm and a length from the patellar tendon bar to distal end of 19.2 cm [7]. The different combinations of fiber layup, lamination resin and distal adapter were taken from the current production line of the INAIL Prosthetic Center.

The sockets were tested using the test bench designed and implemented at the University of Padua.

This study was described more extensively in a manuscript that was submitted and accepted with minor revision to *Medical Engineering & Physics*, and that is currently under review.

(a) (b) (c)

Fig. 1: Limb shape (a), example of test socket (b, c).

E. Guidelines for socket manufacturing

The test results allowed drafting lamination guidelines to be used in production at the INAIL Prosthetic Center (Vigorso di Budrio, BO, Italy). For each family of distal adapter, the guidelines were defined based on the sockets that reached the highest ultimate load at failure with lowest weight and with the simpler layup.

III. Results

A. Review of the literature

According to the results of the systematic review [3], only 16 peer-reviewed articles exist in literature that describe socket testing. The same result was also confirmed by recent a scoping review [8]. Given the absence of a standardized test method, most of the articles (13) are based on ISO 10328, each presenting different adaptation modes that were systematically summarized and organized in the review [3].

In particular, the socket was either tested alone or in combination with off-the-shelf components (e.g. prosthetic pylon, foot). Only transtibial sockets were tested, with the shape of the limb varying across studies (subject-specific vs. generalized). Three alignment modes were identified: a neutral and two worst-case alignments (with and without a prosthetic pylon). Among the two possible test conditions described in ISO 10328 (condition I, heel loading and condition II, forefoot loading), forefoot test condition was the most used across studies. Most of the articles performed static testing using the ISO 10328 passing conditions, which depend on test condition (I or II) and on loading level (P3 to P8), associated to different ranges of body weight.

B. Collaboration with the AOPA Socket Guidance Workgroup

The discussion paper of the AOPA Socket Guidance Workgroup identified knowledge gaps and solution approaches for four key domains: 1) mock residual limb shape and composition; 2) prosthetic socket coordinate system and alignment; 3) components and requirements of test samples; 4) test conditions, loading parameters and passing conditions.

All four knowledge gaps were deemed to lack sufficient high-quality literature for resolving via literature review alone. The group concluded that six of the gaps within these domains may be resolved adequately by expert consensus combined with existing literature, but three knowledge gaps will require new research studies to adequately address.

C. Design and implementation of a test bench for sockets

The test bench was designed starting from one of the adaptations of ISO 10328 described in the reviewed literature [7]. The test bench allowed to reproduce heel loading and

forefoot loading, i.e. the two most critical events during the stance phase according to ISO 10328 [1].

In the bench, the load was applied vertically through a uniaxial hydraulic cylinder used in force control. Load was then applied to the socket through a mock residual limb made of hard PU resin with the interposition of a soft styrene liner (Shore A 30) and cotton socks to ensure proper press fit. The load was transferred from the machine to the mock limb-socket system using rigid mounting elements (loading plates) that allowed applying the lever arms prescribed by ISO 10328 in forefoot loading for a patient weighing more than 100 kg (P5 to P8 condition). The bench could be used to perform both static and cyclic testing, according to the test procedures specified in ISO 10328.

(a) (b)

Fig. 2: Test bench for testing of lower-limb prosthetic sockets for the activity of daily living, CAD model (a) and implementation (b).

D. Socket testing

Among the twenty-three sockets tested, 50% weighted more than 600g and were therefore deemed too heavy for the size of the limb. 30% of all sockets did not reach the required strength (4500 N). Altogether, only 26% met the required strength (>4500 N) with acceptable weight (<600g) [6].

E. Guidelines for socket manufacturing

Among the sockets with required strength (>4500 N) and acceptable weight (<600g), five sockets were identified, one per type of distal adapter, and were used to define the lamination guidelines for the INAIL Prosthetic Center (Vigorso di Budrio, BO, Italy).

It was quantified that these new lamination guidelines allowed reducing material waste of manufacturing by 50%.

IV. Discussion

The aim of this study was to define a well-structured plan that should serve as a groundwork in the prosthetic field for the definition of a unified testing method for prosthetic sockets and thus help overcome the current limitations derived from the absence of a dedicated standard.

The systematic review of the literature [3] was the first element in this plan and highlighted that the literature regarding socket testing is very limited. ISO 10328 was commonly used as a guide for socket testing, but details of its adaptation to sockets varied considerably among articles. The main reason for this heterogeneity is that ISO 10328 was not designed for socket testing and consequently it is missing specific definitions and recommendations that would allow unambiguous implementation of such a testing.

Nevertheless, the findings of the systematic review were very valuable in the drafting of the discussion paper by the AOPA Socket Guidance Workgroup. The available evidence was organized in key domains, and for each of them the authors highlighted the knowledge gaps and proposed recommendations to address them. The discussion paper confirms that establishing a unified testing method for sockets is not an easy task. In fact, none of the knowledge gaps can be solved by simple application of the available evidence, and most of them will require the formation of study groups to carefully assess the problem. Nevertheless, it is the hope of the authors that the discussion paper will help spur the prosthetic field and serve as a roadmap for stakeholders to take coordinate action in their respective field of interest.

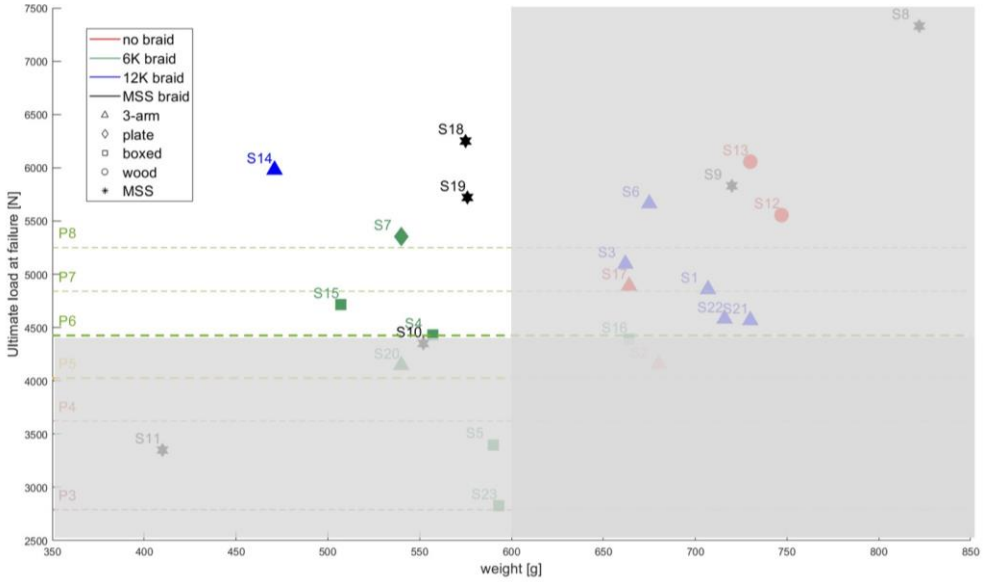


Fig. 3: Distribution of tested sockets according to ultimate load at failure and weight.

The systematic review and the discussion paper allowed to identify the topic areas that should be considered when defining a testing method for sockets. For each topic area the authors had to make decisions when evidence did not provide sufficient guidance. In the design of the test bench, the authors chose to adopt a worst-case approach that tended to maximize the bending moment at the socket distal end. We did so by implementing the adaptation of ISO 10328 proposed by Gerschutz et al. [7], which described testing the socket in isolation, in forefoot loading condition and P6 loading level. In addition, the limb increased dimensions represented a worst-case condition for pulled sockets and contributed to making the test more conservative. Even though it was the intent of the authors to establish a conservative testing system, the actual effect of different adaptations is unknown, and the decisions made on certain knowledge gaps will need to be confirmed once study groups are formed and/or consensus in the prosthetic community is reached.

Even with the limitations described above, the implementation of a test bench allowed to carry out a first test campaign with the objective of exploring existing combinations of layup-adapter-resin and establishing a benchmark based on the current practice of the INAIL Prosthetic Center (Vigorso di Budrio, BO, Italy). The study showed that the absence of an established method to quantify socket strength leads to a tendency of over-dimensioning. Half of the sockets were in fact deemed too heavy for the size of the limb. Overall, only 26% displayed sufficient strength (> 4500N) and acceptable weight (<600g).

Despite its limitations, this exploratory study allowed to identify correlations between certain combinations of layup resin and distal adapter and socket strength and/or weight. In addition, based on the sockets that produced the best output, it was possible to draft manufacturing guidelines for the INAIL Prosthetic Center, aimed at reducing material waste, unnecessary weight and maximize strength. The introduction of these guidelines in the production line of the Center has in fact allowed reducing the material waste by 50%, creating sockets that are lighter and stronger.

Overall, the path to the definition of a standardized method for socket testing is still long. Nevertheless, thanks to the activities described in this manuscript, the foundations have been laid and hopefully will guide other researchers of the prosthetic community to take coordinate in the definition of a unified method for socket testing.

V. Conclusion

The current manuscript outlines a possible approach to lay the foundation in the definition of a standardized method to test prosthetic sockets. This approach was intended to guide other researchers of the prosthetic community to take coordinate action in pursuing this objective.

***Abstract*—In order to compare different approaches for cardiac tissue regeneration, it is fundamental to estimate the contractile behavior of cardiomyocytes interacting with hydrogel scaffolds. Direct measurement of specific mechanical parameters is difficult due to the small size of the treated samples and the complex mechanical behavior of tissues and scaffolds. Finite Element Method (FEM) models can be usefully adopted to estimate these parameters, as shown in this work. We have developed a constitutive model to describe the mechanical response of cardiomyocytes (CMs) and we are using this constitutive model in numerical models aimed at *in silico* analysis of original experimental tests involving human pluripotent stem cell–derived cardiomyocytes (hPSC-CMs).**

***Keywords*—cardiomyocyte, contractile behavior, constitutive modelling, Finite Element Analysis.**

I. Introduction

The heart is the first organ to be formed during embryonal development and this is the reason why cardiac abnormalities represent a massive cause of fetal death [1]. At week 3, the embryo consists of three layers, i.e. the endoderm, the ectoderm and the mesoderm, from which the cardiac tissue originates [2].

Embryonic cardiomyocytes (CMs) develop into a linear heart tube that eventually undergoes rightward looping and forms a primitive heart structure. Afterwards, the septal development and the formation of the valves provide the separation of the pulmonary and systemic circulations [1]. The human heart is a muscular organ and consists of several types of cells such as CMs, endothelial cells, fibroblasts and smooth muscle cells [3].

The main function of the newly formed heart is to pump blood during the contraction–relaxation cycle of the working myocytes, which represent the fundamental contractile cell of the heart. CMs are made of groups of myofibrils containing sarcomeres, consisting of myosin and actin proteins, which appear respectively as thick and thin myofilaments.

Human pluripotent stem cell–derived cardiomyocytes (hPSC-CMs) are an inexhaustible source of CMs for potential therapeutic applications and are very promising for the investigation of early developmental processes in human cardiomyogenesis and future cell replacement strategies.

Congenital heart defects (CHDs) are the most common type of birth defect and bring a huge life burden, since babies with a critical CHD need to undergo several surgical procedures in the first year of life.

Regenerative medicine may be an alternative approach to treat CHDs, based on the development of functional models of the heart muscle *in vitro*. These models can be based on different scaffolds in combination with hPSC-CMs. Scaffold biomaterials are required to actively support tissue reconstruction and regeneration by promoting cell-cell adhesion, proliferation and differentiation [4]. Cellular viability and contractile ability of hPSC-CMs on scaffolds shall be evaluated to assess the feasibility of different tissue engineering platforms to support the formation of the heart muscle. Therefore, using numerical methods to analyze the contractile force, mechanical properties and dynamic beating behavior of hPSC-CMs could be of great significance for the design of innovative therapeutic approaches.

A quantitative analysis of CMs and hPSC-CMs contractility can be carried out *in silico* to properly select the best scaffold biomaterial or structural shape to support cells growth and differentiation.

In this work, we propose a constitutive model to simulate the mechanical behavior of CMs and hPSC-CMs. The model is implemented in a general-purpose FEM software and adopted to simulate *in silico* different experimental assays involving the mechanical interactions of hPSC-CMs with structures made of different biomaterials, such as hydrogels. We show the general capabilities of the numerical procedures developed and how the contractile forces of hPSC-CMs adopted in original experimental tests can be assessed by means of FEM modeling.

II. Materials and Methods

A. Constitutive modeling

To describe the phenomenology of CMs and hPSC-CMs we have modified a constitutive model previously proposed for skeletal muscle tissue [5] and based on Hill's three-element model [6], composed of a contractile element (CE), an elastic element (SE), in series with CE and an elastic element (PE) in parallel with CE and SE. This model is a simplified version of the actual structure of the sarcomeres, where both SE and CE are affected by the cross-bridge properties. The tension on SE is equal to the one on CE, since the two elements are placed in series, while the element PE is responsible for passive elasticity. The stress response of contractile fibers is assumed as the sum of a passive term P_p and an active term P_a. The passive term is defined as:

$$P_p = \begin{cases} 0 & \lambda_f \le 1 \\ E_f \left(\lambda_f - 1\right)^2 & \lambda_f > 1 \end{cases} \quad (1)$$

where λ_f is the stretch of the fibers and E_f a parameter with stress-like dimension. The active stress is defined as:

$$P_a = P_0 \, f_a(t) \, f_l(\lambda_m) \, f_v(\dot{\lambda}_m) \quad (2)$$

where the scalar P_0 is the maximum isometric stress, f_a the activation function, f_l the force-length function and f_v the force-velocity function. The activation function depends on time t and is assumed in the following form [7]:

$$f_a(t) = (t/t_0)^2 \, exp\left[1 - (t/t_0)^2\right] \quad (3)$$

where the constant t_0 determines the time of contraction. The force-length function depends on the stretch λ_m of contractile element CE:

$$f_l(\lambda_m) = \begin{cases} \dfrac{\lambda_m - \lambda_{min}}{\lambda_{opt} - \lambda_{min}} \cdot \\ \cdot exp\left[\dfrac{\left(2\lambda_{min} - \lambda_m - \lambda_{opt}\right)\left(\lambda_m - \lambda_{opt}\right)}{2\left(\lambda_{min} - \lambda_{opt}\right)}\right] & \lambda_m > \lambda_{min} \\ 0 & \lambda_m \le \lambda_{min} \end{cases} \quad (4)$$

The function is fitted to experimental data by setting the values for the minimum λ_{min} and optimal λ_{opt} stretch. Finally, the force-velocity function depends on the stretch rate $\dot{\lambda}_m$ of the contractile element:

$$f_l(\lambda_m) = \begin{cases} \dfrac{1 - \dot{\lambda}_m / \dot{\lambda}_{max}}{1 + 1 - k_c \, \dot{\lambda}_m / \dot{\lambda}_{max}} & \dot{\lambda}_{max} < \dot{\lambda}_m < 0 \\ 0 & \dot{\lambda}_m \le \dot{\lambda}_{max} \end{cases} \quad (5)$$

The previous function is fit to experimental data by setting the parameters $\dot{\lambda}_{max}$ and k_c.

The mechanical response of a three-dimensional construct of CMs with contractile fibers aligned to a specified direction $\boldsymbol{a}_0$ is described as an isotropic fiber-reinforced material and, in terms of the first Piola-Kirchhoff stress tensor $\boldsymbol{P}$, it is written:

$$\boldsymbol{P} = \boldsymbol{P}_{iso} + \left(P_p + P_a\right) \boldsymbol{F} \cdot \left(\boldsymbol{a}_0 \otimes \boldsymbol{a}_0\right) \quad (6)$$

where $\boldsymbol{F}$ is the deformation gradient. Since for these constructs it is usually accepted and almost-incompressible behavior, the elastic response associated to $\boldsymbol{P}_{iso}$ is deduced via a standard derivative from a strain energy function of the type:

$$w_{iso} = \alpha_{m1} \, exp\left[\alpha_{m2}\left(\tilde{I}_1 - 3\right)\right] + \frac{k_{mv}}{4}\left[J^2 - 1 - 2\,ln(J)\right] \quad (7)$$

where J is the Jacobian of the deformation and $\tilde{I}_1$ the first invariant of the iso-volumetric part of the right Cauchy–Green strain tensor $\tilde{\boldsymbol{C}} = J^{-2/3}\boldsymbol{F}^T\boldsymbol{F}$. The scalars α_{m1} and α_{m2} are constitutive parameters related to the iso-volumetric response, while represents the bulk modulus**.** Finally, the stretch of contractile fibers λ_f is deduced as:

$$\lambda_f = \sqrt{\tilde{\boldsymbol{C}} : \left(\boldsymbol{a}_0 \otimes \boldsymbol{a}_0\right)} \quad (8)$$

A relevant aspect of muscle tissues and muscle-like construct obtained in tissue engineering pertains to the spatial orientation of the fibers, which can follow a statistical distribution respect to specific directions, according to the level of maturation and the mechanical stimulus applied [8].

This results in a different level of anisotropy that is described in this model by assuming a 2D Von Mises distribution, as proposed for connective tissues [9]. This is suitable for modeling the experimental assays where hPSC-CMs are disposed in thin layers, therefore, with a local planar disposition. The local 2D Von Mises distribution of a group of fibers with respect to a specified direction $\boldsymbol{a}_0$ is considered by a modified structural invariant:

$$\tilde{I}_4 = \kappa \tilde{\boldsymbol{C}} : \left(\boldsymbol{I} - \boldsymbol{t}_0 \otimes \boldsymbol{t}_0\right) + \left(1 - 2\kappa\right) \tilde{\boldsymbol{C}} : \left(\boldsymbol{a}_0 \otimes \boldsymbol{a}_0\right) \quad (9)$$

where $\boldsymbol{I}$ is the second rank identity tensor, $\boldsymbol{t}_0$ the local normal to the plane of the fibers in the undeformed configuration and κ a fiber dispersion factor that is deduced from the density function of the fibers [9]. Fibers are totally aligned to $\boldsymbol{a}_0$ with $\kappa = 0$, while they are randomly disposed in the plane normal to $\boldsymbol{t}_0$ if $\kappa = ⅓$. The density distribution of the fibers around the reference direction $\boldsymbol{a}_0$ for different values of the dispersion factor κ is represented in Figure 1.

The constitutive model has been implemented through FORTRAN subroutines in the general-purpose FEM software ABAQUS (SIMULIA™, Dassault Systèms, France). The subroutines allow the use in nonlinear static, implicit dynamic, as well as explicit dynamic procedures. Continuum 3D and plane-strain elements can be used with the constitutive model, also for hybrid formulation – when available – to overcome numerical instabilities due the almost-incompressible behavior, that is typical of tissues and materials considered in this study. Additional capabilities of the subroutines are represented by the possibility to provide 3D Von Mises distribution of the fibers and statistical distribution of other constitutive parameters, such as the maximum isometric tension of the fiber, which can be defined with spatial distribution at the level of Gauss points.

Since the numerical approach is aimed at evaluating specific constitutive parameters based on experimental data, it is helpful to have an inverse iterative procedure of model fitting. This has been obtained by linking ABAQUS and MATLAB (MathWorks, USA). A user script [10] is adopted to optimize the constitutive parameters by defining an objective function of error between numerical results and experimental data and by using a built-in MATLAB function to find the minimum of constrained nonlinear multivariable functions.

B. FEM models

FEM models were developed using ABAQUS CAE software (SIMULIA, Dassàult Systems, France) to test the general capability of the constitutive model and to simulate a specific experimental assay involving hPSC-CMs.

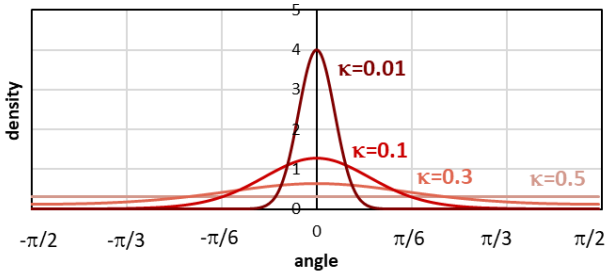

Fig. 1 Density distribution of the fibers around the reference direction $\boldsymbol{a}_o$ according to different values of the dispersion factor κ. For κ = 0 the fibers are totally aligned to $\boldsymbol{a}_o$.

To test the effect of fiber angular dispersion (parameter κ), a model with simple geometry was conceived, consisting of a free flat disc with 1 mm diameter and 0.1 mm thickness, and assuming the constitutive model described in section A. The reference direction for the fibers $\boldsymbol{a}_0$ is aligned with a diameter of the disc and different levels of fiber angle dispersion are considered, corresponding to the parameter κ equal to 0, 0.1, 0.3 and 0.5, while all the other constitutive parameters are considered fixed. The disc is free to deform under contraction of the fibers and the deformation is compared for the four conditions. Moreover, to test the capability of our numerical procedures to simulate large deflection problems we were inspired by the work of Shim et al. [7], modelling a composite flat rectangular sheet (2 mm × 4 mm) made of two overlapping layers: the upper layer (4 μm thickness) consists of cardiomyocytes while the lower layer (14 μm thickness) is made of hydrogel. The two layers are perfectly bounded at their interface and fixed at one of the short edges (Figure 2a). The sheet deflects under contraction of cardiomyocytes that are considered with two different spatial orientation in the plane of the sheet, lengthwise fibers, or oblique fibers with angle of 45°, with total alignment to the reference direction (κ = 0). The hydrogel is considered as an almost-incompressible neo-Hookean hyperelastic material with initial longitudinal elastic modulus of 10 kPa.

In addition, original experimental assays have been developed using tubular shape scaffolds with length of about 0.4 mm, made of hydrogel coated with an external layer of hPSC-CMs. The contraction of hPSC-CMs generates a deformation of the scaffold, which is analyzed by experiment specific models. Confocal microscope images of the tubular scaffold (Figure 2b) are used to reconstruct a model that consists of the hydrogel tube covered by a layer of cardiomyocytes. The transversal section of the hydrogel tube is roughly ellipsoidal with external diameters of about 200 μm and 170 μm, and internal diameters of about 150 μm and 70 μm.

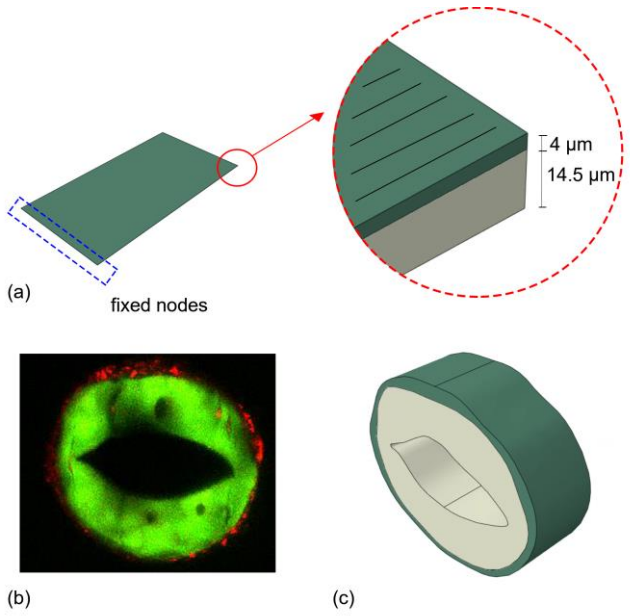

Fig. 2 Geometric reconstruction of a hydrogel sheet covered by a layer of cardiomyocytes (a); Confocal microscope image of a hydrogel tube coated by an external layer of cardiomyocytes (b); Geometric reconstruction of the structure of a tube slice and layer of cardiomyocytes (c).

The layer of hPSC-CMs has a thickness of about 5 μm (Figure 2c). The fibers are assumed to be aligned circumferentially to the external boundary of the tube.

The hydrogel is described as adopting an almost-incompressible neo-Hookean hyperelastic constitutive model with an initial longitudinal elastic modulus of 10 kPa (value deduced from experimental indentation). The contractile force of hPSC-CMs and the characteristic time of contraction are estimated via an inverse method based on the deformation of the transversal section of the scaffold.

In the three proposed examples, the models are discretized using linear hybrid hexahedral finite elements. A static non-linear procedure is adopted, according to the low value of the mass and the consequent negligible value of inertial forces.

III. Results

The numerical analyses performed using the flat disk and the flat sheet models allow to evaluate the effect of the fiber dispersion and orientation in the contractile response of cardiomyocytes. Figure 3 shows that the deformation at the same level of activation is different based on the dispersion level of fibers, where κ = 0 corresponds to fibers totally aligned to $\boldsymbol{a}_0$ and κ = 0.5 to fibers totally dispersed around $\boldsymbol{a}_0$.

Figure 4 shows the large folding of the sheet due to CMs contraction and the different resulting deformation according to the fiber orientation. A lateral component of displacement emerges in the case of fibers with a non-zero angle with respect to the lengthwise direction.

Regarding the tubular shape scaffold, the deformation induced by hPSC-CMs contraction is evaluated through the length change of the pseudo-diameters the internal cavity (Figure 5a). The maximum stress value (3.5 kPa) and time of contraction (about 0.45 s) in the constitutive model of cardiomyocytes are estimated through the fitting of the numerical model deformation to experimental data (Figure 5b).

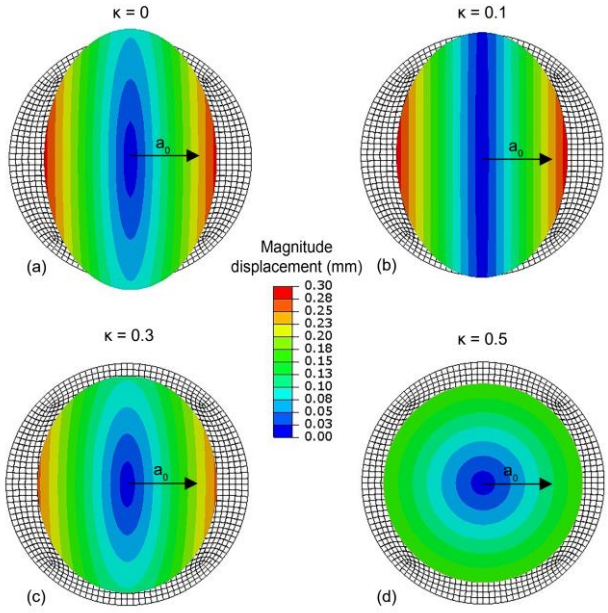

Fig. 3 Deformed configuration and magnitude displacement field (mm) for the flat disc, at the same level of contraction, according to the different angular distribution of the fibers around the direction represented by the vector $\boldsymbol{a}_0$. The value κ = 0 corresponds to the total alignment of the fibers along $\boldsymbol{a}_0$, while κ = 0.5 to the totally random dispersion of the fibers in the plane of the disc.

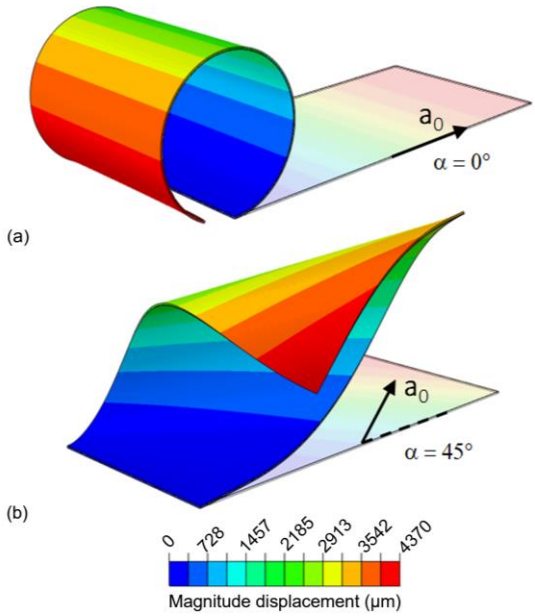

Fig. 4 Sheet folding at the same level of activation for a different spatial orientation of the fibers in the plane of the sheet. In both models, it is set $\kappa = 0$ (fibers perfectly aligned to $\boldsymbol{a}_0$).

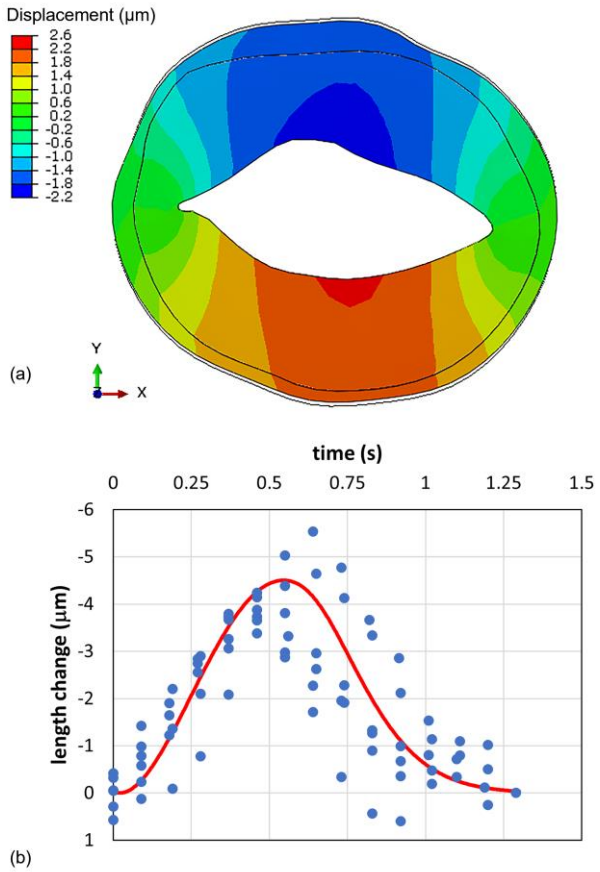

Fig. 5 Displacements field (μm) in Y direction in a specific transversal section of the tubular scaffold under cardiomyocytes contraction, compared to undeformed configuration (a); length change of the shorter internal diameter vs. time (b): numerical results (solid line) are compared with experimental data taken from 6 contraction cycles (dots).

IV. Conclusion

The proposed models allow to evaluate contraction capability of cardiomyocytes in different situations, and are also able to numerically reproduce experimental analyses on human embryonic stem cell-derived cardiomyocytes.

The development of such models is essential to study the relationship between cardiomyocytes mechanical behavior and cardiac pathologies, since many cellular alterations caused by cardiovascular diseases may induce a variation in the activation or the force generation processes of CMs.

However, there are still several aspects of these models that could be improved, for example, by considering that the hydrogel microtubes with hPSC-CMs layers are immersed in saline solution in the experimental set-up. Therefore, an improved model may also take into consideration the liquid flow through the microtube and its effect on cardiomyocytes contraction and on the microtube occlusion.

Despite some limitations, these models represent the first step towards the analysis of the active mechanical behavior of hPSC-CMs on hydrogel scaffolds and their future developments will enable to assess how CMs can organize on scaffolds to properly mimic the cardiac muscular tissue for tissue engineering applications.

***Abstract*— The proper connective tissue, which defines the fascial system, plays a central role in supporting the biomechanics of the body. Fasciae can be classified between superficial and deep according to their anatomical structures and bodily functions. However, despite the importance of fascial alterations in different clinical conditions, the literature is still lacking in evidence comparing superficial and deep fasciae in terms of biomechanical properties. The present work, therefore, aims to offer an in-depth study on this topic. The experimental results showed a site-dependent anisotropy and a viscoelastic behavior of the fascial tissues. Mechanical comparison between fasciae is the key to tailor and target the most appropriate clinical intervention.**

***Keywords*— connective tissue, musculoskeletal system, fascial system, biomechanical properties.**

I. Introduction

THE PROPER CONNECTIVE TISSUE (CT) has many roles in body functioning such as structural support and connection of musculoskeletal system. In daily life, it is subjected to in vivo loads that arrange its structure according to multi-axial movement directions. Thus, the mechanical response of connective components (cells, collagen and elastin fibres, ground substance) is key for mechanotransduction. These properties are expressed by dense and loose connective substrates, which, between the skin and the deep muscle layers, are organized at several levels to slide over each other. The proper gliding between layers allows forces transmission between body structures and it could be altered in case of clinical conditions [1]. This specific arrangement of CT defines the fascial system made by a) Epidermis and Dermis, b) SAT with retinaculum cutis superficialis, c) Superficial Fascia (SF), d) DAT with retinaculum cutis profundus e) Deep Fascia (DF) f) Muscle [2]. Therefore, the continuity between skin layers and deep muscles is ensured through the retinacula that connect to SF and DF (Fig. 1). SF and DF have been shown to have different anatomy and are implicated in different disorders [3]. Despite the clinical implications of fasciae in several musculoskeletal diseases, literature is still poor of evidence that compares the structural characterization of SF and DF through mechanical tests. Therefore, in this research work we have investigated this open topic. Our contribution could guide the clinician in planning the most appropriate treatment modality according to the mechanical response of the fascial tissues.

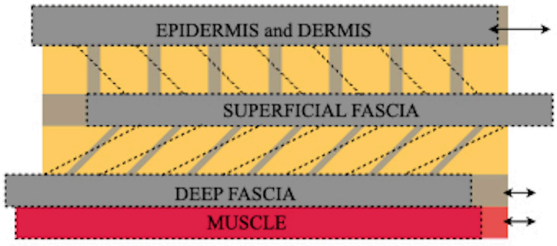

Fig. 1: Fascial system continuity from skin to muscles and gliding between layers.

II. Material and Methods

A. Samples collection

Fascia patches have been harvested from fresh-frozen human donors (Table I) according to Body Donation Program of the Institute of Anatomy of the University of Padua [4]-[6]. From the clinical history of the subjects, no alterations of the fascial tissue were reported.

TABLE I: Human Donors Information

Subject	*Gender*	*Age*	*Site*	*Patch*
1	1 Male	76 y/o	Fascia Lata	DF
2	1 Male	87 y/o	Abdomen	SF
3	1 Male	76 y/o	Thorax	

Table I: Harvested tissues and donors' information. Sites were selected based on donors' availability.

B. Micro and macrostructure of SF and DF

Samples of SF can be macroscopically isolated as a well-defined membrane but microscopically SF shows a multilamellar structure, where the various sublayers are interconnected to each other's and interspersed with irregular islets of fat cells.

Meanwhile, DF (in this case as aponeurotic fascia of the thigh) both macroscopically and microscopically shows a double-layer organization of dense connective tissue (well-separated by loose connective tissue), where collagen bundles follow specific directions, forming an inter-layer angle of 85° (Fig. 2).

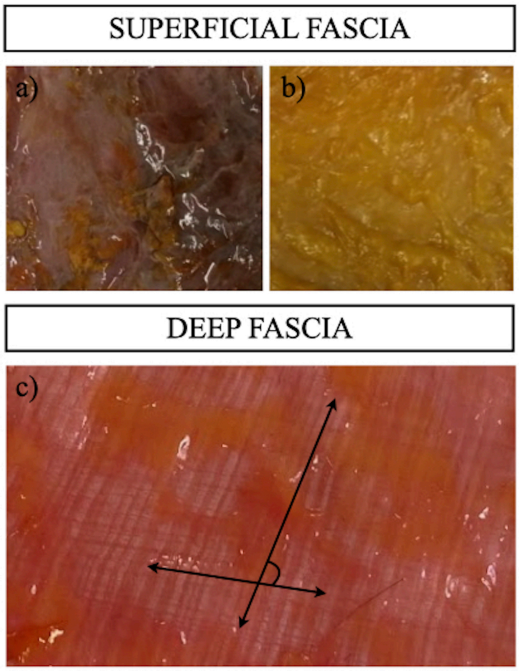

Fig. 2: Samples from donors a) thorax b) abdomen c) fascia lata, examples of collagen fibres directionality. The directions of the DF fibers form an inter-layers angle, while the SF samples do not show a specific orientation of the bundles.

C. *Experimental tests*

After thawing, the samples were cut into rectangular strips in two orthogonal directions (D1 and D2). The temperature and dimensionality of the strips were acquired at multiple points of the samples and recorded. Samples were kept moist with saline solution for the overall testing procedure. Then, each specimen was mounted on a mechanical tester (Model Mach-1, ©Biomomentum, with a load cell capacity of 250N and accuracy ±0.0125N) and loaded for uniaxial tensile tests. Preconditioning (10 cycles of loading-unloading) was performed before two different protocols of Failure and Stress-Relaxation (Table II), to evince potential tissues anisotropy and viscoelastic behaviours.

TABLE II: EXPERIMENTAL PROTOCOLS

Patch	*Preconditioning*	*Failure*	*Stress-Relaxation*
SF	10 cycles, 0.25 Hz, 4% strain	1%/s strain rate	15%/s strain rate, 5 ramps, 5% strain each, 300s resting time
DF	10 cycles, 0.125 Hz, 3% strain		1%/s strain rate, 5 ramps, 2% strain each, 300s resting time

Table II: Failure and stress-relaxation protocols information, designed and tuned based on experimental evidence.

D. *Statistical Analysis*

Mechanical results have been analysed with MATLAB 2021b (The MathWorks, Inc., MATLAB and Statistics, Natick, Massachusetts, United States). To compare the potential difference according to sites and directions, a statistical analysis was performed with Minitab Statistical Software (Software, Minitab, State College, Pennsylvania 2010 Minitab, Inc.). Inferential statistics compared the results for different sites (Two-sample t-test, two-tail, level of significance 0.05) and loading directions (Paired-sample, two-tail t-test, level of significance 0.05).

III. RESULTS

In the current section, the results for different sites and loading directions have been detailed. Specifically, the comparison of ultimate tensile strength (UTS)/strain at break/Young's Modulus (linear region) was reported for failure tests, while % stress decay was discussed for stress-relaxation curves.

A. *Failure test*

The comparison between SF and DF for different sites and directions was summarized in Table III and in Fig. 3.

TABLE III: FAILURE RESULTS

Patch	*Site*	*Direction*	*UTS (MPa)*	*Strain at break (%)*	*Young's Modulus (MPa)*
SF	*Abdomen*	*D1*	0.34 ± 0.12	47.0 ± 9.00	1.32 ± 0.82
		D2	0.66 ± 0.37	50.0 ± 11.0	2.25 ± 1.04
	Thorax	*D1*	8.86 ± 2.44	39.0 ± 5.00	37.76 ± 11.19
		D2	3.66 ± 0.92	34.0 ± 3.00	17.39 ± 4.43
DF	*Fascia Lata*	*D1*	10.53 ± 2.60	17.0 ± 8.00	155.88 ± 66.91
		D2	1.45 ± 0.76	16.0 ± 5.00	8.47 ± 6.47

Table III: Experimental results (mean ± SD) from failure curves for different sites and directions.

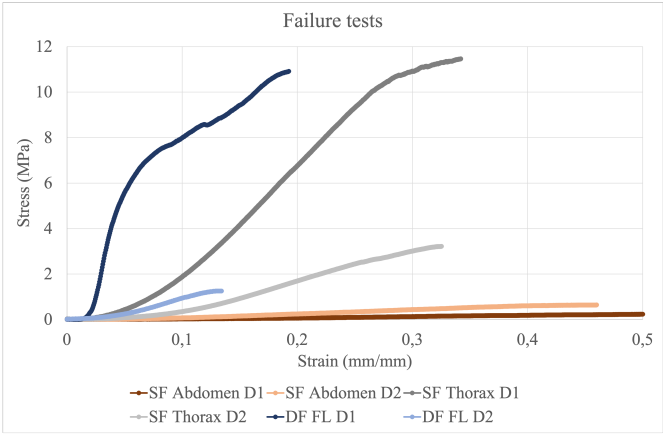

Fig. 3: Examples of stress-strain curves for different sites and directions.

Both SF and DF exhibited a non-linear stress-strain behaviour.

TABLE IV: INFERENTIAL STATISTICS, FAILURE RESULTS - COMPARISON BETWEEN DIRECTIONS

Patch	*Site*	*Direction*	*UTS*	*Strain at break*	*Young's Modulus*
SF	*Abdomen*	*D1* / *D2*	0.199	0.593	0.295
	Thorax	*D1* / *D2*	**0.014***	0.119	**0.030***
DF	*Fascia Lata*	*D1* / *D2*	**0.001***	0.845	**0.002***

Table IV: Statistical results (p-value) from failure curves for different sites between loading directions (*p-value < 0.05).

SF of thoracic region and DF showed an anisotropic behaviour between directions in terms of UTS and Young's Modulus values. Meanwhile, there are no specific differences between loading directions for all districts in terms of strain at break values (Table IV). In any case, from the statistical tests, the strain at break values between the sites were found to be significantly different (p-values < 0.05) and higher for SF than for DF. In general, in one direction, DF was stiffer and stronger than SF, meanwhile, the SF of the abdominal region was less stiff and strong than the other districts.

B. Stress-Relaxation test

The comparison between SF and DF for different sites and directions was summarized in Fig. 4, Table V and Fig. 5.

Normalized stress was obtained as the ratio of stress to the peak value recorded at the beginning of each relaxation curve. A two-term Prony series Eq. (1) was used to fit the normalized stress-relaxation curves:

$$\sigma_{norm} = 1 - \gamma_1 \left(1 - e^{\frac{t}{\tau_1}}\right) - \gamma_2 \left(1 - e^{\frac{t}{\tau_2}}\right) \quad (1)$$

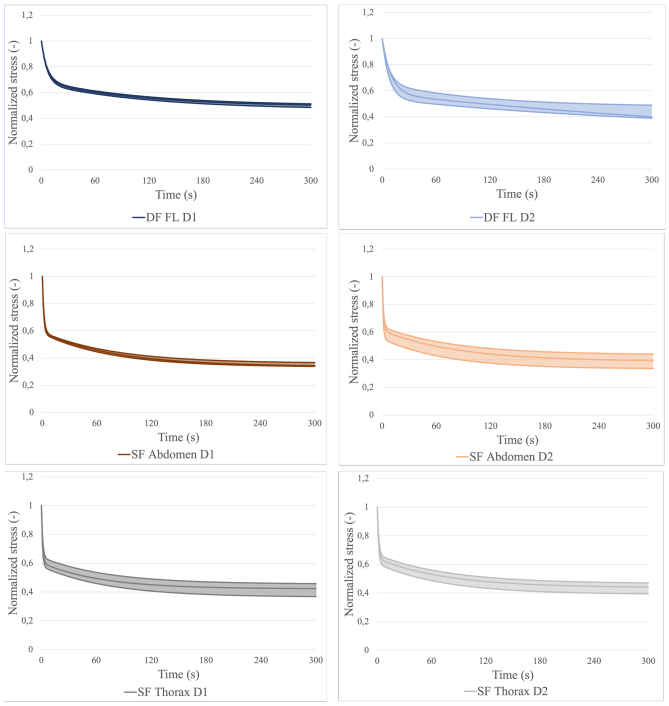

Fig. 4: Experimental results (median values) from stress-relaxation curves for different sites and directions. Color bands depicted the first and third percentiles.

TABLE V: STRESS-RELAXATION RESULTS

Patch	*Site*	*Direction*	*Residual stress*			
			After 10s	*After 30s*	*After 120s*	*After 240s*
SF	*Abdomen*	*D1*	0.56	0.51	0.40	0.35
		D2	0.59	0.54	0.44	0.40
	Thorax	*D1*	0.58	0.54	0.45	0.43
		D2	0.62	0.57	0.48	0.45
DF	*Fascia Lata*	*D1*	0.73	0.64	0.56	0.51
		D2	0.72	0.57	0.50	0.43

Table V: Median values of normalized residual stress (% of the peak, which is equal to 100%) from stress-relaxation curves for different sites and directions.

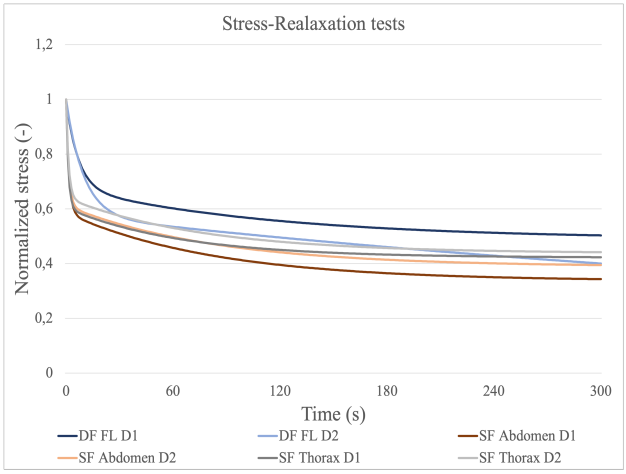

Fig. 5: Experimental results (median values) from stress-relaxation curves for different sites and directions.

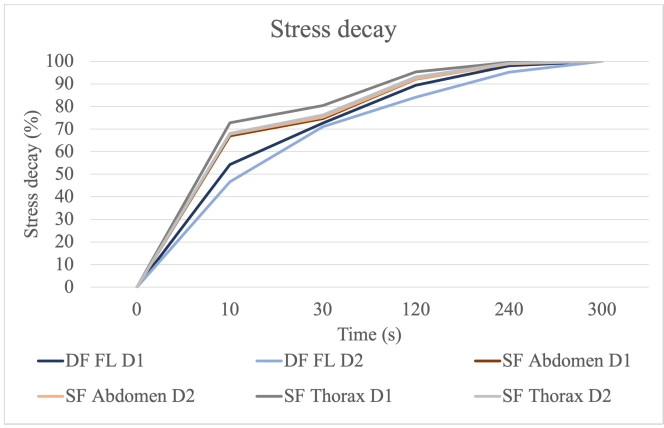

Fig. 6: Experimental results (stress-decay, % of the total relaxation which is equal to 100%) from stress-relaxation curves for different sites and directions.

Both SF and DF exhibited a viscoelastic response. SF of the abdominal region relaxed at lower levels of initial stress than other sites. A difference for stress decay was found in the early 30s between SF and DF. After 30s the stress decay is at least 64% of the initial stress for all specimens. In fact, most of the stress relaxed in the early 30s (at least 70% of total relaxation). Between 240s and 300s the stress decay reached a plateau (steady state) for all the samples. Fig. 6.

IV. DISCUSSION

The results of mechanical tests conducted on human SF and DF helped highlight the variability between the layers of the fascial system, as potential evidence of their structural differences and roles.

The stress-strain curves for both SF and DF showed a nonlinear behavior as for connective tissue [7]. At the beginning of each curve, in the so-called "toe" region, the collagen fibers of the fascia were in a crimped conformation, then reached a progressive uncrimping in the linear region until they broke.

Regardless of the direction of loading, the SF districts resisted greater strain before failure than DF, and in particular the abdominal region greater than the thoracic one. One hypothesis could be justified by the presence of a higher percentage of elastin fibres in SF than in DF, as characterized by reference [8]. This difference could also be explained in

terms of deformation changes of these body sites during activities of daily living.

In terms of UTS and Young's Modulus, anisotropy between loading directions was confirmed for the thoracic and fascia lata sites, but for the abdominal fascia, thus, increasing the importance in tissue placement (i.e., orientation), for example during the surgical procedure. Furthermore, in one direction the DF was stiffer and stronger than the SF, where the abdominal region showed lower values than the thoracic one. This confirmed the results concerning fascia lata anistotropy, as constituted by parallel layers of collagen fibers which contribute differently with reference to tissue strength and stiffness, in accordance with inter-layer angle. This fact reflects the ability of the fascia lata not only to adapt to muscle contraction but also to transmit the mechanical forces of in vivo loads along specific anatomical lines. As the literature still lacks evidence on the mechanical behavior of the SF of the abdominal and thoracic sites, we cannot compare our results. Explanatory hypotheses for the difference in tissue anisotropy could be found in the presence of anatomical connection between superficial fascia and different superficial veins/lymphatic vessels [3] and muscle groups. In fact, reference [9] already demonstrated SF variability in accordance with body location and gender.

The viscoelastic nature of connective tissues has been confirmed for both SF and DF by the results of stress relaxation. In general, for all the samples, at least 70% of the total stress decay occurred in the first 30s, while 300s could be considered sufficient for the completion of the stress relaxation phenomena (as rearrangement of tissue components for body optimization strategy), thus, potentially providing a reference for stretching practitioners in terms of maintaining a position for the aforementioned time intervals during their exercise (see [10] for further comparison with DF of the leg). In particular, the abdominal SF final stress (plateau) relaxed to lower levels than the other districts. Otherwise, the relaxation of the DF tissue in the early 30s behaved differently than that of the SF. The composite nature of DF with loose and dense layers of connective tissue could potentially account for this finding, as well as the different strain rates used to test the samples could impacted the results.

The challenges of the current work were the lack of data from literature in terms of protocol design and study comparison. A limitation of the present study is the low number of donors. As further proof of the concept, more studies should be performed on a larger sample size (i.e., additional sites of the same subjects and more subjects) to overcome the limitations of subject variability (i.e., gender, clinical history, BMI, age and so on) and with different protocols/parameters (i.e., strain rate).

In the future, the collection of additional data could permit the modelling of the overall fascial system in different clinical scenarios as physiological (such as pregnancy, aging) or pathological (such as musculoskeletal disorders) conditions. For example, it has been demonstrated that the functional role of SF in supporting the integrity of subcutaneous structures through stress adaptation could be modified with aging or in pathological conditions (e.g., as scar formation), thus leading to an alteration in nerve/vascular patency as well as in sliding/transmission of the forces between the muscles and the skin [1].

V. Conclusions

This work primarily helps to compare the superficial and deep fascia of different body regions as well as characterize the superficial fascia of the abdominal and thoracic sites.

The fascial system has demonstrated different mechanical properties according to site and directions.

The mechanical characterization of the different layers of the fascial system represents a fundamental information to deepen the knowledge of its arrangement, as a key connection for the transmission of mechanical loads. These findings have practical clinical implications such as in tissue engineering, graft surgery and rehabilitation planning.

***Abstract* — Biomechanical analysis of Paralympic amputee sprinters has implications for the design of prosthetic components and for the improvement of the athletic performance. Field measurements are the optimal condition to collect data for this purpose. Therefore, the aim of this study was to complete a kinematic and kinetic analysis of a unilateral transfemoral amputee sprinter running on track. Data were gathered with a 28-camera motion capture (mocap) system and wearable kinetic sensors. Joint kinematics of the prosthetic limb and the intact limb were compared. The results presented here provide an example of outcomes which can support the improvement of athletes' safety and performance.**

***Keywords*—Running Biomechanics, Paralympic Sprinters, Load Cell, Motion Capture.**

I. INTRODUCTION

IN the last decades there has been growing interest in the running biomechanics of individuals with lower limb amputation [1]. Research has allowed to gain greater insight into how lower-extremity amputees regain running capacity. Running Prosthetic Foot (RPF), carbon fibre blade with a spring-like function, has been introduced since the '90s and over the years its design has been improved in order to better compensate for the replacement of an active leg.

It has been observed that laboratory measurements with subjects running on a treadmill, despite having high precision and resolution, cannot be entirely realistic, because sprinters are not used to running in such an artificial environment and at a constant speed [2]. In contrast, overground running tests can reproduce sprints very close to those performed during races. Thus, the results obtained from these tests better correlate with the actual athletic performance and are more useful for the structural optimization of running prosthesis. However, data collected in indoor or outdoor tracks are challenging for the cost of instrumentation, which should cover kinematics and kinetics over a convenient portion of the track.

Several studies make use of force platforms placed on the running track to measure Ground Reaction Forces (GRFs) during overground running [3], [4]. Except in cases where the number of platforms is very large [5], the results of this type of studies depend to a large extent on the probability of obtaining valid steps for the analysis (athlete hitting the plate and whole foot placed on the plate). Instrumented prosthesis have been demonstrated to overcome this issue by allowing realistic and numerous performance data to be obtained [6]. Various attempts have been made at kinematic analysis using inertial sensors attached to the athlete's body, but results are less accurate than those obtained with the mocap system, considered the gold standard [7].

The purpose of the present study was to present kinematic and kinetic in-field collected data, obtained through an integrated motion capture and kinetic acquisition system, of a world-class athlete running unrestrained on a familiar track surface. These data will form the basis for a more in-depth analysis of the effects of the prosthesis configuration on running strategy and the minimization of injury risk.

II. MATERIALS AND METHODS

A. Participants

One elite, gold medallist, Paralympic female athlete (mass: 55 kg; height: 1.60 m) with left unilateral transfemoral amputation, participated in this study. She wore the Ottobock 1E91 standard RPF, category 3.5, and she used the mono-axial Ottobock 3S80 prosthetic knee.

B. Instrumentation

Tests were performed in a 60m indoor athletics track (Palaindoor, Padova). In detail, the athlete ran on the eighth lane of the central straight runway.

Motion capture cameras (25 *Vero* (fs = 300 Hz) and 3 *Vantage* (fs = 300 Hz) - Vicon Motion System, Oxford, UK) were placed in the central part of the runway, covering an approximated 20-metres-long acquisition volume. 22 cameras were mounted on tripods placed along the runway, while the remaining 6 were installed on a double portal structure made of aluminium trusses with an overall size of 2.5 x 3 x 3.5 metres (length x width x height) positioned in the midpoint of the runway (Figure 1).

The Running-Specific Prosthesis (RSP) was instrumented with a 6-axis ultra-thin load cell mounted in between the prosthetic knee and the clamp of the RPF, and connected through wires to an ultra-small, standalone acquisition system (*DTS SLICE NANO* (fs= 2000 Hz) - DTS, Seal Beach, USA). The acquisition system was placed inside a small running backpack, together with its battery and a power bank for the load cell power supply.

C. Experimental protocol

The subject wore the prosthesis and the orthopaedic technician set the inclination of the socket with respect to the vertical line passing through the greater trochanter and the centre of the prosthetic knee. Specifically, the alignment adopted in the tests consisted in a socket pre-flexion angle equal to 15°[8]. The athlete then warmed up to familiarize with the track and the prosthesis setup.

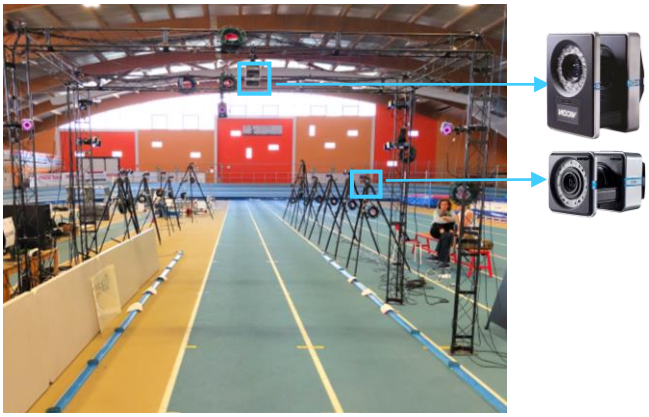

Fig. 1: Motion Capture system installed in the indoor athletics track. 28 Optoelectronic cameras (Vicon, fs = 300 Hz) placed on tripods and on the double portal structure.

Sixty-five retroreflective markers (14 mm diameter) were attached to the subject at specific anatomical landmarks and locations of the prosthetic components (Figure 2a, 2b), such as on the proximal and distal tip of the RPF, on the clamp, on the mechanical knee and on the socket. A wand calibration procedure was employed to identify 12 additional points, including four reference points on the loadcell, relative to technical clusters of markers. After the static acquisition, the calibrated markers, both placed medially on body segments (medial femoral epicondyle, medial malleolus, first metatarsal head, medial side of the prosthetic knee) and on the neck, thorax and posterior iliac spines were removed, because the former would have been likely to fall during the subsequent running trials and the latter would have been obstructed by the backpack and its straps.

The tests consisted of a series of sprints where the athlete started running from a line outside of the acquisition volume, accelerated to approximately 60% of her maximal speed (self-reported) and maintained this constant speed along the acquisition volume located 25 m from the start line. To avoid fatigue, the participant performed only three Steady State Running on track tests (TSSR).

D. Data analysis

Kinematic data were collected at 300 Hz. The labelling procedure was performed using Vicon Nexus 2.12 through an automatic algorithm. Subsequently, labelling was revised through careful frame-by-frame manual inspection to correct possible label swapping and gaps in the trajectories. Data were then low-pass filtered using a zero-lag fourth-order Butterworth filter with cut-off frequency equal to 10 Hz. Kinematic analysis was then carried out in MATLAB, with each body segment identified by a coordinate system (CS), i.e. an orthogonal triad defined through markers relative to that segment. The x-axis of the CS represented the anterior-posterior direction (pointing forward), y-axis the longitudinal direction (pointing upward) and the z-axis the medial-lateral direction (pointing rightward).

Ankle, knee and hip joint kinematics, as well as the prosthetic knee joint kinematics, were described by the orientation of the distal CS with regard to proximal CS using the Cardan angles. The sequence adopted was 'ZXY', except for the ankle angles, for which the 'ZYX' sequence was chosen instead. Trunk inclination in the sagittal plane was calculated as the angle – with respect to the vertical – of the vector joining

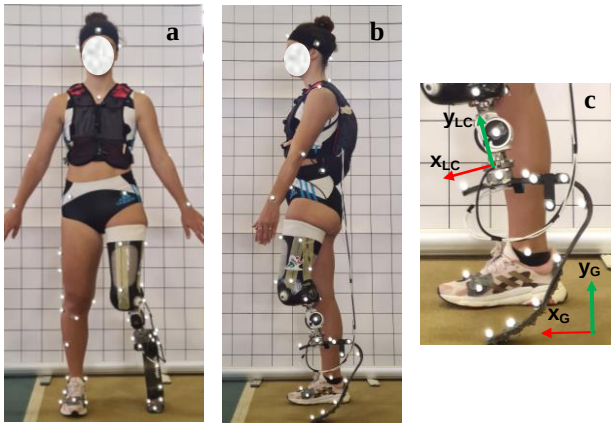

Fig. 2: 2a-b) Markerset adopted during the experimental session. Markers were applied on a headband worn by the subject, on arms, trunk, pelvis and right leg bony prominences and on the prosthetic components (socket, prosthetic knee, clamp and RPF). 2c) Detail of Load Cell coordinate system and ground coordinate system (sagittal view).

the centroid of the markers placed on the posterior iliac spines and the marker placed on the seventh cervical vertebra. The inclination in the sagittal plane of the unaffected shank (Theta Shank θ_S) and of the load cell installed in the prosthesis (Theta Load Cell θ_{LC}) were likewise calculated as the angle between the longitudinal axis of the segment and the vertical global axis. As far as shank is concerned, longitudinal axis corresponded to the anatomical axis, while for the load cell it was the normal to the sensor surface.

Reaction Forces at the load cell were collected at 2000 Hz, therefore they were downsampled to 300 Hz and synchronized to correspond to kinematic data. Next, kinetic data were filtered using a zero-lag fourth order low-pass Butterworth filter with cut-off frequency equal to 52 Hz, which was the optimal value chosen from the spectral analysis. Eventually, vertical and horizontal forces expressed in the reference system of the load cell (Fy_{LC} and Fx_{LC}) were resolved in the Ground reference system (Fy_G and Fx_G), by using the instantaneous orientation matrix of the load cell (Figure 2c).

Gait cycle events for the left leg were detected from filtered vertical force data, using a 5 N threshold, whereas for the right leg they were detected from the trajectory of the marker placed on the second metatarsal head, by identification of its minimum regions. Kinematic and kinetic data of each test were segmented into steps, averaged and normalized over the time of the right and left stride respectively.

Forward velocity was calculated as the distance divided by the elapsed time that the centroid of the pelvic cluster passed across the acquisition volume.

III. RESULTS

The results here provided are relative to the third test performed. Average speed over strides during this trial was 6.58 ± 1.12 m/s. Kinematic data are referred to both limbs, while kinetic data to the affected limb (AL) only, because in the unaffected limb (UL) neither force nor pressure sensors were used, and force platforms were not available.

A. Kinematics

The mean and standard deviation of lower-limb joint angles in the sagittal plane over stride time (5 strides AL, 4 strides UL) are reported in Figure 3, and analogous graphics were

obtained for joint kinematics in the transverse and frontal plane.

During stance phase (0-25% of stride time) UL hip extended from 40° until reaching maximum extension of -10° at toe off. During swing phase it flexed up to 90° and then extended rapidly in the terminal part of swing. AL hip behaved similarly to the UL hip, but at foot contact it was 55° flexed, then it extended until foot off, reaching 12° as maximum extension angle.

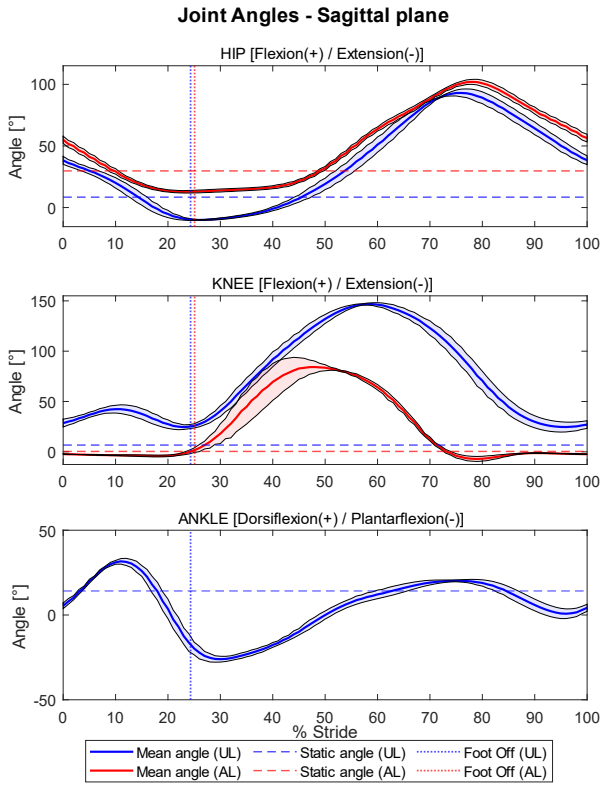

Fig. 3: Joint angles in the sagittal plane for hip, knee and ankle joint. Unaffected limb angles (mean ± 1 SD) are represented in blue and affected limb angles in red (mean ± 1 SD). Dashed horizontal lines represent the static angle (blue for UL, red for AL) and dotted vertical lines represent the average foot off instants (blue for UL, red for AL).

UL knee showed two periods of flexion, one during support and one during swing. Conversely, AL knee was completely extended during stance. The maximum flexion angle of the UL knee was nearly 60° higher than that of the prosthetic knee and it also happened later in swing.

The ankle joint was analysed for the UL only. Ankle was about 5° dorsiflexed upon foot contact, and then continued dorsiflexing rapidly to 31°. After midstance it plantarflexed and reached a maximum extension of -26° immediately after toe off. During the swing phase, ankle again dorsiflexed to 20°, and slightly extended prior to the next foot contact.

Figure 4a shows the trunk absolute inclination (positive forward). During AL support time the subject leaned forward, while during UL support time the trunk reduced its inclination. The total oscillation ranged from 3° to 18 °.

Figure 4b shows θ_S and θ_{LC}, i.e. the inclination of the shank (UL) and of the load cell (AL) normalized to the AL stride time. Despite the offset, the two angles had a similar trend and similar ranges. Both angles had an average excursion of 50° from foot contact to foot off, but while θ_{LC} (AL) increased from -25° to +25°, θ_S (UL) increased from +5° to +55°.

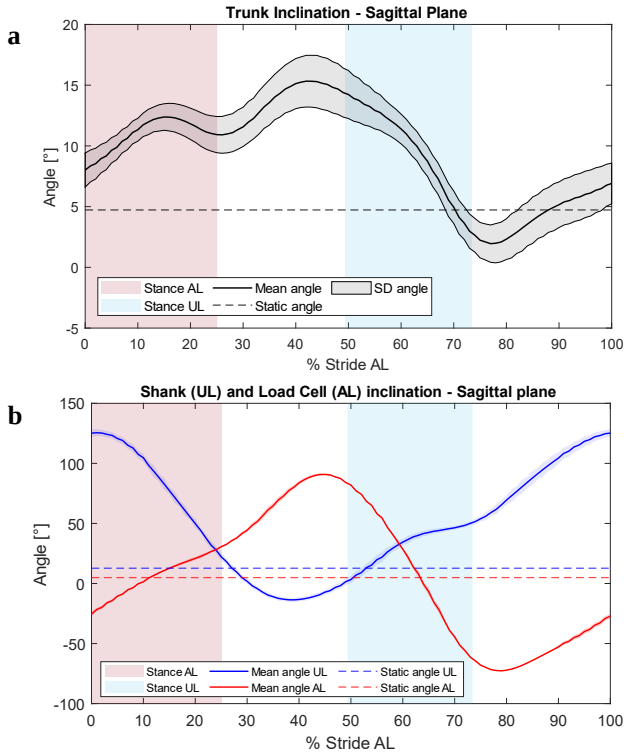

Fig. 4: Absolute angles in the sagittal plane of trunk (4a), shank and loadcell (4b) averaged and normalized over left stride time. Solid lines are the average angle during the running trial, horizontal dashed lines are the segments inclination in the static acquisition (black: trunk, blue: shank UL; red: load cell AL). Black shade in Fig. 4a is ±1SD relative to trunk average inclination. Red and blue vertical stripes represent the left and right stance time respectively.

B. *Kinetics*

Analysis of Reaction Forces (Figure 5) gave in output the average vertical and horizontal forces either in the Load Cell and in the Ground reference system. Vertical Forces, $F_{y_{LC}}$ and F_{y_G}, showed no relevant differences. They both peaked at nearly 3.5 N/BW, but in the second portion of the stance (40%-100%) F_{y_G} decreased more rapidly than $F_{y_{LC}}$. While horizontal Force $F_{x_{LC}}$ was always positive, F_{x_G} was negative until 50% of stance and then became positive. Just before the horizontal GRF changed from braking to propulsive, θ_{LC} turned from negative to positive.

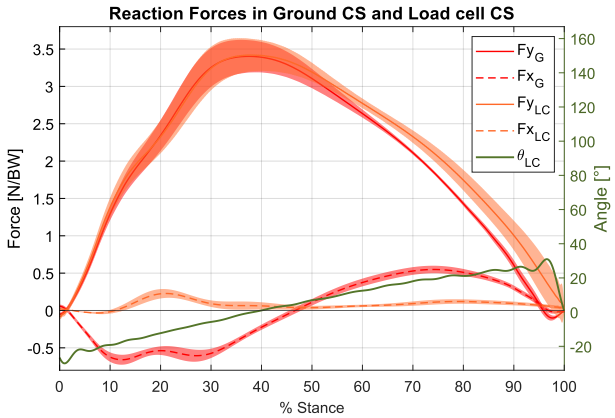

Fig. 5: Reaction forces measured by load cell averaged over 5 AL steps. Red lines represent the vertical (solid) and horizontal (dashed) forces in the Load Cell reference system (mean ± 1 SD). Orange lines depict the same forces projected onto the Ground reference system (mean ± 1 SD). Force values can be read in the left y axis, while the load cell inclination angle θ_{LC} (solid green) can be read in the right y-axis.

IV. DISCUSSION

With regard to sprinting kinematics, in literature there is little information on the joint kinematics of para-athletes with unilateral transfemoral amputation. The present work showed that AL hip is expectedly more flexed than UL hip during the entire stride: this is related to the alignment of the prosthesis adopted, which allowed AL hip to work in a more comfortable range [8]. Substantial differences can be highlighted by comparing the joint angles of UL and AL knee, as the former is a biological knee, while the latter is a mechanical knee. In fact, due to its intrinsic functioning principle, AL knee did not flex during the stance phase, whereas UL knee did.

Many studies in the literature report the asymmetry between the GRFs exerted by AL and UL, pointing out that the GRFs in AL are lower than that of UL [3],[4],[6],[9]. Although inter-limb GRFs comparisons cannot be made in the present work, as no information on forces on the UL is available, we can observe that vertical peak force for the AL approached 3.5 N/BW, which is consistent with AL values presented elsewhere [6]. However, these values are much higher than the AL peaks reported in previous studies [3],[4],[9], but differences could be ascribed to inter-subject variability and the higher running speed reached by the athlete during the present pilot test. Kinetic results also differ from those obtained during tests with the same athlete running on a treadmill. This could be due not only to the fact that the athlete ran at a higher running speed (6.6 m/s vs 5 m/s), but also to the better confidence of running on track compared to running on the treadmill [10].

In the next months, the athletics track used in the present pilot test will be equipped with nine force platforms installed on the sprint track and on the long jump track, and with ten motion capture cameras hanging from a moving support structure [11]. This configuration will allow for a more extensive data collection and subsequent comparison of multiple subjects.

V. CONCLUSIONS

This paper illustrated an experimental procedure to collect in vivo-indoor data during a pilot test of an elite Paralympic athlete running on a track. Mocap cameras and a wearable kinetic sensor installed in the RPF were used. Biomechanical analysis revealed differences between AL and UL joint kinematics and revealed high GRF values. These results could be useful for athletes and trainers in the fine-tuning of running strategy. However, it should be noted that this is a single case study, so the results will have to be confirmed by a larger analysis including more trials and more subjects, which will be carried out in the forthcoming months.

ACKNOWLEDGEMENT

The authors intend to thank the athlete and FISPES for their involvement in the study, INAIL for funding through the OLIMPIA project PR19-PAI-P4 and Comune of Padova for hosting the tests.

Abstract— Anomalous aortic origin of the coronary artery (AAOCA) can be associated with sudden cardiac death (SCD) usually related to physical effort. We aim to develop a patient-specific (PS) hemodynamic non-invasive tool based on clinical data to assess the coronary blood flow (CBF) in AAOCA and understand how the disease affects myocardial perfusion. A good correlation between CBF simulated and in-vivo measurements is demonstrated. Physiological changes will be integrated into the model to simulate different degrees of effort.

Keywords— AAOCA, coronary flow, lumped-parameter model, effort.

I. Introduction

AAOCA is a rare congenital disease that can cause sudden cardiac death (SCD) during physical effort. Our group has already developed a structural model that showed a limited expansion of the anomalous coronary artery (CA) during intense effort, particularly within the intramural tract [1]. Starting from this encouraging result our project aims to understand how this phenomenon affects myocardial perfusion computing coronary blood flow (CBF) at different effort conditions. Using multi-patient clinical data our goal is to develop a non-invasive computational tool to simulate CBF. We currently use a lumped-parameter model, its design, definition and first results are described in the following sections. A schematic representation of the work is presented in Fig.1.

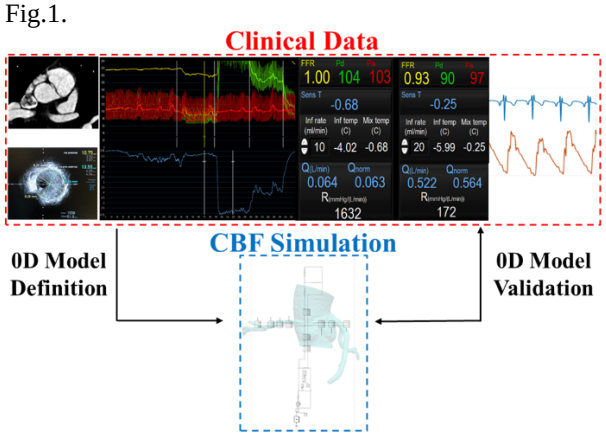

Fig. 1: Clinical data are used to define a PS 0D Model in order to assess the CBF. In-vivo measurements are used to validate the results of the model.

II. Materials and Methods

A. Clinical data and model definition

Multimodal diagnostic data are integrated to define a patient-specific (PS) lumped-parameter model to evaluate CBF under different hemodynamic conditions. The model describes each arterial segment as an electrical circuit (Fig. 2 A) whose components depend on the geometry of the vessel, its material, and blood properties [2]. Geometrical data to define electric parameters value is carried out from medical images. One of the project aims is to reduce the number of data retrieved from invasive procedures, for this reason, we test the model using both invasive and non-invasive imaging technique data. The aortic model and its parameters are calibrated using the measurements of computational tomography (CT) data, while the models of CAs are defined using both CT and intravascular ultrasound (IVUS) images, since our aim is to compare the accuracy of the model using different data sources.

B. Boudary conditions (BCs)

A PS pressure waveform is used as inlet condition (Fig 2 B). The aorta outlet is modeled with a Windkessel circuit (Fig. 2 C), whereas the CAs outlet is defined by a 6-elements circuit (Fig. 2 D) with an intramyocardial pressure source (Fig. 2 E). The total resistance of each outlet is split among circuit resistive parameters following the algorithm proposed by Sankaran et al. [3]. The total aortic resistance is evaluated with the patient's cardiac output (CO) and mean arterial pressure [3]. The total coronary resistance is defined during catheterization measurements under resting and hyperemic conditions. The left ventricular pressure (LVP) waveform is rescaled based on the PS data, the right one is evaluated as 20% of LVP [3].

To simulate effort, it will be required to integrate into the model changes related to coronary vasodilation mechanisms, increasing arterial pressure and heart rate. The first aspect we considered is related to vasodilator mechanisms that reduce peripheral coronary resistances. This variation is measured in vivo by inducing the condition of maximum hyperemia.

C. Statistical analysis

The CBF simulated values obtained with IVUS and CT images are compared with the Wilcoxon signed-rank test for paired data. Continue variables are expressed as median and interquartile range (IQR).

To study the correlation between CBF computed by the model and in-vivo measurements is used Kendall's τ coefficient. For

each comparison, the coefficient correlation value and the corresponding p-value are shown.

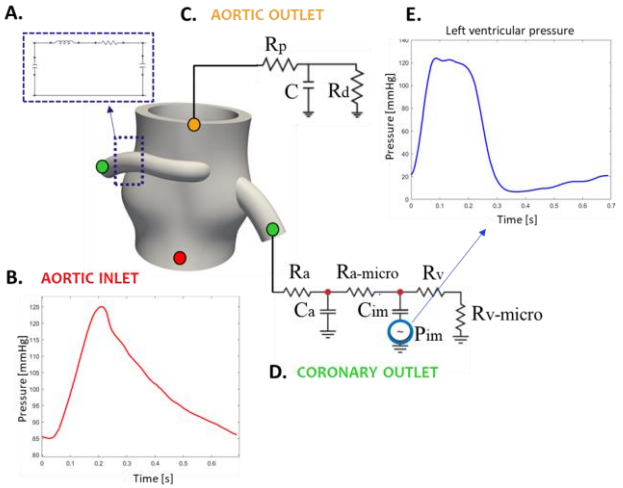

***Fig. 2*:** Schematic representation of the model: A) arterial segment circuit, B) aortic inlet pressure wave, C) aortic BC, D) coronary BC, E) LVP wave.

III. RESULTS

Resting and hyperemic conditions are simulated using data from 9 and 12 patients respectively. The simulated CBF are compared with in-vivo data to validate the numerical tool.

Considering in-vivo data the right median CBF value is 1.02(0.62) ml/s, the left one is 1.37(0.98) ml/s. Inducing vasodilatation hyperemic right and left CBF rise to 4.27(3.08) ml/s and 6.19(3.63) ml/s respectively. Considering the CBF simulated using IVUS to size the coronary circuits, results for resting condition are 0.92(0.62) ml/s at rest and 4.27(2.73) ml/s at hyperemia for right CA (RCA), 1.08(0.96) ml/s at rest and 6.27(3.62) ml/s at hyperemia for left CA (LCA). Using all geometrical data taken from CT, the CBF simulated results are 0.91(0.61) ml/s at rest and 4.39(2.84) ml/s at hyperemia for RCA, 1.08(0.99) ml/s at rest and 6.27(4.19) ml/s at hyperemia for LCA.

The results related to the two methodologies used to define the geometrical characterization of CAs are comparable (Fig. 3) and do not show significant differences (rest RCA p = 0.6523; rest LCA p = 0.3008; hyperemic RCA p = 0.7910; hyperemic LCA p = 0.6772). Both results are also well correlated with in-vivo measurements with statistical significance ($p<0.001$). The τ coefficient correlation values for the RCA and LCA are shown in Table I.

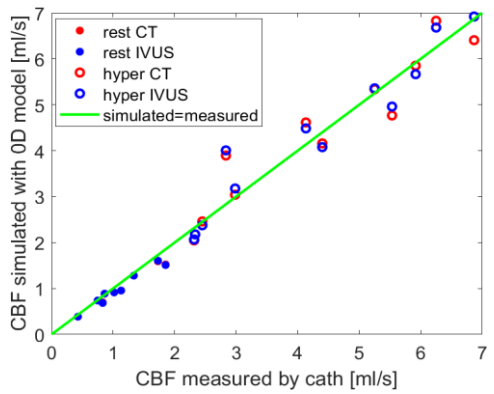

Fig. 3: 0D model results vs in-vivo measurements.

TABLE I: CORRELATION BETWEEN MODEL RESULTS AND IN-VIVO MEASUREMENTS

Hemodynamic condition	*comparison*	*side*	*τ*
Rest	In-vivo vs IVUS	RCA	0.8889
		LCA	0.7778
	In-vivo vs CT	RCA	0.8889
		LCA	0.8333
Hyperemia	In-vivo vs IVUS	RCA	0.9091
		LCA	0.8182
	In-vivo vs CT	RCA	0.8788
		LCA	0.7273

τ coefficient correlation value is presented for each comparison.

IV. CONCLUSION

The model is able to compute CBF in a non-invasive way with good accuracy. The results show a good correlation with in-vivo measurements in both hemodynamic conditions simulated: rest and maximum hyperemia. These first results suggest that our computational model could be a valuable tool to quantify myocardial perfusion in AAOCA allowing us to replicate conditions that cannot be reproduced during catheterization or clinical exams.

We plan to include physiological changes for stress simulation. We aim to define a relation between the coronary peripheral resistance changes and the magnitude of effort simulated. Furthermore, we want to integrate this relation with an algorithm to analytically calculate the rest values of coronary resistances. In-vivo measurements will allow us to validate the tool. In this way, we will reduce the number of PS data to have a non-invasive model to assess CBF in AAOCA without losing accuracy.

To study the impact of IM tract in effort simulation we will use the results of corresponding structural analysis to include in the model the percentage of IM tract narrowing at each degree of effort.

In future work, we could study a more complex and realistic fluid-structural interaction (FSI) between the IM tract and CBF through a PS 3D FSI simulation.

ACKNOWLEDGMENT

The project was supported and funded by the Italian Ministry of Health (GR-2019-12369166).

***Abstract* — The abdominal aortic aneurysm (AAA) is one of the most frequent aortic wall pathologies and it is defined as a local dilation of the vessel, typically more than 50% of the physiological diameter. When surgical intervention is needed, AAA can be treated by a minimally invasive technique, endovascular aortic repair (EVAR). EVAR is becoming established as the primary treatment for AAA, given the high short-term success of the procedure. EVAR consists of placing a self-expandable device - called stent-graft (SG) - into the diseased aorta to restore the original lumen. In particular, the device is crimped and placed into a catheter; the catheter is inserted through the femoral artery into the patient and is delivered to the aorta; once the correct position is reached, the catheter is withdrawn, and the SG expands.**

Some studies are present in the literature adopting the finite element analysis to predict the SG behaviour after implantation and its interaction with the aortic wall.

This work aims at recreating stent-graft models similar to commercial ones including both the SGs main body and additional limb extensions and developing a methodology to replicate the EVAR procedure in patient-specific anatomy.

***Keywords* — stent-graft, in silico, FEA, AAA.**

I. INTRODUCTION

THE abdominal aortic aneurysm (AAA) is a localized enlargement of the abdominal aorta such that the diameter is greater than 3 cm or more than 50% larger than nominal. It is a potentially life-threatening condition, as it usually causes no symptoms, except during rupture [1]–[3]. Surgical intervention should be considered when the aneurysm diameter 55 mm, or in the case of rapid growth (>10 mm per year) [2], [4]. In that case, aneurysms can be treated either by open surgery or by an endovascular minimally invasive technique. The minimally invasive technique, called EVAR (endovascular aortic repair), is becoming the primary treatment choice for AAA and consists of placing a self-expandable stent-graft (SG) into the diseased aorta to restore the original lumen [5]. [6]. In particular, the device is crimped and placed into a small delivery system, the catheter. The catheter is then inserted through the femoral artery of the patient, and it is delivered to the aorta; once the correct position is reached, the catheter is withdrawn, and the SG expands [7]. The SG is composed of the stent, a metallic structure, usually made of Nitinol (Nickel-Titanium alloy) or Stainless steel, sutured to the graft, a fabric typically made with either polytetrafluoroethylene (ePTFE) or polyethylene terephthalate (PET)

Despite the high short-term success, the risk of late-onset complications (16-30% of cases [8]) is still present. When a persistent blood flow perfuses the pathological region, endoleaks occur, increasing the risk of rupture of the vessel. Endograft migration is another complication, defined as a SG displacement of 5-10 mm from its original fixation. This could result in endoleaks, and eventually aneurysmal rupture [8].

The Finite Element Analysis (FEA) is largely adopted in the literature to predict the structural behaviour of the SG and the aorta after the EVAR procedure and different approaches are present [9]. In the *virtual shell method* [10], [11] a tubular shell is placed around the device and then morphed to reach the vessel anatomy of the patient. In the *direct placement method* [12], [13] the stent-graft is placed within the patient's aortic lumen through a 3D morphing algorithm. Other studies [14], [15] followed the *virtual catheter method* in which the stent-graft is crimped, deformed by a cylindrical catheter, placed along the vessel centerline and then expanded by removing the catheter. Ramella et al. [16] developed the *tracking method* for the thoracic endovascular aortic repair, in which the stent-graft is crimped into a catheter, displaced along the vessel centerline and then gradually released in the desired aorta landing zone.

In this study CAD models of typical commercial SGs are recreated including both the main bodies and iliac extensions. Then, the *tracking method* is applied to model the EVAR procedure in a patient-specific abdominal aorta replicating both the main body and iliac extension insertion and deployment.

II. MATERIALS AND METHODS

A. Stent-graft CAD models and discretization

For the purpose of the study, two SGs were considered. The SGs are composed of a main body with two leg bifurcations and additional iliac components. The main body in SG1 has a longer ipsilateral leg with respect to SG2. Also, while for SG1 only a straight iliac extension was considered, the SG2 comprised two iliac extensions, a straight and a tapered one. They are suprarenal fixating as the proximal suprarenal stent ring extends above the graft proximally, ensuring the device fixation at the level of the suprarenal arteries.

The CAD modelling procedure to create the SGs main bodies and iliac extensions was performed in SolidWorks (Dassault Systèmes). Considering the stent struts, four types of shapes were identified: Suprarenal, V-type, W-type and

Regular W-type (Fig. 1.a). All the measurements related to the SGs such as diameters, lengths and cross-sections and graft thickness were collected from the literature [17]+(A). Complete models of the two SGs are reported in Fig. 1.b.

The SGs discretization process was performed in ANSA (BETA CAE). The stent rings were discretized using linear two-node beam elements. After a mesh sensitivity, an element size of 0.8 mm was selected. As regards the graft, a free mesh was constructed in ANSA using triangular shell elements with an average length of 0.8 mm and thickness of 0.1 mm (Fig. 2.a). The total number of nodes in the stent and graft for both SG main bodies and iliac extensions is reported in Table I.

The stent and graft in the real device are joined together by some suture points. As they were not directly included in the model, a node-to-node connection between the stent and graft meshes was defined to model the sutures between the two.

Nitinol shape memory material formulation for the stent and a fabric material formulation for the graft were adopted. Details on material parameters can be found in Ramella et al. [16].

TABLE I: NUMBER OF NODES IN THE STENT AND GRAFT FOR EACH STENT-GRAFT COMPONENT

SG component	*#nodes in the STENT*	*#nodes in the GRAFT*
Main body SG1	2464	13297
Main body SG2	2885	10797

B. *Aortic model*

Starting from clinical CTA images provided by Azienda Ospedaliera Universitaria di Parma (Italy), a patient-specific model of the aorta was reconstructed through an image segmentation process using the software VMTK (Orobix srl.). The aorta presents an aneurysm in the abdominal region.

The vessel model was discretized using triangular shell elements, with an average target length of 0.8 mm and a thickness of 1.8 mm was assigned [18] (Fig. 2.b). It was modelled as a rigid material as the focus of the methodology is on the SG deployment steps.

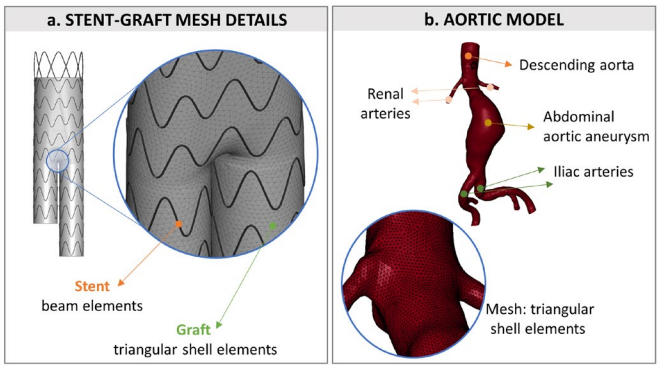

Fig. 2: (a) stent-graft mesh detail; (b) aortic model and mesh detail.

C. *EVAR Finite Element simulation set-up*

During the clinical procedure, the SG is crimped inside a catheter, inserted into the patient through the femoral artery and released into the aorta. As the numerical simulation has to mimic the surgery, these three main steps were simulated starting from the *tracking method* [16] and modifying it for the category of SGs used in the abdominal EVAR procedure.

The EVAR tracking simulation comprises three steps: (1) SG crimping, (2) SG tracking, and (3) SG deployment. In particular, as the SGs included two (SG1) or three parts (SG2), firstly the SG main body was implanted and then the iliac extensions. However, for each component, the simulations follow the three steps listed above.

The two input files (one for SG1 and one for SG2) were created in LsDyna (ANSYS) and included the following parts, as depicted in Fig. 3.a:

- SGs main body and iliac extension meshes;
- SG crimping cylinder was used to perform the device component crimping before the insertion into the femoral arteries.
- Patient-specific rigid aortic model fixed in space.
- Aortic centerlines, which represent the paths for the SGs and extensions displacement in the tracking phase.
- SG catheter, which maintained the SG crimped during the tracking into the aorta. The catheter was modelled as a rigid cylinder morphed on the aortic centerline.

Steps of the simulations for one main body and one iliac extension were reported in Fig. 3.b. In particular, in the first step of the simulation (*crimping phase*), the device was crimped by a cylinder up to a diameter of 10mm. Then, during the *tracking phase*, displacement boundary conditions were imposed on the most proximal stent ring (e.g., suprarenal ring in the case of the SG main body) to displace the device along the vessel centerline within the catheter until the desired landing zone is reached. Lastly, in the *deployment phase*, the SG was gradually released and expanded into the vessel lumen.

During the simulations, soft penalty-based contacts were defined between the SGs and the catheters, between the SGs and the aorta, between the main body legs and between the main body leg and iliac extensions.

For all the simulations, damping was imposed on the stent and graft with a factor equal to 1 ms^{-1} during the crimping, to 0 ms^{-1} during the displacement, and to 5 ms^{-1} during the deployment [16].

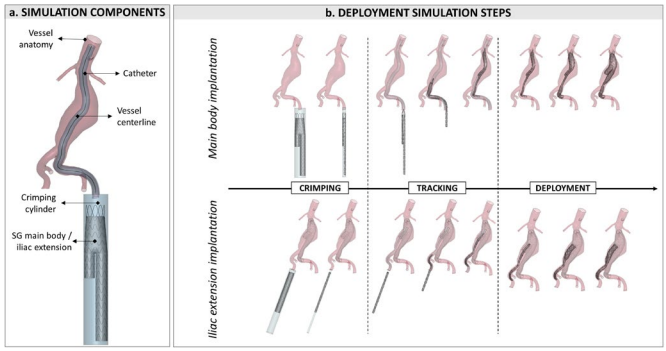

Fig. 3: (a) lists of components involved for the FE simulation; (b) three main steps of the EVAR simulation for the main body and one iliac extension of SG1.

Simulations were run on 20 CPUs with 120 GB of RAM, with a timestep equal to 0.009 ms.

The simulation results were analysed in terms of qualitative deployed configurations, the distance between the SGs and aorta, the maximum principal strain on the graft, and von Mises (VM) stress distribution in the stent and graft.

III. RESULTS

Fig. 4 reports the SGs main bodies and iliac extension deployed configurations.

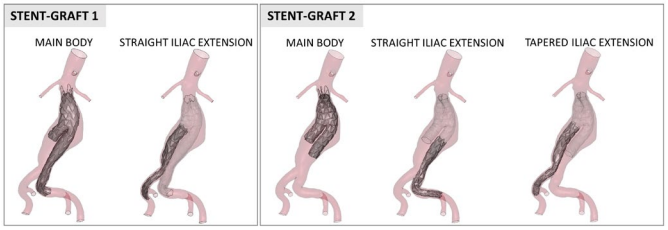

Fig. 4: Main bodies and iliac extensions deployed configurations for the two stent-grafts models

The distance between the device and the vessel is plotted on the aorta (Fig. 5) blue means the SG is completely in contact with the aorta. The distance increases in the aneurysmatic region.

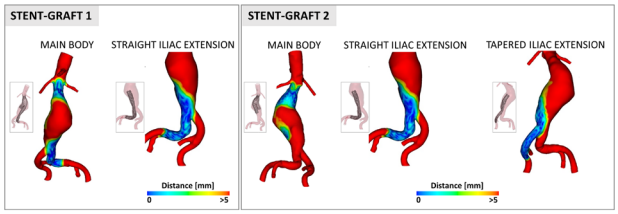

Fig. 5: Distances between the aorta and the main bodies and iliac extensions for both stent-grafts plotted for the vessel.

Maximum Principal Strains are shown in Fig. 6.a. The grafts (both the main body and iliac components) do not fully recover their initial configuration: some folds are present as the vessel has a lower diameter with respect to the initial configuration of the SGs due to the device oversizing. The strains reach higher values in the proximal aortic neck and in the two iliac bifurcations where the vessel is more tortuous and narrower.

Fig. 6.b report the VM Stress distribution on the grafts. The stress is higher in the regions where the grafts are in contact with the vessel, and in the portion of the graft close to the connection with the stent struts. Stresses and strains increase in the main bodies legs after the iliac extension implantation in the overlapped regions (not shown in the figures).

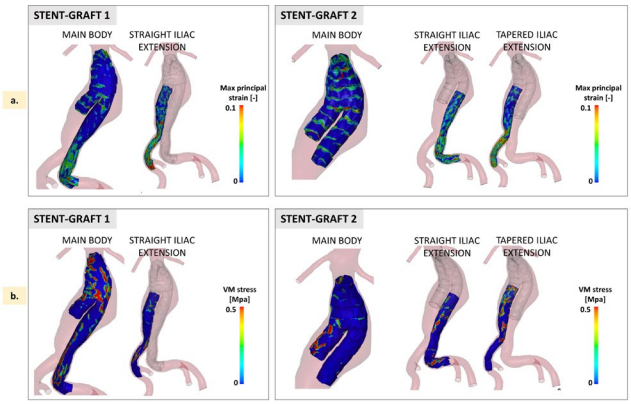

Fig. 6: (a) Maximum principal strain [-] and (b) Von Mises stress [MPa] in the graft of the main bodies (before iliac implantation) and iliac extensions for both stent-grafts.

Fig. 7 reports the VM Stress distribution in the stent struts. In all the configurations, stresses are higher in the regions where the stents are in contact with the vessel (abdominal aortic neck and iliac bifurcations) and in more tortuous regions (e.g., iliac bifurcations). In the aneurysmatic region, stresses are close to zero, as the stent struts have almost completely recovered their original stress-free configuration.

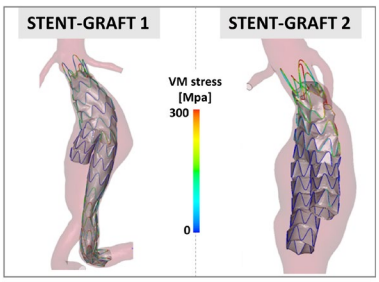

Fig. 7: Von Mises stress distribution in the stent struts for both stent-grafts main bodies.

IV. CONCLUSION

The developed numerical methodology allows simulating the EVAR procedure for the treatment of abdominal aortic pathologies, such as aneurysms. EVAR is a minimally invasive procedure that aims at restoring the physiological fluid dynamics in a pathological vessel by introducing a SG in the interested region [8].

Numerical simulations play an important role in pre-clinical planning to predict the biomechanical interaction between the SG and the aorta [19]. For example, in a pre-procedural patient-specific planning phase, the correct model and size of the device, as well as its positioning into the patient's vessel, can be optimized through FEA.

The present study aims at applying a previously validated methodology – specifically developed for the TEVAR technique – to model the EVAR procedure. Different from other literature methods [9], [11]–[13], the proposed strategy replicate the steps of the real clinical procedure considering also the crimping and gradual release phase for both the main bodies and iliac extensions implantations which could have a major impact on the success of EVAR.

The modelled devices are similar to two commercially available SGs. Both are composed of Nitinol stent rings sutured to a PET graft. To simulate the procedure, finite element domains of the devices were created. A patient-specific aortic model was segmented from clinical CTA images and then discretized. The structural simulation consisted of the following phases: crimping, tracking, deployment of the main body SG into the aorta, and iliac extension implantation. In the first two phases, the main body is crimped and displaced in the correct position of the vessel. During the deployment, the main body is gradually released, entering into contact with the abdominal aorta. During the iliac extension implantation phase, the previous three steps are replicated to implant the additional iliac components within the corresponding main body legs.

This study is not free from limitations. The SGs used in this work were similar to commercial ones but do not include all the peculiarities often found in abdominal SGs as the anchoring hooks, and they were modelled with geometries and materials taken from the literature. More accurate models of commercial SGs can be realized and validated with experimental tests. Also, a rigid aortic model was considered as the focus of the work was on the SGs implantation during EVAR. The EVAR simulation itself might be validated with an ad-hoc experimental set-up as proposed in Ramella et al. [16].

Despite the simplifications, after proper validation, the obtained results can be generalized to any size of a stent-graft and patient-specific deformable anatomies reconstructed from clinical images can be easily adopted for pre-procedural planning, device optimization or, in the future, in-silico clinical trials.

Abstract- Running Prosthetic Feet (RPF) enable athletes with lower limb amputation to compete in track races. Both Ground Reaction Forces (GRFs) and kinematics analyses allow evaluating running performance but they are seldom measured together. This work aims to compare kinematic and kinetic biomechanical parameters of an elite amputee Paralympic sprinter in a pilot feasibility study. Tests were performed on a commercial treadmill placed on four force platforms. Two conditions were tested: Steady State Running (SSR) and Resisted Accelerated Running (RAR). SSR results show that unaffected limb (UL) vertical GRF was 70% higher than affected limb (AL). Differences in trunk, hip, knee, and ankle angles were observed both between AL and UL sides (e.g., knee extension during stance), and between SSR and RAR tests (e.g., trunk inclination). Results obtained could be helpful to trainers to improve overall sprinting performance.

***Keywords*— running prosthetic feet, ground reaction forces, kinematics, treadmill.**

I. INTRODUCTION

Since the introduction of Running Prosthetic Feet (RPF) the interest in studying sprinting biomechanics of Paralympic athletes has grown. Indeed, RPFs enabled many athletes with leg amputations to compete with nonamputees in track races [1] On this matter, some authors speculated about a possible advantage in performance when using RPF vs biological legs. However, a debate is still open about this possibility [2], and further studies regarding amputee's sprinting biomechanics and adaptations are ongoing. This knowledge will allow specific rehabilitation and training strategies, as well as developments in prosthetic devices to be objectively evaluated. Kinematic alterations between sound and prosthetic limbs result from using RPF. Findings suggest that in case of transtibial amputation prosthetic could have similar behaviour of the intact one [3]. Conversely, in case of transfemoral amputations affected limb is considerably different compared to the sound limb or able-body subjects [3].

About Ground Reaction Forces (GRFs) authors reported a significant difference in average vertical GRF production between intact and prosthetic limbs among elite sprinters with lower limb amputations [4], [5]. In the above studies, affected side has lower GRFs than the intact one.

Differences in force production and joint kinematics between prosthetic and intact limbs in sprinters with unilateral transtibial amputations are due to the lack of the ankle joint [6].

The current research aims to better understand sprinting biomechanics and improve racing performance. As well known, during sprinting athlete accelerate their body forward to develop velocity in the shortest possible time. Speed is dependent upon a number of factors which include technique and force production capability, in particular lower limb musculature. Moreover, sport scientists have observed that one the most effective way to improve the overall performance is through resisted sprinting training which is usually done on track [7]. Pairing instrumented treadmill and motion capture system allows to measure GRFs and kinematics. However, treadmill was usually used to perform SSR only, while little was done to implement RAR tests.

The aim of this work is to perform a feasibility study on an elite amputee Paralympic sprinter, comparing GRFs and kinematics during SSR and RAR tests performed on treadmill.

II. METHODS

A. Participants

A female, gold medallist, elite Paralympic sprinter with unilateral transfemoral amputation was recruited for this study. The athlete (mass: 55 kg, height: 1.60 m) used Ottobock 1E91 standard RPF Cat. 3.5, mono-axial Ottobock 3S80 knee, and a specific alignment of the socket and the foot [8]. In this case the angle between socket axis and the axis passing through grand trochanter and knee joint centre was 15°.

During all tests the subject wore a safety harness.

B. Experimental Procedure

Tests were performed in a laboratory using a commercial treadmill (SkillRun Technogym) placed on four force platforms (BTS P6000- acquisition rate 1000 Hz). Kinematics was measured using a BTS motion capture system composed of eight infrared cameras (DX-6000, acquisition rate 250 Hz). This setup, as evaluated in [9] could give reliable results as concern SSR GRFs measurements compared with literature.

In this session two type of conditions were studied: Steady State Running (SSR) and Resisted Accelerated Running (RAR).

SSR was performed on the treadmill and consisted in reaching a self-selected constant speed and maintaining it for 7 seconds, time necessary to acquire at least six consecutive steps of each limb. The speed reached during this session was 5 m/s.

As regards RAR, athlete reached a steady speed of 3.11 m/s starting from zero. During RAR the treadmill motor was switched off to simulate passive inertial and air resistance. A load cell (FS 1000 N, acquisition rate 1000 Hz) was fixed to athlete's back through a pre-loaded elastic band with elastic constant K=120 N/m to measure the instantaneous resistance applied to the harness at the sacrum bone. In Figure 1 a schematic representation of both configurations is shown.

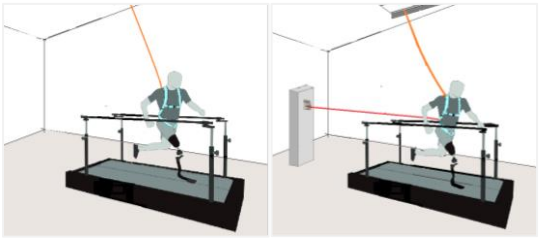

Fig. 1: Schematic representation of SSR (left) and RAR (right).

GRFs analysis

GRFs were collected at 1000 Hz and filtered to remove noise in input. After a spectral analysis of the GRF signal, a zero-phase low-pass Butterworth filter (15 Hz cut-off frequency, second order) was applied to data. Foot-contact and toe-off were detected using a threshold of 100 N on the filtered vertical GRF. For both SSR and RAR tests, GRFs obtained are in ground coordinate system: X- anterior posterior axis pointing forward; Y- vertical axis pointing upward; Z- medial lateral axis pointing rightward.

In the SSR test average curves of GRF_X and GRF_Y of the last 6 consecutives steps for each limb were collected.

In the RAR test, we focused on the acceleration phase and only the first 10 consecutive steps for each limb were considered, starting from the first ground contact of the prosthetic side at the beginning of the running phase. Therefore, to analyse acceleration phase we have considered for each limb 3 steps: one at the start, one during the acceleration, and one at the end. Indeed, from the 10th step onwards, the acceleration became considerably lower and a steady state running was achieved.

C. Kinematics analysis

During tests passive markers were applied to athlete's anatomical landmarks. The full marker set was composed of 56 markers: 23 applied on the upper part of the body, 4 on the pelvis and 33 on the lower part of the body.

The goal of the kinematics analysis was the calculation of Cardan Angles of hip, knee and ankle joints. The sequence used was *'ZXY'* for hip and knee, while *'ZYX'* for foot, considering X- anterior posterior axis pointing forward, Y- longitudinal axis pointing upward, Z- medial lateral axis pointing rightward. For the sound limb hip, knee and ankle Cardan angles were calculated after defining each relative coordinate system. Conversely, for the prosthetic limb, hip and knee joint angles only were calculated. Hip angles were obtained considering the rotation between pelvis and socket, while knee angles were calculated from rotation between socket and foot.

In the SSR test average curve of joint angles of the last 6 consecutive steps for each limb were calculated. In the RAR test, joint angles of the first 10 steps were presented for both limbs.

Finally, to better understand sprinting technique and athlete position during tests, trunk angle was calculated. This angle was obtained considering inclination in the sagittal plane of the segment joining 7th cervical vertebra to midpoint of posterior superior iliac spines with respect to global vertical axis.

III. Results

A. GRFs results

In Figure 3, GRFs average curves of affected (AL) and unaffected (UL) limbs are shown as percentage of stance for SSR test. GRF_Y peak values are of 4.43 N/BW and of 2.60 N/BW for UL and AL, respectively. As concern $GRFs_X$ UL has mainly a braking effect, while AL is mostly propulsive.

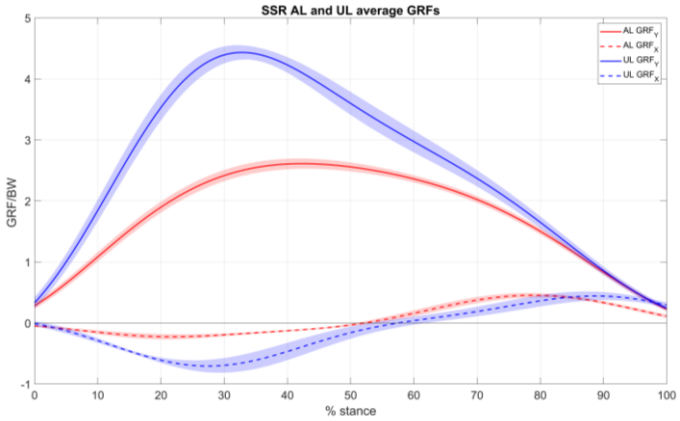

Fig. 3: Average GRFs curves for AL and UL during SSR test

In Figure 4, GRFs from RAR test are shown for three steps of the acceleration phase: 1st, 5th and 9th for AL and 2nd, 6th and 10th for UL. GRF_Y peak values are greater for UL, rather than AL. It could be observed that UL GRF_Y peak values increase from 2nd to 10th step. As regards GRF_X, during the acceleration phase: the braking phase is almost zero for both limbs, and the athlete was pulling an average of 0.185 N/BW on the rope.

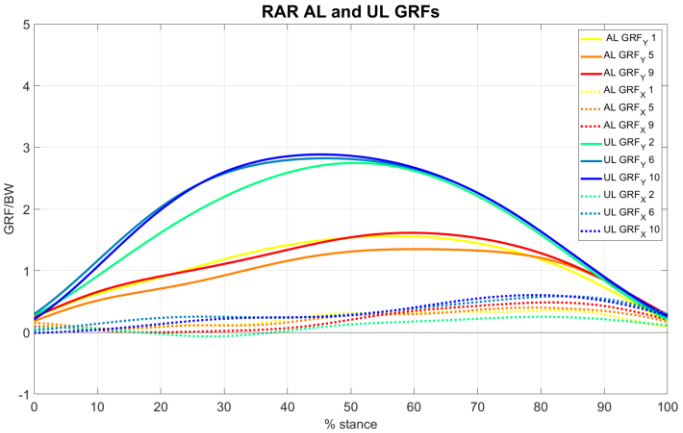

Fig. 4: GRFs curves of three steps for AL and UL limbs during RAR

Table 1 reports spatial-temporal parameters during the acceleration phase for all the steps analysed. The athlete started to run at 1.00 m/s and at the 10th step she reached a speed equal to 80 % of her maximum velocity. As concerns stance time, it could be observed that for both limbs it decreased at increasing speed. AL stance times were higher

than those of a consecutive UL step (51 %, 40% and 27 %, respectively).

TABLE I: SPATIAL-TEMPORAL PARAMETERS DURING ACCELERATION PHASE

Step	*Side*	*Speed [m/s]*	*Stance time [s]*
1	AL	1.00	0.236
2	UL	1.15	0.156
5	AL	1.69	0.216
6	UL	1.82	0.152
9	AL	2.19	0.188
10	UL	2.29	0.148

B. Kinematics results

In Figure 5, joint angles of both limbs are presented as percentage of stride. For what concern hip angles, it could be observed that AL has a greater flexion angle during stance, rather than UL. At foot off AL hip angle is slightly extended, but considering the initial contact angle, the range of motion varies during stance. Regarding knee angles, differently than UL, the prosthetic knee keeps in extension during the whole stance phase. Indeed, if otherwise, the sprinter would have fallen. Conversely, biological knee is in flexion along the entire stride. Trend shows two flexion peaks: one during stance and one during swing. For the ankle joint only the unaffected limb is presented. During the initial contact with the ground the foot is in plantarflexion and then changes
into dorsiflexion until foot off, where it is again in dorsiflexion.

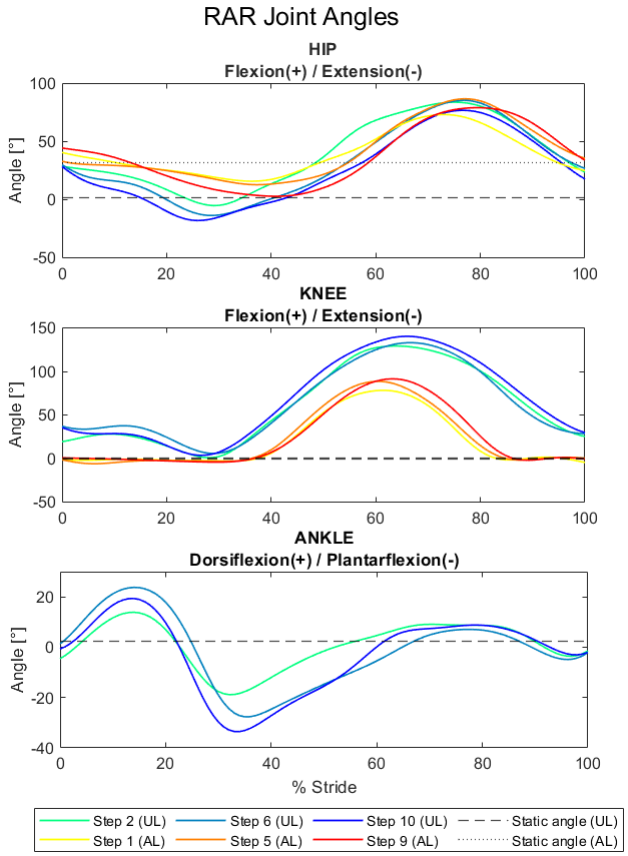

Fig. 5: Joint angles of AL and UL during SSR

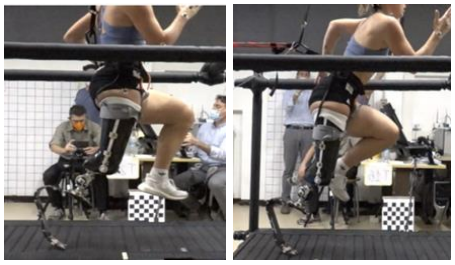

Fig. 7: Trunk inclination during SSR (left) and RAR (right)

Figure 6 presents joint angles of RAR test. As for GRF analysis, we have focused on some steps of the acceleration phase. Regarding hip angles, it could be seen that moving from the first step to the last one, for each limb the range of motion increases. Angles become more and more flexed during the acceleration phase. With reference to knee angles, it is possible to observe that the mechanical knee shows little variability between steps. Its range of motion is different from that of the unaffected one. During swing phase mean values of knee flexion are about 130° and 83° for UL and AL, respectively. Ankle angles presented are referred only to the UL. Ankle range of motion varies from step 2nd to 10th: it increases both in swing and stance phases.

Finally, trunk angle is calculated for both configurations: SSR and RAR. For SSR trunk angle is about 10.92°±2.8°, while for RAR is about 36.5°±2.63°. During RAR trunk is more inclined as shown in Figure 7. Indeed, it is well known that to reach higher speeds athlete propels the body forward.

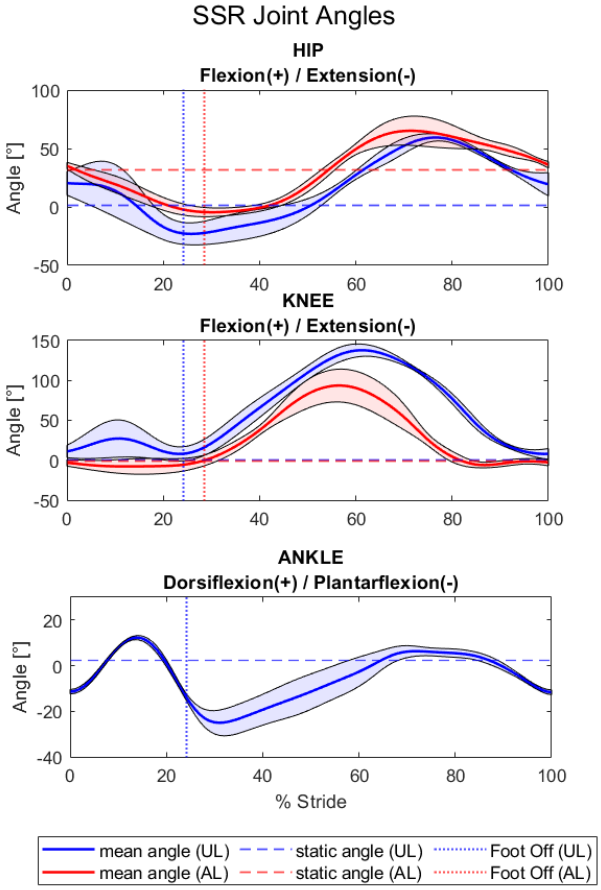

Fig. 6: Joint angles of AL and UL during RAR

IV. Discussion

Biomechanical analysis of GRFs and kinematics is necessary to better understand running technique and help trainers to improve athletes' performance. Concerning differences in GRFs between RAR and SSR, it could be observed that for both limbs vertical GRFs are higher for UL, consistently to previous findings[10], [11]. About horizontal GRF, in RAR no braking phase was present. As expected, during the acceleration phase the athlete needs propulsion to increase the running speed. In RAR test, stance time decreases as speed increases, accordingly with literature [6].

As regards kinematics, the main difference between AL and UL is knee angle. For both tests, during stance, prosthetic knee is always extended, unlike a biological knee where a small flexion occurs [3]. When comparing RAR and SSR tests, main difference regarding knee joint, is that the angle at foot contact is higher in the former case. This different behavior that we measured, agrees with literature which states that knee flexion at foot strike is greater during acceleration rather than maximum velocity sprinting [7]. We would like to verify with further tests if the two conditions are ideally represented by RAR and SSR performed on our instrumented treadmill.

In both tests performed, AL hip is almost entirely in flexion. Indeed, during sprinting as body's center of mass lowers, hip, knee and ankle flexion increases [3]. As observed during RAR trial, hip angles at foot strike keeps constant as speed changes [7].

About differences in kinematics found between SSR and RAR tests, a noticeable change was found in trunk inclination. Coaching observations suggest that during the initial stages of acceleration the body should be at an angle of 45°, compared to 36.5° that were measured in the present work. Then, as sprinter's velocity increases, the body become more upright [7]. Another difference regarded ankle joint, it could be observed that during SSR and RAR ankle angle has different values at foot strike. In SSR foot is more plantarflexed than in RAR. This may be related to trunk position; the more the trunk is inclined the more the foot is dorsiflexed. Results obtained during treadmill session will be compared with those obtained in track [12].

V. Conclusions

The aim of the present work was to compare GRFs and kinematics during SSR and RAR tests of an elite amputee Paralympic sprinter. Results confirmed that in both tests AL and UL have different behaviour. At the same time, analysis evidenced differences between the two configurations studied: SSR and RAR. However, the presented work is a case study and further tests are needed to perform an inferential statistical analysis and draw general conclusions on the observed data.

***Abstract*—The shoulder is widely considered as a complex system characterized by peculiar biomechanics and involving different joints, including glenohumeral one. Indeed, the inherent shoulder structure allows for high mobility, but at the same time - in case of injuries, traumatic events, or pathologies – the overall structure is easily exposed to articular and periarticular problems.**

Scientific literature presents several procedures devoted to the functional evaluation of shoulder complex, including - above all - movement analysis and assessment of muscular contribution. In the last years, ultrasonography has been also proposed to quantitatively assess anterior humeral head displacement, which represents an important metrics for shoulder dislocation.

The aim of this study was to present a non-invasive multidimensional testing procedure aiming at assessing the function of the shoulder complex, specifically focusing on the glenohumeral joint.

The proposed setting included the integration of marker-based optoelectronic stereophotogrammetric system, surface electromyography, and ultrasonography, so as to allow an instrumental evaluation able to provide information about overall kinematics, muscular activations and synergies, and joint tissues constraining behaviour in terms of humeral head displacement. In this feasibility analysis the subjects were asked to execute two specific dynamic tasks, which overall covered glenohumeral joint movements.

From this feasibility study, the proposed protocol allowed indeed to have information about the overall joint kinematics in terms of flexion/extension, abduction/adduction, and intra/extra-rotation, the corresponding muscular activations and, above all, the possibility of tracking the humeral head displacement.

All the available information record may enhance the possibility to identify altered patterns in shoulder biomechanics. This multidimensional approach may be used to help clinicians characterizing the glenohumeral joint during defined motor tasks and thus designing tailored rehabilitative interventions for the shoulder joint complex.

***Keywords* — Human motion analysis, surface EMG, Ultrasonography, Shoulder complex, Glenohumeral joint**

I. Introduction

The global range of motion of the arm is the result of a coordinated motion of the shoulder complex including glenohumeral (GH), scapulothoracic, sternoclavicular and acromioclavicular joints [1]. Evidence suggested that individuals with shoulder disorders present abnormal kinematic patterns and weakness in muscles activations [2]. As reported by Lucas et al. [3], shoulder pain presents an important incidence in the general population, up to 55.2%, and a prevalence of from 7.7 to 62 per 1000/persons year.

In general, to track the movement of the humerus and scapular joint angles, marker-based optoelectronic stereophotogrammetric systems are the most adopted [4,5]; indeed, this technology – by exploiting infrared reflective markers applied directly on the skin of the subjects – represents the state-of-the-art for non-invasive investigations of shoulder kinematics [6]. However, kinematics reflects only a part of the shoulder biomechanics. In this frame, surface electromyography (EMG) has been demonstrated to be an accurate, reliable, and non-invasive method to measure muscle activity and muscle timing of superficial muscles as, for instance, in the scapulothoracic joint [7].

However, the clinical evaluation of shoulder function is challenging because of the complex three-dimensional (3D) movement realized and the presence of surrounding soft tissues, which prevent – for instance - a reliable measurement of glenohumeral joint behaviour.

To overcome these limitations, shoulder biomechanics has been explored by in vitro cadaveric studies and in vivo magnetic resonance imaging (MRI), fluoroscopy, and computed tomography (CT) [8–10]. In these contexts, the imaging technique allows the accurate estimation of the translation of humeral head in different arm positions, which is indeed important to support clinicians in the functional evaluation. Furthermore, ultrasonography has been reported to enable the assessment of glenohumeral joint, without any invasion or radiation exposure; for instance, Inoue et al. [11], measured the translation of the anterior humeral head by ultrasound measurements, statically, at various shoulder abduction angles.

Although most of the realized imaging studies on GH joint provided accurate assessment of bone-bone relationships, they were not focused on depicting the overall movement characteristics, being mostly static techniques with a limited volume of acquisition [12]. On the other hand, most of the shoulder pathologies present important dynamic components, which must be highlighted during clinical examination [13].

Therefore, in this paper we preliminary presented an original evaluation protocol addressing shoulder function in a multidimensional perspective through the integration of different technologies, i.e., marker-based stereophotogrammetry, surface electromyography and ultrasound imaging; in this way, we hypothesized to obtain reliable information related to different characteristics of shoulder biomechanics during the execution of dynamic tasks, including kinematics, muscular activations and humeral head displacement.

II. MATERIALS AND METHODS

The proposed protocol included the exploitation of different technologies able to provide information about joint kinematics, muscular activations, and humeral head displacement.

A. Kinematics

In our feasibility study, the kinematics of the glenohumeral joint were acquired by using a marker-based stereophotogrammetric optoelectronic system (SMART DX 400; BTS Bioengineering), which consisted of 10 infrared cameras detecting the position of thirteen reflective spherical markers placed on subject's skin at a sampling rate of 100 Hz. The proposed protocol contemplates that the markers are positioned on the subject's dominant arm following the recommendations of the International Society of Biomechanics (ISB) [14], in particular: one marker on the incisa jugularis; one on the processus xiphoidus, one on the seventh cervical vertebra; one on the spinous process of the eight thoracic vertebra; one on the most ventral point on the sternoclavicular joint; one on the most dorsal point of the acromioclavicular joint; one on trigonum scapulae; one on the angulus inferior of the scapula; one on the angulus acromialis of the scapula; two markers on the elbow in the lateral and medial humerus epicondyle, respectively; and two markers on the wrist in the radius and ulnar styloid process, respectively.

After reconstructing the 3D positions of the markers during the movement, their raw trajectories undergo standard post-processing, including low-pass filtering and interpolation. Subsequently, we calculated shoulder joint angles following the ISB recommendations for the upper limbs [14]. The kinematic outcome parameters of the humerus and scapula, in particular, are be: i) humeral elevation angle; ii) arm abduction angle; iii) glenohumeral angle (angle between humerus and scapula); iv) scapulothoracic angle (angles reflecting upward rotation of the scapula); v) the ratio between the glenohumeral angle and the humeral elevation angle; vi) the ratio between the scapulothoracic angle and the humeral elevation angle; vii) the ratio between the glenohumeral and scapulothoracic angle [15].

B. Electromyography

The proposed protocol defines that surface electromyography (EMG) signals are recorded using ten bipolar surface probes obtained from ten muscle groups of the dominant arm, following the SENIAM (Surface ElectroMyoGraphy for the Non-Invasive Assessment of Muscles) guidelines [16], covering – in particular – the activities of: trapezius descens, trapezius trasversalis, deltoideus anterior, deltoideus medius, deltoideus posterior, biceps brachii, triceps brachii, pectoralis major, latissimus and sternocleidomastoid. In our preliminary analysis, EMG signals were collected via wireless system (Free EMG, BTS Bioengineering) with a sampling frequency of 1 kHz.

Before the execution of the required tasks, for each muscle, maximum voluntary contraction is recorded in order to normalize the amplitude of the signals. The raw EMG signals will be filtered with a fifth order high-pass Butterworth filter with 20 Hz cut-off frequency and then rectified and smoothed with a 20 ms moving window average. Then, muscle activity expressed as a percentage of the activity during maximal voluntary isometric contraction, muscle activity length, time broadness, and the onset of muscle activity are computed [15].

C. Ultrasound

In order to reliably acquire the behaviour of glenohumeral joint, we propose to follow the ESSR (European Society of MusculoSkeletal Radiology) guidelines [17], and the modified positions proposed by Vincenzo and Levent [18] for the dynamic measurement of the posterior capsule view. To focus better on the behaviour of the inferior joint capsule, we introduce also the reference proposed by Lee et al [19]. These projections can support the clinicians in the evaluation of the movement of the humeral head and, further, estimate the stiffness of the capsule joint.

In our feasibility analysis, we used an ultrasound system (Mindray M9GI, Mindray Medical international limited, China) in B-mode configuration; this system was specifically also equipped three different probes, i.e., two linear array (L14 – 6Ns, and L12 – 4s) and a convex one (C5 – 1s), and allowed also to perform strain elastography analysis. The ultrasound evaluation is recorded and video data is used to calculate the translation of the humeral head, following the procedure proposed in [11].

D. Experimental protocol

An expert operator is required to perform marker and surface EMG electrodes placement on subjects' skin. In order to minimize the impedance due to skin and sweating, the selected areas are initially rubbed with alcohol. After sensors placing, subjects were asked to perform isometric contractions to have the reference values of maximum voluntary contractions of EMG signals.

Subjects are required to seat on a stool, which is positioned oblique with respect to the absolute reference system to avoid occlusion due to the placement of the ultrasound probe. Each subject is required to perform two tasks characterizing glenohumeral function and described as follows:

- *Task 1*: the starting position is 40° of shoulder abduction in the scapular plane and subjects should perform intra/extra rotation movement of gleno/humeral joint with the elbow flexed at 90°. The ultrasound probe is located in front of the subject with the probes L12 – 4s and or C5 – 1s placed around the anterior axillary line, to visualize in longitudinal plane the cortex of the humeral head and its capsular joint.
- *Task 2*: the starting position is 90° of shoulder abduction in the scapular plane and subjects should perform shoulder flexion in the horizontal plane. Sonographer is located behind the subject with L14 – 6Ns probe placed on the posterior aspect of the shoulder, to visualize the posterior part of the humeral head in transverse oblique plane (close to the scapulae spine).

Each subject should perform ten repetitions of each task. The experimental setup is depicted in figure 1. Figure 2 shows two examples of images of the glenohumeral joint acquired via ultrasonography.

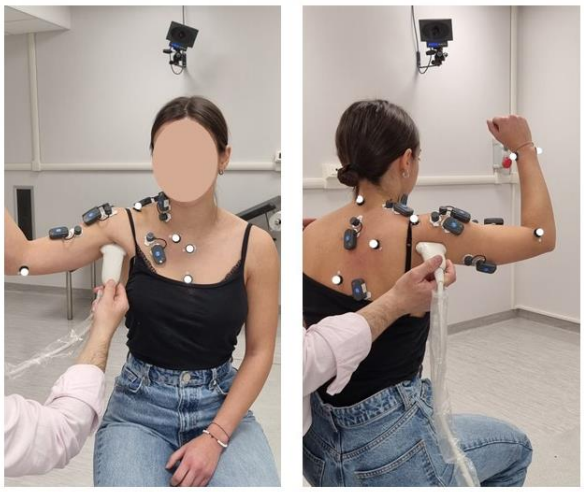

Fig. 1: Experimental setup. In the left side the ultrasound probe is placed around the anterior axillary line; in the right side the ultrasound probe is placed on the posterior aspect of the shoulder.

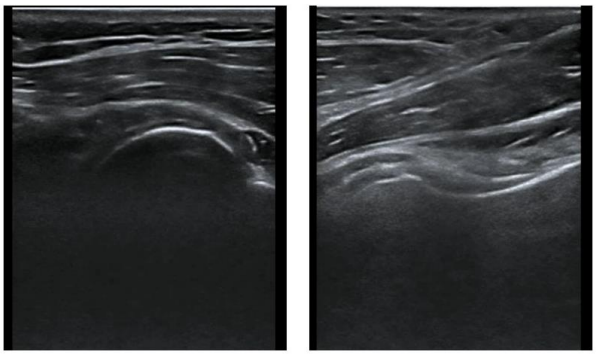

Fig. 2: Ultrasonography images of the humeral head. On the left side, the posterior capsule of the right shoulder in a posterior projection is shown; on the right side, the inferior capsular of the left shoulder in an anterior-inferior projection is shown. On both sides, the L14_6Ns probe is used.

III. Conclusion and Future Works

In this paper, we proposed an experimental setting which was designed to obtain multidimensional information concerning glenohumeral joint during dynamic tasks by integrating different technologies including marker-based stereophotogrammetric optoelectronic system, surface EMG and ultrasonography.

This work represents a preliminary feasibility analysis of the protocol, but further studies will involve a cohort of subject affected by shoulder disorders in order to characterize their movement patterns in terms of shoulder joint kinematics, muscles activation, and humeral head displacement (supporting diagnosis of shoulder instability) and compare them with respect to a control group of healthy subjects.

Therefore, the main purpose of this work is to analyse in depth the complexity of shoulder joint and define reliable features and characteristics for the identification of altered patterns of function by exploiting non-invasive approaches for in vivo assessment in inpatient settings. This protocol was designed to support clinicians to better understand the aetiology of the shoulder disorders and develop tailored treatment for the patients who suffering of shoulder pain.

***Abstract*— The aim of the study was to provide a quantitative evaluation of the motor performances of female athletes through a standardized test battery to create a normality dataset.**

Seventy-six female soccer players from AC Trento Women were assessed during the pre-season period (September 2021) through the test battery included in the Riablo™ medical device (Euleria Health, Rovereto (TN), Italy). The evaluations comprised stability test (ST) (two-leg and one-leg), countermovement jump (CMJ) test (two-leg and one-leg), plyometric jumps (PJ) test, parkour (PK) test (one-leg) and quick feet (QF) test. After verifying normal data distribution, for the test characterized by one-leg experimental set-up (one-leg test), the statistically significant differences between the two limbs are highlighted through the paired samples t-test ($\alpha = 0.05$). The normality values of the tested female athletes were obtained. In the one-leg test, the comparison between the performances of the two limbs showed no statistically significant differences.

The present study represents an attempt to identify a standardized test battery that can be used to evaluate the female soccer players performance. The data collected in this study can be used by the stakeholders involved in the female performance evaluation as normative reference data or to conduct further comparative analysis.

***Keywords*— Women's soccer, female performance evaluation, test battery, normative data**

I. Introduction

SOCCER is widely recognised as the most popular sport in the world [1]. One of the main aspects, especially when considering young soccer players, is to provide an adequate performance evaluation (PE) [2]. It can be conducted considering a myriad of factors such as physical, physiological, technical, tactical, and psychological aspects [3] and it requires a large amount of data to be carried out correctly.

The increasing of the financial support from the Union of European Football Associations (UEFA) [4] and of the participation rates over the last 10 years [5], shows a growing interest in women's soccer in the last years. Nevertheless, according to the FIFA executives (2019), there is still potential for further improvements in the quality women's soccer competition through the fundamental passage from "grassroots to elite" [6]. However, to date, the lack of information available on female soccer players limits the predictability of the future female players careers [7]. Consequently, there is a need to provide coaches and others stakeholder with relevant information that allows them to optimally support young athletes as they progress from the youth to elite level [6].

The aim of this study is to analyse the performance of seventy-six female soccer player through a standardized test battery. The data collected in this study can be used by the stakeholders involved in the female performance evaluation as normative reference data or to conduct further comparative analysis.

II. Methods

A. Participants

A group of female soccer players was recruited accordingly to the following criteria:

I. No injuries at the time of the evaluations.
II. No injuries in the two weeks prior the evaluations.

Following the inclusion criteria, 76 female soccer players from AC Trento Women (between 12 and 19 years old) were enrolled for the study and subjected to the test battery before the beginning of the sport season, in September 2021 (T0).

The tests were conducted at the Euleria Health headquarters (Rovereto (TN), Italy) in an indoor environment, on a tiled surface and making athletes wear sneakers.

Written informed consent was obtained from all participants or by their parents.

B. Experimental set-up

After a 10-minute standardized warm-up, all the athletes were subjected to the physical evaluation which included firstly an anthropometry evaluation and then the actual performance assessment.

1) Anthropometry

Height (cm) and weight (kg) were measured for each player before the beginning of the physical test, and the BMI (Body Mass Index, Kg/m^2) was calculated. Height was measured to the nearest 0.1 cm using a stadiometer and body weight was measured to the nearest 0.1 kg using a calibrated analogue scale. The athletes were wearing light indoor clothing, without shoes.

2) Physical tests

The test battery, used to perform the PE, is part of the Riablo™ medical device (Euleria Health, Rovereto, TN, Italy) and includes five different tests that allows to derive eight metrics which allow to assess different aspects of the physical performance:

I. Stability test (ST) performed on a MFT Challenge Disc (TST - Trend Sport Trading, Grosshöflein, Austria) free to move in all directions and connected to a PC. It is performed both with two-leg and with one-leg, and the subjects were expected to maintain their balance for 30 seconds. In case of a loss of balance, the test was restarted. The variable obtained from this test is named level of stability (LoS, index) and can assume values

between 1 and 5 where low values indicate a better postural control.

II. Countermovement jumps (CMJ) test performed placing a wireless IMU (EXL-S3, Exel, Bologna, Italy) above the greater hip trochanter through a waistband. In the case of the two-leg test, it was placed above the dominant leg while, in the case of the one-leg test, it was placed above the tested leg. After the calibration phase, the athletes had to perform a CMJ maintaining their arms on the hips trying to jump as high as possible. The variables obtained were the jump height (in cm) and the power developed (in W/kg).

III. In the plyometric jump (PJ) test, the athletes had to complete four consecutive vertical two-leg jumps focusing on maximizing the jump height minimizing the ground contact time between two consecutive jumps. The variables obtained from the wireless IMU were the ground contact time (in ms) and the reactivity (in mm/ms).

IV. Parkour test (PK) performed using the Speedy Basic Jump Set (TST Trendsport, Grosshöflein, Austria) to create a jump coordination path (as shown in **Errore. L'origine riferimento non è stata trovata.**a) in which the athletes had to perform 16 consecutive one-footed jumps. Double jumps without overcoming an obstacle, twisting of the hip or the touch of the raised leg on the ground were not allowed. The variable obtained was the time needed to fully complete the coordination path.

V. Quick-feet (QF) test performed with the Speedy Basic Jump Set (TST Trendsport, Grosshöflein, Austria) to create an obstacle (as shown in **Errore. L'origine riferimento non è stata trovata.**1b) used by the athletes to step in and out with one foot after the other until the completion of 15 repetitions. Also, in this test, the variable obtained is the time spent to complete all the repetitions.

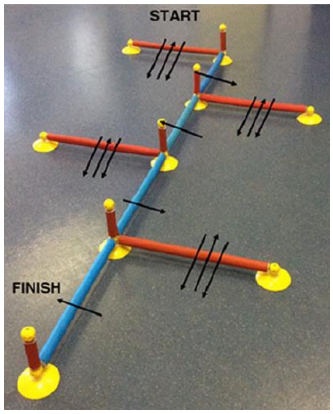

Figure 1a - Coordination path set-up for the PK test (sx)
Figure 1b – Obstacle set-up for the QF test (dx)
Source [8]

C. Statistical analysis

Data normality was verified using the Shapiro-Wilk test. The statistics were computed and reported in terms of mean and standard deviation (SD).

For the tests characterized by a one-leg experimental set-up, the statistically significant differences between the two limbs are highlighted through the paired samples t-test ($\alpha = 0.05$).

The data were analyzed and represented using Microsoft Excel® and MATLAB R2022a.

III. Results

The results for each variable are expressed as mean ± SD and reported in **Errore. L'origine riferimento non è stata trovata.**.

Data obtained from the tests conducted in both two-leg and one-leg modality has been represented through the boxplots (**Errore. L'origine riferimento non è stata trovata.** 2-5). To highlight statistically significant differences between the limbs, the results concerning the one-leg tests (ST; CMJ-Height, CMJ-Power and PK) have been compared.

TABLE I: Performance assessment results

Test	*Modality*	*Mean (± SD)*
Body mass (Kg)	-	56,04 (±8,29)
Height (cm)	-	162,84 (±7,09)
BMI (Kg/m^2)	-	21,09 (±2,62)
ST (LoS, Index)	Two-leg	2,87 (±0,68)
	One-leg-right	2,77 (±0,62)
	One-leg-left	2,76 (±0,60)
CMJ_Height (cm)	Two-leg	29,34 (±4,98)
	One-leg-right	17,15 (±3,65)
	One-leg-left	16,78 (±3,38)
CMJ_Power (W/Kg)	Two-leg	40,16 (±5,53)
	One-leg-right	26,77 (±5,35)
	One-leg-left	26,39 (±5,13)
PJ_Height (cm)	Two-leg	26,41 (±6,84)
PJ_ContactTime (ms)	Two-leg	174,4 (±39,15)
PJ_BIA (mm/ms)	Two-leg	1,58 (±0,40)
PK (s)	One-leg-right	6,80 (±2,28)
	One-leg-left	7,28 (±2,98)
QF (s)	Two-leg	9,21 (±1,86)

Table 1 - Mean (±SD) calculated in each test for the seventy-seven female athletes enrolled.

The evaluations obtained from this test battery, could highlight the characteristics in which the athletes are lacking and could give a hint on the performance area that have to be improved during the sport season.

For example, the mean value obtained in the two-leg ST (2,87 (±0,68)) is located almost in the middle of the evaluation scale (between 1 and 5) and this highlights a good, but not excellent, postural control by the female athletes that should be improved through specific training programmes.

The results in the CMJ test (both for the jump height and for the jump power) shows values that are double in the two-leg versus the one-leg tests.

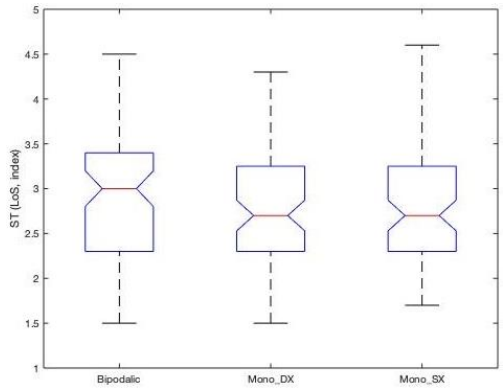

Figure 2 - Boxplot with the comparison of the results obtained in the ST (two-leg and one-leg)

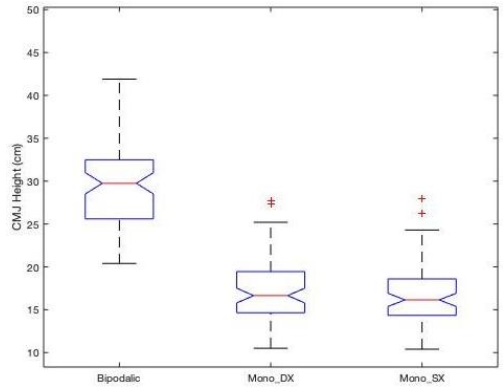

Figure 3 - Boxplot with the comparison of the height reached in the CMJ (two-leg and one-leg)

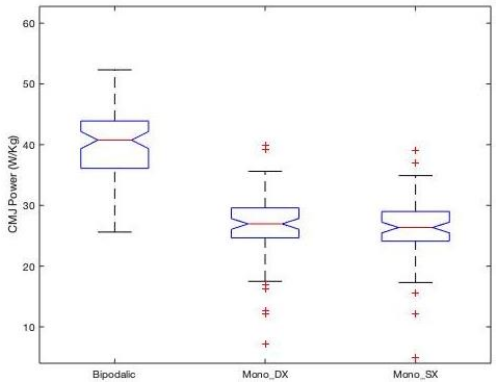

Figure 4 - Boxplot with the comparison of the power developed in the CMJ (one-leg and two-leg)

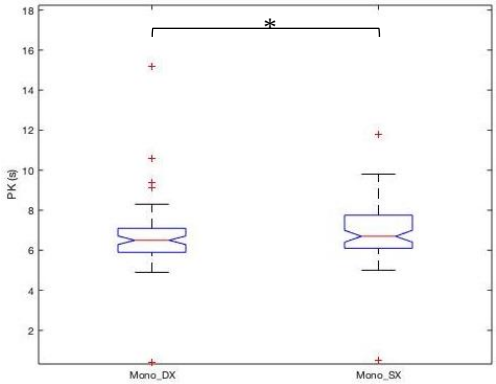

*Figure 5 - Boxplot with the comparison of the execution time in the PK test. * = p < 0.05*

TABLE II: T-TEST RESULTS

Test	*Comparison*	*P-value*
ST (LoS, Index)	DX vs SX	0.933
CMJ_Height (cm)	DX vs SX	0.204
CMJ_Power (W/Kg)	DX vs SX	0.259
PK (s)	**DX vs SX**	**0.017**

*Table 2 - P-values obtained from the limbs' comparison in the one-leg tests. In **bold** is reported the test correspondent to the statistically significant p-value.*

From presented data, the results of the LoS index and of the CMJ height and power seem to be not influenced by the change of the evaluated limb ($p > 0.05$) with the exclusion of the PK test ($p < 0.05$).

IV. DISCUSSION

The aim of the study was to introduce a standardized test battery, used to assess the female soccer players physical performance. When designing a study, the usage of an easy-to-use and standardized test battery is fundamental: in this way, the data collection is faster and easier, and provides to the stakeholders involved in the PE a large quantity of data.

In this study, the assessment of 76 athletes allows the creation of normative data that can be used as comparative data to assess if an athlete who has suffered an injury is able to safely return-to-sport because the performance returned to pre-injuries values. Moreover, with the addition of another test session, the collected data can be used to evaluate the effectiveness of training programs focused on the improvement of the deficient characteristics.

The symmetry between the two limbs is an important aspect to be assessed especially when considering the injuries risk [9]. Eventual asymmetries, in fact, have been described as one of the possible internal injuries risk factors: athletes may perform tasks in an efficient manner, causing fatigue or micro-trauma that can increase the probability of an injury [10]. In this case, while the stability and jumps performance shows no differences between the two limbs, the PK test highlights a significant difference that has to be monitored and constantly assessed in order to decrease the risk of injuries.

ACKNOWLEDGEMENT

The authors would like to acknowledge the staff of Euleria Health in particular David Tacconi, Ilaria Conforti, Gabriele Cera and Paolo Errico for their valuable contribution to the project. Moreover, we would like to thank the staff and the athletes of AC Trento Women involved in the project.

***Abstract*—Aiming to promote comprehensive imaging approaches integrating information about the microstructure of mineralized and soft tissues, because the latter are transparent to X-ray, the use of contrast-enhanced micro tomography (CE-µCT) is increasing significantly. In the present work, two tissue preparations – with PTA as contrast agent and by HMDS chemical drying – were tested on human meniscal tissue to evaluate their effectiveness in enhancing µCT tissue contrast. Eventual macroscopic alterations induced by such approaches were investigated through size/weight measures and mechanical testing, i.e., unconfined compression. Preliminary results showed that both strategies were able to enhance the µCT material contrast, albeit with different efficacy in tissue quote revealed and in highlighting microstructure; despite the promising evidence, alterations in the mechanics of the sample – in comparison with non-contrasted tissue – occurred.**

***Keywords*—contrast-enhanced µCT, phosphotungstic acid, hexamethyldisilazane, meniscus.**

I. INTRODUCTION

CONTRAST-ENHANCED micro tomography (CE-µCT) is an emerging tool for quantitative virtual 3D anatomical analysis of tissues in healthy conditions and, above all, when affected by a pathology. This approach aims at enhancing X-ray contrast of originally low-density materials, such as soft tissues. Before promoting CE-µCT as a standard technique complementary to immuno-histomorphometry, several limitations must be overcome: 1) operating procedures for sample preparation and imaging should be optimized and standardized; 2) contrast agent diffusion within the sample should be maximized together with minimizing tissue shrinkage; 3) tissue alteration due to the protocol should be minimized to ensure a not biased structural analysis and the complementarity with other assays and functional testing [1].

In this field, very few works are reported on human meniscus, a biphasic fibro-cartilaginous tissue present within the knee joint, despite its important role in knee biomechanics and homeostasis [2]. Phosphotungstic acid (PTA) was used to preferentially reveal collagenous structures [3], which are abundant in the meniscus; in fact, this approach was tested as contrast agent on animal models [4].

In this study, PTA for CE-µCT was investigated on human meniscal tissue and compared with chemical drying, a common procedure to enhance contrast in biological wet samples, already experimented on human meniscus [5]. Dimensional and weight measures served to reveal eventual tissue alterations due to the CE-µCT protocol. Moreover, the protocol was evaluated for complementarity with mechanical characterization, i.e., functional testing.

II. MATERIALS AND METHODS

Cubic samples were extracted from human menisci (ethical approval 952/2021/Sper/IOR), as needed by unconfined compression mechanical test [2].

For PTA CE-µCT, three adjacent samples were extracted from the central part of a same meniscus, and fixed in 4% formalin. Subsequently, a sample was contrasted with 1% (w/v) PTA in 70% ethanol (EtOH) solution [4] for 84 hours, a sample was contrasted with 1% (w/v) PTA in phosphate buffered saline (PBS) solution [6] for 84 hours, a sample was not contrasted (reference control). Samples were µCT scanned with source voltage 70 kV and current 250 µA, without metal filter (*Skyscan 1172, Bruker*, Belgium).

As for µCE-CT by chemical drying, two adjacent samples were extracted from the central part of a same meniscus and fixed in 4% formalin: one sample was dehydrated in ascending ethanol concentrations (1 hour each), treated with HMDS (1 hour) and air-dried in a fume hood overnight; a sample was not dehydrated (reference control). Samples were µCT scanned with source voltage 40 kV and current 250 µA, without metal filter.

After CE-µCT, samples contrasted with PTA were rehydrated with PBS immersion for 84 hours, while HMDS dried samples were rehydrated with immersion in decreasing alcohol concentrations up to water.

Samples' volume and weight were measured respectively by caliper and microbalance, before CE-µCT (PRE), before (INTERM) and after rehydration (POST). Unconfined compression tests (*Mach-1, Biomomentum*, Canada) were performed with the same schedule, in strain control, with a sequence of five incremental ramp-stress relaxations, loading along the sample vertical direction [2].

III. RESULTS

PTA resulted important for contrasting human meniscal tissue, otherwise transparent in µCT imaging. Nevertheless, staining concentration and time were not enough to reach a full tissue contrast, both in EtOH and PBS solution (Fig. 1A). After rehydration, samples appeared diffusely contrasted (Fig. 1B).

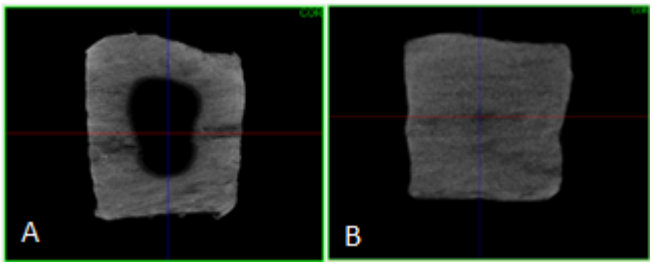

Fig. 1: µCT section of the sample (A) contrasted by PTA in PBS and (B) rehydrated.

Instead, HMDS treatment permitted full drying and imaging contrast.

Dimensionally, PTA in EtOH solution caused a tissue shrinking, not recovered by rehydration; conversely, PTA in PBS resulted more stable (Table I). Volume and weight loss, i.e., shrinking, was evident for chemical drying by HMDS, it was partially recovered by rehydration (Table II).

Mechanically, compression test highlighted a macroscopic change – overall stiffening – in the tissues entering µCT. Rehydration was effective in reversing the impact of sample preparation only in case of HMDS treatment (Fig. 2), while it even increased the stiffness of samples subjected to PTA treatments (Fig. 3,4). Indeed, after rehydration these samples showed a full µCT image contrast (Fig. 1B), even if with lower intensity, suggesting a complete diffusion of the PTA, that could increase tissue resistance to deformation.

TABLE I: DIMENSIONAL MEASURES ON SAMPLES CONTRASTED WITH PTA

Sample	*Volume (mm3)*	*Weight (mg)*
PTA-EtOH (PRE)	95	151
PTA-EtOH (INTERM)	74	96
PTA-EtOH (POST)	87	105
PTA-PBS (PRE)	164	227
PTA-PBS (INTERM)	166	207
PTA-PBS (POST)	172	204
CONTROL (PRE)	123	166
CONTROL (INTERM)	151	161
CONTROL (POST)	150	168

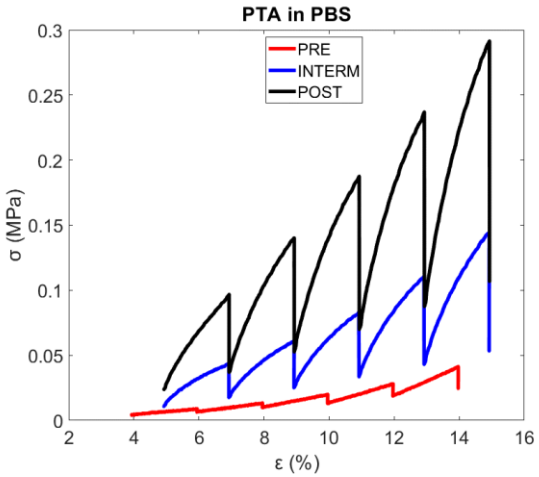

Fig. 4: stress (σ, MPa)-strain (ε, %) graph from unconfined compression on PTA in PBS sample, before CE-µCT (PRE), after CE-µCT (INTERM) and after rehydration (POST).

IV. DISCUSSION

This pilot study supported the development of reliable and repeatable CE-µCT protocols on human meniscal tissue, pointing out important aspects still not properly rated. Indeed, both the reference approaches [4,5] described several correspondence between µCT and histological imaging, validating their CE-µCT protocols, but only in a partial way; in fact, eventual tissue alterations, e.g., shrinking, were not discussed. Moreover, the complementarity with methods other than histology – such as the mechanical characterization – was not investigated.

The protocol with PTA as contrast agent in EtOH solution on equine meniscus described in [4] was here replicated on human meniscus: PTA may not reach the innermost parts of the tissue; PBS instead of EtOH as solvent could avoid shrinking, but not PTA partial diffusion and tissue stiffening. Moreover, an attempt to recover the original status of the meniscal tissue was here added, even if failed.

Overall, chemical drying appears as more effective in revealing tissue microstructure than PTA; however, PTA is a collagen-specific marker, can characterize collagen distribution and indirect interpretations could potentially be made based on the alignment of the extracellular matrix [6]. For this reason, our intent is the optimization of the PTA strategy, e.g. by increasing its concentration in solution and/or exposition time and by trying a different solvent, e.g. water [7]. Shrinking and stiffening phenomena in input to µCT will be always analysed for verifying if alterations are only compositional (e.g. dehydration), or even structural producing a bias. Finally, other strategies for washing out PTA after CE-µCT will be tested, in analogy with experiences on cartilage [8].

V. CONCLUSION

The evidence collected in this pilot study paves the way for further investigations aiming to develop an optimal CE-µCT protocol, capable of enhancing the detection of meniscus microstructure and preserving its main features. Integrating this approach with complementarity techniques would represent a comprehensive framework to face the complexity of soft articular tissues, crucial in validating advanced tissue models and regenerative medicine studies.

***Abstract*— Anomalous Aortic Origin of Coronary Arteries (AAOCA) with intramural course could represent a life-threatening pathology that leads to ischemia due to compression of the anomalous vessel. We developed a computational workflow to investigate variations in the coronary lumen cross-sectional area under simulated effort conditions. Preliminary results appear to confirm the clinical hypothesis of the intramural segment compression. Our pipeline is proposed as a tool that can provide useful information on the pathological mechanism of AAOCA.**

***Keywords*— AAOCA, intramural course, finite element analysis, cross-sectional area.**

I. Introduction

Anomalous Aortic Origin of Coronary Arteries (AAOCA) is a congenital condition where one or more coronary vessels originate from an ectopic site within the aorta and may take different courses [1]. Among these variants, the presence of an intramural segment (IM) is associated with the risk of ischemia and sudden cardiac death [2] probably related to lumen compression caused by the aorta expansion [3]. In this work, we propose a pipeline to assess changes in the coronary cross-sectional areas during simulated effort conditions using patient-specific finite element analyses (FEA).

II. Materials and Methods

A. Reconstruction of the patient's anatomy

The aortic and coronary lumen were segmented from the diastolic sequences of coronary computed tomography angiography (CCTA) scans of patients with AAOCA. The cross sections along the aortic and coronaric centerlines were then extracted from the STL reconstruction to build a three-dimensional computer-aided design (CAD) model of the anatomy of interest with vessel walls (Fig.1, panels A-B-C-D).

B. Simulation settings and analysis

FEA simulations were carried out through the commercial finite element package Abaqus/Standard 2019 (Dassault Systemès, Providence, RI). Static analyses were performed assuming that the geometric model, i.e., the computational domain, is subjected to an initial pressure equal to the patient's mean intraluminal pressure measured during catheterization. Incremental pressure loads were applied to the aortic lumen to simulate systolic peaks under normal and stress conditions, in a range between 120 and 250 mmHg. The coronary lumen was uniformly pressurized with an increment of 10 mmHg, with reference to the patient's initial pressure, and this value was kept constant throughout the simulation. A neo-Hookean model was used for the aorta and coronary arteries [4]. The models were discretized using hybrid 4-node tetrahedral

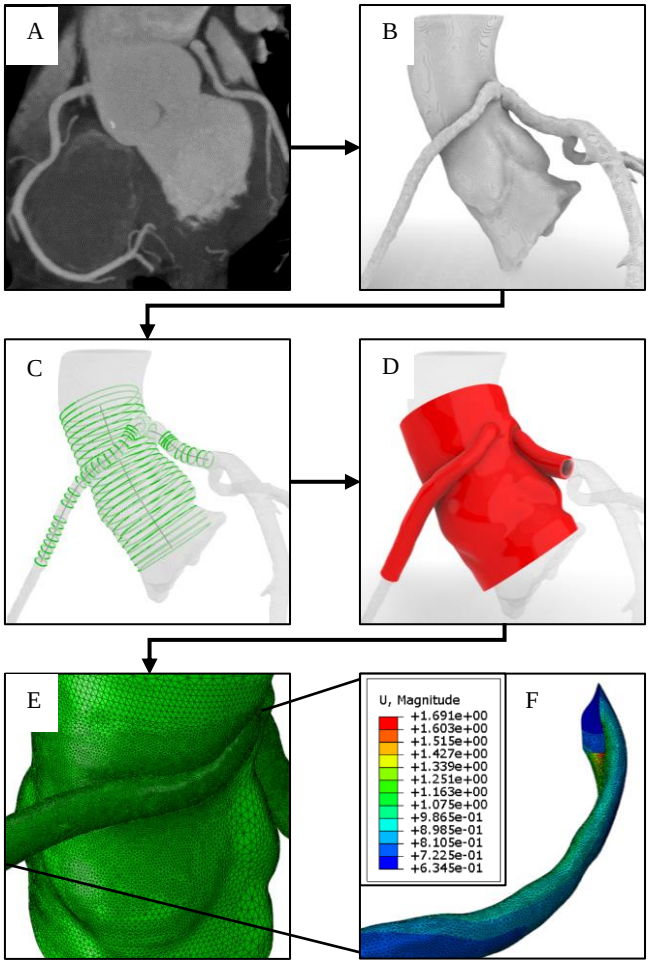

Fig. 1. Pipeline for AAOCA patient-specific simulation. Panel A: CCTA scan. Panel B: STL reconstruction of the aorta with coronary arteries. Panel C: slicing of the STL reconstruction and extraction of the profile curves (Vmtk v1.4 software, Orobix, Bergamo, Italy). Panel D: CAD model of the aortic root with healthy left coronary and anomalous right coronary with intramural course originating from the opposite sinus (Rhinoceros v6.0 software, McNeel and Associates, Seattle, Wash). Panel E: tetrahedral mesh with local refinement. Panel F: extraction of the anomalous luminal surface in its deformed configuration; legend: magnitude of nodal displacements.

elements with local refinements in the IM regions (Fig. 1, panel E). Boundary conditions were applied as done in our previous work [5].

C. *Post-processing of Simulation Results*

The deformed configuration of the coronary lumen was processed for each defined pressure increment (Fig. 1, panel F). The cross-sectional areas of the vessel were calculated from the ostium along the entire length of the coronary arteries and used to assess potential enlargement/narrowing. The anomalous coronaries were divided into three zones to better localize the phenomenon: the ostial zone (OST), from the origin up to a length of 1.5 mm; the intramural or middle zone (MID), from the end of the ostial zone to the end of the IM segment; and the distal zone (DIS), from the end of the intramural zone to the end of the coronary model. In the case of AAOCA without an intramural course, the length of the middle zone was considered equal to the average length of the intramural segments. Healthy coronaries were divided into two zones: the ostial zone, defined as above, and the distal zone, from the end of the ostial zone to the end of the coronary model.

D. *Statistical Analysis*

Comparison between homologous segments was made by Mann-Whitney U tests to assess whether there are differences in behavior between healthy and anomalous coronaries and between anomalous coronaries with and without IM segment.

III. Results

Our preliminary analysis was carried out on a group of 22 subjects with AAOCA, including 17 with the IM segment and 5 without the IM segment. The mean luminal areas of OST, MID, and DIS zones in the anomalous and healthy coronary arteries are summarized as median and interquartile range (IQR) in Table I for three aortic pressures: the basal value, i.e., the patients' mean intraluminal pressure at rest (90 ± 15 mmHg); 180 mmHg (effort condition); 240 mmHg (intense effort condition).

TABLE I: MEAN LUMINAL AREA

	Basal		180 mmHg		240 mmHg	
	median	IQR	median	IQR	median	IQR
OST						
NO-IM	8.45	5.37	8.84	5.35	8.83	5.51
IM	5.76	3.53	5.14	2.38	4.67	1.89
HEALTHY	13.02	8.64	13.86	9.17	14.42	9.17
MID						
NO-IM	5.37	2.76	5.29	2.67	5.19	2.56
IM	6.23	1.98	5.89	1.81	5.63	1.67
DIS						
NO-IM	2.91	2.85	2.92	2.76	2.92	2.66
IM	8.65	5.98	8.70	6.00	8.70	6.01
HEALTHY	13.37	9.28	13.62	9.60	13.74	9.79

Mean luminal areas (in mm^2) expressed as median and IQR. OST: ostial zone; MID: intramural or middle zone; DIS: distal zone. NO-IM: anomalous coronary without intramural segment; IM: anomalous coronary with intramural segment; HEALTHY: healthy coronary.

Variations in the MLA of coronary vessels, with reference to the undeformed configuration at the basal pressure value, were calculated at the OST, MID and DIS levels of the anomalous coronaries and at the OST and DIS level of the healthy ones (Fig. 2). Anomalous coronary arteries with the IM segment show a degree of narrowing in the OST and MID zones that increased in severity with increasing pressure loads. The

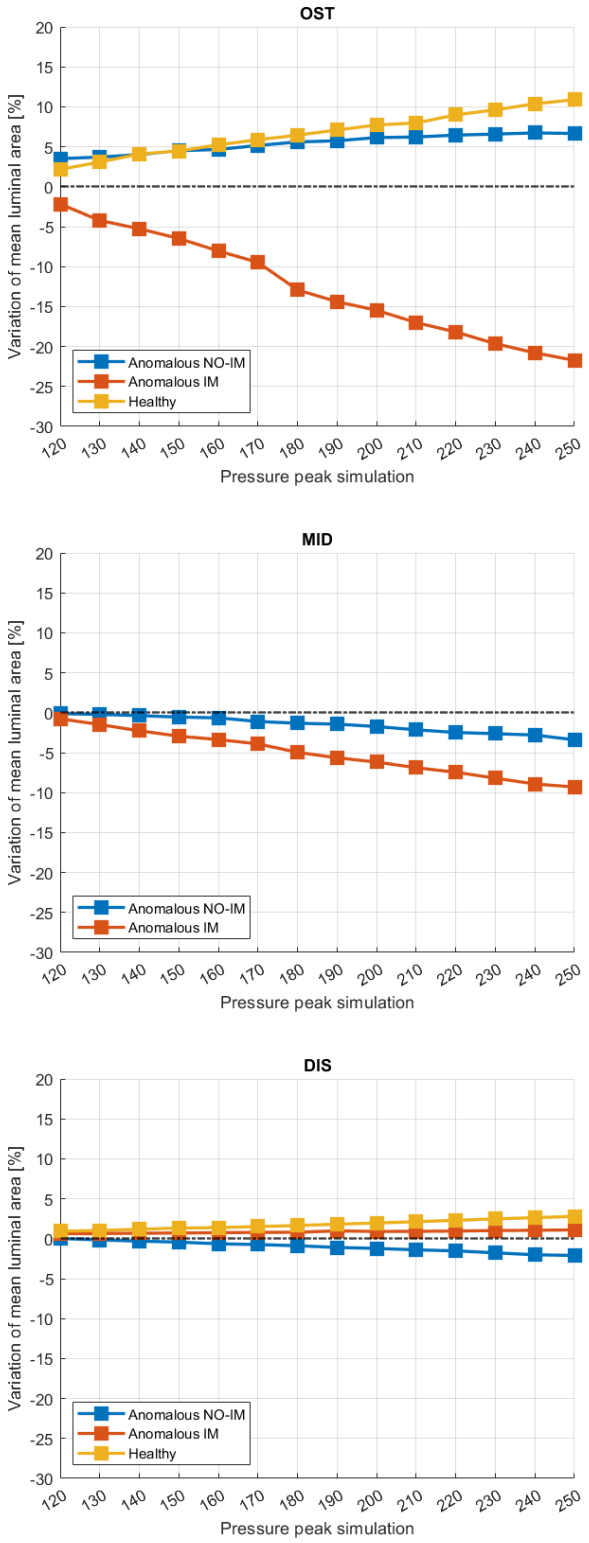

Fig. 2. Variations of the mean luminal area in the OST, MID and DIS zones for: healthy coronaries (yellow), in anomalous coronaries with intramural segment (red) and in anomalous coronaries without intramural segment (blue).

reduction in ostium caliber at 120 mmHg is -2.16% and increases to -21.7% at 250 mmHg. The anomalous coronaries without IM segment have a similar, though less pronounced, trend in the MID tract, while the ostial zone shows an expansion as the healthy ostium. No reduction in the caliber of healthy coronary arteries is observed. In the ostial zone, at all simulated pressures, MLA variations in anomalous coronaries with IM segment are significantly different from variations in anomalous coronaries without IM segment and substantially different from those in healthy coronaries. In the MID zone, at all simulated pressures except for 120 mmHg, variations of the MLA in anomalous coronaries with IM segment are significantly different than variations in anomalous coronaries without IM segment. Regarding the distal zone there are significant differences between the various types of coronary arteries at all simulated pressures.

IV. Discussion

In basal conditions the anomalous coronary with intramural segment has a mean luminal area of 5.76 and 6.23 mm^2, respectively at the OST and MID level, and a reference mean luminal area, in the distal zone, of 8.65 mm^2. Although the latter remains almost unchanged during effort conditions, the MLA in the OST and MID zones decreases, respectively, to 4.67 and 5.36 mm^2 applying a simulated aortic pressure of 240 mmHg. Therefore, the severity of stenosis of the anomalous lumen increases. Our preliminary results corroborate the clinical hypothesis that the expansion of the aortic root compresses the IM segment in systole, a mechanism that can lead to adverse events during physical exertion when the demand for oxygenated blood to the heart increases.

Limitations. The model does not account for vessel pre-stress; consequently, the unloaded, initial configuration of the arterial model resembles the geometry extracted from the diastolic phase of the CT scan that is paired to the mean pressure measured during catheterization. Then this configuration is updated to reach the corresponding 120 mmHg configuration and subsequently, progressively pressurized. Regarding the constitutive model, the assumption of a neo-Hookean formulation does not take into account the highly nonlinear, anisotropic and viscoelastic behavior of the aortic wall. Further development of the study should target these approximations and include comparisons with clinical data.

V. Conclusion

Our pipeline, based on patient-specific structural simulations, may allow retrieving the degree of narrowing and the critical locations of the phenomenon in AAOCA, which might be indicators for surgical planning.

***Abstract* — The definition of consistent experimental test benches for the estimation of mechanical characteristics of surgical meshes is still challenging due to the absence of specific standards for mechanical characterization of synthetic meshes. A meticulous test protocol for the mechanical comparison between surgical meshes having the same intended use is hereby proposed. The test protocol comprised three quasi-static test methods: (1) ball burst test, (2) uniaxial tensile test, and (3) suture retention test. For each test, the computation of relevant mechanical properties is detailed. The proposed test protocol was applied on 14 polypropylene meshes, 3 composite meshes (Comp), and 6 urogynecologic devices (UD) to verify its universal applicability towards meshes of different types and intended uses. The repeatability of the test methods is assessed in terms of coefficient of variation. The test protocol, easily performed to all the selected surgical meshes, exhibited an intra-subject variability characterized by coefficient of variations settled around 0.05. Its use within other laboratories could allow the determination of the inter-subject variability assessing its repeatability among users of alternative universal testing machines.**

***Keywords* — surgical meshes, urogynecologic devices, standard test protocol, mechanical characterization**

I. Introduction

SURGICAL meshes represent at present the gold standard for the repair of herniated abdominal wall and for the treatment of pelvic floor disorder (i.e., pelvic organ prolapse and stress urinary incontinence). Nevertheless, no specific standard regulates the functionality and the effectiveness assessment of these implantable devices. For this reason, a plurality of test methods arose to assess the mechanical characteristics of surgical meshes and urogynecologic devices [1], [2]. International or National Standards developed for textile industry are often adapted in terms of specimens dimensions and other test parameters (e.g., strain rate, ratio between the clamped region and the sphere diameter in ball burst test) [3]–[6]. In addition, the post-processing of raw data is reported with different methods in literature [7]. The aim of the post-processing is mainly the computation of the mechanical properties of the mesh. Some properties (e.g., anisotropy, membranal tension, and strain) can indeed lead to a better knowledge of implant acceptability, while others (e.g., maximum uniaxial tensile force and tension, uniaxial stiffness) are mainly useful for mechanical comparison [8], [9]. Differences in raw data manipulation can be found, for examples, considering the stiffness of the meshes computed from the uniaxial tensile test data [10]–[12] or the anisotropy between the two main directions of the knitted patches [4], [13]. The issues described above impact the repeatability and reliability of the results and are the main cause of the meaningful variability founded in literature [1], [12], [14]–[17]. Therefore, this study fits in this panorama proposing a comprehensive test protocol comprising: (1) a set of mechanical testing methods adapted from the International Standards and (2) the post-processing algorithms used to extract from the raw data the mechanical parameters useful to compare different devices. The defined test protocol is tested on 23 different devices to confirm its repeatability on devices having different knitted structures and different intended use.

II. Materials and Methods

The test protocol was designed selecting three quasi-static test methods characterized by ease of implementation and adaptability in terms of specimens dimensions. In detail, given its in vivo-like solicitation pattern, the static ball burst test was selected for performance assessment, to evaluate rupture behaviour at high loads and deformability behaviour under physiological or pathological stresses (Fig. 1a). The static uniaxial test represents the most performed mechanical test and was therefore chosen to provide basic mechanical characteristics (Fig. 1b). Finally, a static suture retention test completes the mechanical characterization of surgical meshes providing parameters related to the mesh positioning procedure (Fig. 1c). For each test method and configuration five specimens are tested in order to give statistical consistency of results. Specimens from the two principal knitting direction of each mesh type are tested in uniaxial tensile test and in suture retention test.

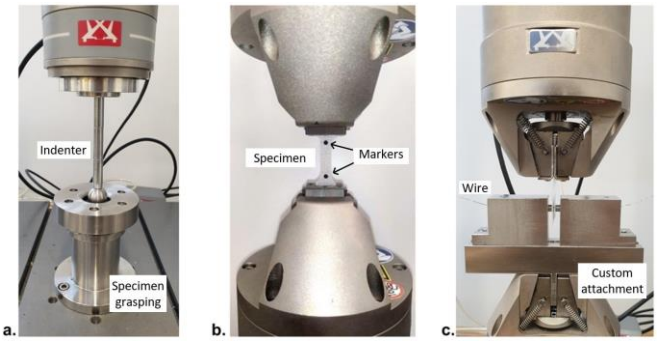

***Fig 1:** Test benches: a) Ball burst test; b) Uniaxial tensile test; c) Suture retention test*

A. Ball Burst test protocol and parameters computation

ASTM D6797-15 is used as reference standard for this test. Given the small and variable size of commercial products, reduced circular specimens (diameter = 55 mm) and ball-burst attachment dimensions (ring clamp internal diameter (aperture) = 35 mm and polished steel sphere diameter = 20 mm) are used in place of the recommended ones. The new dimensions were selected taking care of maintaining the same

ratio between the aperture and the ball diameter suggested by the standard (44.45 mm / 25.4 mm = 1.75).

After specimen positioning in the custom test grasping shown in Fig 1a, the spherical indenter is moved towards the mesh at 300 mm/min as the standard prescribes, while recording the force and the displacement.

The bursting strength is then computed as the maximum force value from the raw data. The dependency of the maximum force by the ratio between sphere and aperture diameter makes mandatory the computation of maximum membrane tension and dilatational strain for comparison purposes. These parameters are computed through an analytical method developed by [18], [19]. The true membrane tension depends on the radius in the truncated cone portion of the specimen free from the ball, decreasing as the considered radius increases. The true tension in the portion of the mesh in contact with the sphere, T, is indeed the greatest tension that the specimen stands and is therefore used to compute the maximum membrane tension and the corresponding dilatational strain.

On the other hand, the true membrane tension at the aperture, T_a, is the tension that affects the entire area of the specimen and can be thus considered to assess the dilatational strain of the graft corresponding to a membrane tension of 16 N/cm and at 32 N/cm, that correspond to the most reported tension requirements for surgical meshes [20], [21].

A one-way ANOVA analysis, followed by a Tukey-Kramer post-hoc test was implemented to compare inter material variability for the meshes grouped by density.

B. Uniaxial tensile test protocol and parameters computation

The ISO 13934-1:2013 international standard for textile fabrics is adapted in order to test medical devices in terms of specimen shape and dimension. The actual specimen design (Fig 1b) was selected in order to avoid specimens rupture within 5 mm from the grip, as prescribed by the standard. The choice of dogbone specimens compels the use of an optical measurement system to record the displacement of the narrow zone of the specimen. To that end, two markers are sewn at a distance of 20 mm on the mesh without interfering with yarns movements. The specimens are then mounted using pneumatic grips on the testing machine without applying a preload, and the upper grip is moved vertically at 20 mm/min while a Digital Image Correlation (DIC) system is used to acquire and analyse markers displacements. The force and the displacement data as well as images are acquired at 5 Hz.

The tension is computed from the force F acquired during the test as in Eq. (1):

$$T = \frac{F}{w_0} \tag{1}$$

where w_0 is the specimen width at rest, equal to 8 mm in the dogbone geometry defined.

Marker coordinates are computed using the acquired images. Hence, the deformation in the central portion of the specimen is computed as in Eq. (2):

$$\varepsilon = \frac{l - l_0}{l_0} \times 100 \tag{2}$$

where l is the incremental marker distance along the motion axis, and l_0 is the initial marker distance at rest along the motion axis.

The tension at rupture and the corresponding strain are reported as meaningful parameters. From the tension vs. deformation curve, the slope of the initial portion, named secant stiffness (k), is computed as the slope of secant line at 10% deformation. The anisotropy of the meshes is thus computed starting from the secant stiffness in the two perpendicular directions as in Eq. (3):

$$\alpha = \left|\log \frac{k_s}{k_w}\right| \tag{3}$$

where k_s is the secant stiffness in the strong direction, the knitted direction with the highest tension at rupture, and k_w in the weak direction.

Two statistical analyses were computed on uniaxial parameters in order to investigate the variability between the two perpendicular directions and differences among the different medical meshes grouped by density or among the urogynecologic devices. A t-test analysis was finalized to assess the intra material comparison, whereas a one-way ANOVA analysis with a Tukey-Kramer post hoc test was implemented for the inter material comparison.

C. Suture retention test protocol and parameters computation

The attachment and the test bench, showed in Figure 1c, were designed, adapting the setup used by [1] and rectangular specimens (70 x 55 mm) are clamped without preload at the upper grip. A Assusteel® monofilament wire with a diameter of 0.350-0.399 mm is then inserted 10 mm from the inferior edge of each specimen. The test is performed at a rate of 300 mm/min in displacement control while recording force and displacement data.

The suture retention strength (F_{max}) for the single specimen is computed from the raw data as prescribed by the ASTM D2261-13. Therefore, the method of computation depends on the number of peaks identifiable in the force vs displacement curves. Intra and inter material differences were examined performing the statistical analyses described above for uniaxial tensile test.

D. Test protocol verification

The suitability and replicability of the test protocol on surgical meshes was verify on fourteen polypropylene meshes, used for abdominal or inguinal hernia repair and three composite meshes used for abdominal hernia repair. The six urogynecologic devices were tested only in the uniaxial tensile test bench.

All the tests were performed using a universal testing machine, Instron E3000 (INSTRON®, Norwood, MA, USA). The optical system used for the acquisition of markers displacement during uniaxial tensile test was the VIC-3D system (Isi-sys GmbH, Kassel, Germany). Finally, the post-processing of the raw data was entirely performed in Matlab (version 9.10.0 (R2021a). Natick, Massachusetts: The MathWorks Inc.). The coefficient of variation (CV) was computed for all the extracted parameters in order to determine the dispersion level around the mean and to verify the test protocol repeatability.

III. Results

For each tested configuration five replicas were performed (335 specimens in total). A frequency analysis was conducted on the coefficients of variation (CVs) of the computed parameters in order to evaluate the repeatability of the test methods. Fig 2 shows the gaussian fits and the heat maps of frequency distributions obtained from the frequency analysis. In particular, the gaussian fits stand out the median values of CVs for the different tests are: 0.14 for the uniaxial tensile test, 0.05 for the ball burst test, and 0.08 for the suture retention test.

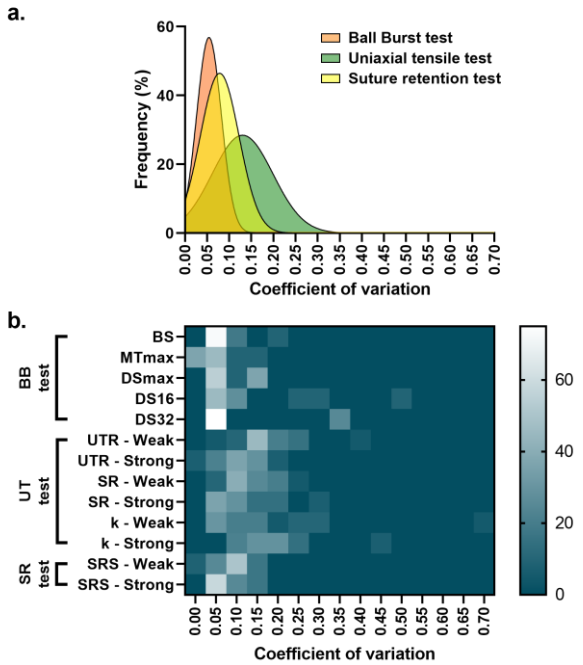

***Fig 2**: CVs frequency analysis among all the parameters for the selected test methods. a) Gaussian fits on the CVs frequency distributions for the three test methos; b) Heat map for the computed parameters where BB test: bursting ball test; BS: bursting strength; MTmax: maximum membrane tension; DSmax: maximum dilatational strain; DS16: dilatational strain at 16 N/cm; DS32: dilatational strain at 32 N/cm; UT test: uniaxial tensile test; UTR: uniaxial tension at rupture; SR: strain at rupture; k: secant stiffness; SR test: suture retention test; SRS: suture retention strength.*

Moreover, the heat map draws the attention on the CVs distribution of the different parameters in each setup. The lightest colours of the heat map highlight a concentration of CV values in a range between 0.05 and 0.20. Ultimately, both graphs highlight negligible differences between the range of CV values of the three test methods.

The range of values of the computed parameters are reported in TABLE I only as reference. From the statistical analysis of BB test results, a great heterogeneity is obtained among most of meshes grouped by density for all the computed parameters except DSmax. The t-test analyses, computed for UT test and SR test parameters, show significant differences between the two directions without regards to mesh density.

IV. Discussion

The variability of tests setups and methods for parameters computation could be reduced by the adoption of International Standards specifically drafted for surgical meshes. Therefore, the aim of this study is to design a test protocol useful to assess and compare mechanical characteristics of various surgical meshes. The chosen test methods turned out easily replicable, using small specimens and simple setups. Moreover, detailed computation of parameters is reported in order to ensure the comparisons between different studies and devices without neglecting the possibility of comparison with physiological conditions. The reduction of specimens dimension is paramount in order to test material collected by small patch such as preshaped devices. In this context, the suture retention test should be excluded if the insufficiency of material precludes the execution of all the test methods. The uniaxial tensile test and the ball burst test provide, in our opinion, the most significant results to assess and compare the mechanical properties of surgical meshes.

TABLE I: Parameters ranges

Ball Burst test

	BS [N]	MTmax [N/cm]	DSmax [%]	DS16 [%]	DS32 [%]
LW	181.07 - 258.37	49.87 - 71.72	34.79 - 45.09	15.02 - 25.18	-
SW	475.67 - 649.05	77.47 - 133.62	55.22 - 109.18	8.60 - 31.84	20.78 - 77.25
Comp	218.26 - 312.35	44.30 - 65.57	51.27 - 63.66	18.33 - 40.25	-

Uniaxial tensile test

	UTR [N/cm]		SR [%]		k [N/mm]		α
	Weak	Strong	Weak	Strong	Weak	Strong	
LW	3.28 - 26.26	13.48 - 36.61	52.03 - 107.59	44.75 - 94.06	0.36 - 2.21	1.45 - 2.21	0.03 - 1.27
SW	14.83 - 51.48	63.78 - 91.88	96.43 - 118.60	65.57 - 102.01	0.9 - 4.07	2.4 - 4.85	0.03 - 0.69
HW	17.38 - 36.75	84.50 - 136.07	58.61 - 155.86	41.72 - 72.22	1.63 - 4.24	16.56 - 22.25	0.59 - 1.07
UD	15.93 - 54.66		35.06 - 121.97		0.54 - 9.87		-

Suture retention test

	SRS [N]	
	Weak	Strong
LW	13.77 - 33.76	21.56 - 35.53
SW	53.01 - 81.95	45.66 - 63.82

The computed parameters are reported as ranges having grouped the meshes by density: light weight (LW), standard weight (SW) and high weight (HW) [22].

The use of dogbone specimens in uniaxial tensile test was essential in order to reduce the specimens dimension and concurrently achieving a failure in the central part of the specimen. This choice made mandatory the use of optical system to measure the local displacement. Although, no mention to local measurements is found in other studies that use dogbone specimens performing uniaxial tensile test on surgical meshes, a local strain measure is needed in order to obtain the correct displacement of the narrow section and therefore correctly estimate strains and tensions [1], [3], [7]. On the other hand, in our protocol all the parameters computed in uniaxial tensile test could be affected by the choice of a small width that results in a small amount of load-bearing threads, especially in lighter meshes [7].

In ball burst test to obtain easily comparable results a change in specimens dimensions must be followed by a comparable change in aperture diameter in order to maintain the ratio between the two dimension equal to 1.75 (as suggested by ASTM D6797-15 standard).

The suture retention strength is mostly affected by the specimen dimension and the distance of the Assusteel wire from the specimen dimension that determine indeed the number of mesh threads withstanding the tear propagation.

Moreover, we provide a detailed description of the extraction of the mechanical parameters which are of greatest interest, to encourage the adoption of easily comparable results. Furthermore, a collection of an extended and uniform set of data could support the determination of acceptability criteria and mechanical requirements for surgical meshes that are to date tough to establish [23]–[25]. Indeed, a crucial aspect of surgical meshes is the need to avoid alteration of the native tissue mobility. In this context, the implant stiffness and anisotropy are the key parameters. The significant differences found between the tested principal directions demonstrate that a mesh misalignment could heavily impact on the mechanical properties of the implant. In regards to patient comfort, the parameters evaluated in multiaxial test (e.g., ball burst test) are, in our opinion, the most suitable parameters for the evaluation of patient's comfort after the implantation [20], [26]. On the other hand, the stiffness computed in uniaxial tensile test is a convenient parameter to determine meshes anisotropy.

V. Conclusion

In this study we proposed a test protocol composed of three quasi-static test methods with the aim of promoting its adoption in other laboratories. The ease and the replicability of execution of the test protocol is verified on 23 surgical meshes with different intended uses and producers assessing an intra-subject variability characterized by a coefficient of variation with similar ranges. Its use within other laboratories could allow the determination of the inter-subject variability assessing its repeatability among users of alternative universal testing machines. Moreover, an extended evaluation of surgical meshes by the mean of the same test protocol could aid the determination of harmonized mechanical characteristic and thus, the definition of acceptability criteria and mechanical requirements for these implantable devices.

***Abstract*— Patient-specific in-silico models of transcatheter aortic valve implantation (TAVI) have gained a high level of complexity and accuracy and may become a relevant tool for supporting clinical decision-making and device design. When focusing on patient-specific material properties, the advanced age and the lack of *ex-vivo* material characterizations makes particularly challenging the utilize of reliable material parameters for patient-specific computational simulations of TAVI. This study focuses on the calibration of patient-specific constitutive descriptors for both the aortic wall and calcific aortic valve using an inverse approach and imaging data. Once the optimal material parameters were obtained, numerical simulations of the pre-TAVI scenario were found in agreement with CT imaging, thereby leading to a robust non-invasive approach for *in-vivo* assessment of material properties.**

***Keywords*—TAVI, Material Calibration, Finite Element Modeling, Linear Regression.**

I. Introduction

GIVEN the increase in transcatheter aortic valve implantation (TAVI) over open-chest surgery, several simulation techniques including finite element analysis (FEA) and fluid–solid interaction (FSI) have been adopted to model this treatment [1-4]. Computational models have been adopted to virtually deploy the device in the patient-specific human host and then quantify structural and hemodynamic parameters related to the device–host interaction [5-7]. Computational models can therefore enhance the preprocedural planning, simulating different implantation scenarios, provide important insights in postprocedural care and metrics for the design of the next generation transcatheter heart valves.

However, simulations should be carried out at an increasingly challenging level related to the need for verification and validation of the model output. A useful and accurate *in-silico* tool should account for patient-specific material properties. Despite the findings reported by several research groups [6, 7], the actual material properties of anatomical parts of interest remain unknown and uncertain. This is due to the fact that patients undergoing TAVI are quite elderly (i.e., age of 82±6.4 yrs.) as suggested by Attinger-Toller et al. [8]. The older the patient is, the stiff the aortic root is. For this reason, recent studies have simple adopted a linear-elastic material model for the aortic root rather than sophisticated anisotropic material models [9, 10]. Moreover, the high surgical risk of TAVI patients does not allow us to collect tissue segments for *ex-vivo* mechanical characterization [11-13]. There are therefore not any realistic material properties for patients undergoing TAVI.

The aim of this work was to estimate patient-specific material parameters of aortic wall and calcified valve leaflets using an inverse analysis and electrocardiogram-gated computed tomography (ECG-gated CT) images. The inverse method is based on the simultaneous minimization of two cost functions which define the difference between model predictions and CT measurements of aortic wall strain and orifice area at systolic phase with respect to the diastolic phase (reference image set).

II. Materials and Methods

A. FE Model Development

Simulations were carried out for a group of n.20 patients underwent TAVI with the SAPIEN 3 Ultra transcatheter heart valve (Edwards Lifesciences, USA). ECG-gated CT imaging was carried out for each patient as part of the routine clinical care and not for the purpose of this study. Retrospective retro-reconstruction of the ECG-gated CT acquisition allowed to collect two sets of images representing the peak systole and early diastole [14]. Echocardiography and blood cuff pressure measurements were also collected for each patient. For each patient, aortic wall strain at systole were measured as the changes in aortic wall diameter between systole and diastole over the diastolic diameter. Additionally, the orifice area at peak systole was measured by an experienced radiologist. All patients were informed of the study purpose, and data were collected after signature of informed consent.

Starting from DICOM images collected at diastolic phase, the 3D medical image processing software (Mimics Innovation Suite v.22, Materialise, BE) was used to segment the LVOT geometry, calcific plaques, and aortic wall. Segmentation was initially performed by means of semi-automatic thresholding of grey images (Hounsfield Unit) and then finalized by manual editing of the coloured mask [5, 15-17]. Morphological operations and smoothing were performed to improve case-by-case the segmentation output. Since the very thin structure of the aortic valve leaflet cannot seen at CT imaging, a parametric design model based on anatomic measurement was used to develop the native valve leaflet geometry [18]. In brief, two 3rd-order NURBS curves interpolating commissures were delineated to model the free edge of valve leaflets, while the belly of each leaflet was considered using one control points. To model the leaflet-to-sinus attachments, a second set of 3rd-order NURBS curves were developed using Rhino software (v.7.1, McNeel & associates, USA). The NURBS curves were constrained to the aortic root surface by curve-to-surface projection, and then native valve leaflets were developed by a multi-patch network of NURBS surfaces [19].

Literature data were used for imposing the material thickness of the aortic wall (i.e., 2 mm) and valve leaflets (i.e., 0.5 mm) [20]. Prismatic elements (size of 0.5 mm) were adopted for the valve leaflets, triangular for the aortic wall (size of 0.6 mm), and tetrahedral elements (size of 0.4 mm) for calcifications as a result of convergence analyses. Given the stiffness of the highly calcified tissues that characterize our targeted patients, linear elastic behaviour was defined for the aortic wall and valve leaflets, with material parameters derived from the inverse approach. In a different way, the calcific plaques were modelled by a linear-elastic material with plasticity using data published by Bosi and collaborators [9, 10]. Patient-specific loading conditions were set for each patient [21]. Specifically, a physiological pressure waveform of 1 Hz obtained from literature data was scaled to match the heartbeat duration of a given patient. The systolic and diastolic peak of the reference pressure waveform were adjusted to match the cuff blood pressure measurement obtained for each patient. For the valve leaflets, the transmural pressure obtained by echocardiography was used as loading condition on the valve leaflet surface model. For boundary conditions, the distal and proximal ends of the aortic wall were constrained in the longitudinal directions. The native valve leaflets were tied to both the calcifications and aortic wall. All simulations were performed with Abaqus\Explicit solver (v.2021hf7, Dassault Systèmes, FR), enabling to account for a dynamic non-linear problem with large deformation and complex contact interactions, using a mass scaling of 1.0e-6.

B. Inverse Approach

The inverse approach adopts a quadratic regression model to link the input variables (i.e., the material properties) to the output variables (i.e., the aortic wall strain or the orifice area). The regression model consisted of an optimization algorithm to minimize the difference between predicted and CT-based measurements. Specifically, the variables of interest for the aortic wall and the calcified valve were the peak systolic strain of the aortic root and orifice valve area, respectively. Assuming linear elastic material behaviours for both the aortic wall and orifice area, the unknown material parameter is represented by only the Young's modulus. Poisson's coefficient was fixed to 0.475 to account of an incompressible material. The objective of inverse analysis is to predict the aortic wall strain or orifice area with respect to Young's modulus. Thus, the regression model can be written as:

$$f(E) = \beta_1 E + \beta_2 E^2 + \beta_3 \qquad \text{Eq.1}$$

For each patient, n.10 simulations of the cardiac beat were carried out varying each time randomly the material properties in their interval of definition [0.8-10 MPa]. For each simulation, the systolic strains (NE) were exported at different anatomic levels identified by several element set using a python script. To calculate the orifice valve area, a python script in the Rhinoceros CAD software was developed to automatically export the nodal coordinates of the valve leaflet free edges. Then, the coordinates were imported into the Grasshopper plug-in of Rhinoceros to automatically fit the point and calculate the orifice valve area (see Figure 1).

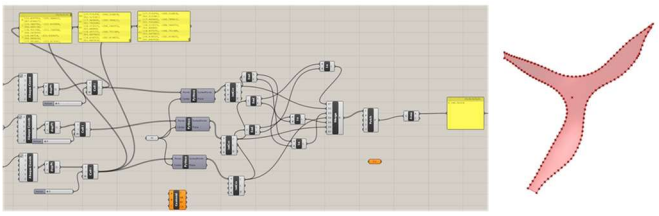

Fig. 1: Grasshopper algorithm to automatically quantify the orifice valve area from FE models

A matrix linking the input (i.e., material parameter for each random value of Young's modulus) and the output (systolic strain/orifice area) was generated in Matlab software. One cost function was therefore defined as:

$$F = f(E) - Strain_{STJ,Sinus,Annulus} \qquad \text{Eq.2}$$

This cost function should tend to zero so that the output variable given by the regression function for each patient tends to the value measured at CT scan. As the solution can lead to two different optimized material parameter sets, the selected set of material parameters was selected from the solution falling in the interval definition. If both values were contained in the range, these were averaged.

III. RESULTS

Figure 2 shows CT-based measurements of systolic strain (with respect to diastole) at different anatomic levels from the left ventricular outflow tract (LVOT) to the sino-tubular junction (STJ). Not any statistical difference was found on strain measurements at ANOVA, though strains at LVOT were slightly higher than those of Sinus of Valsalva.

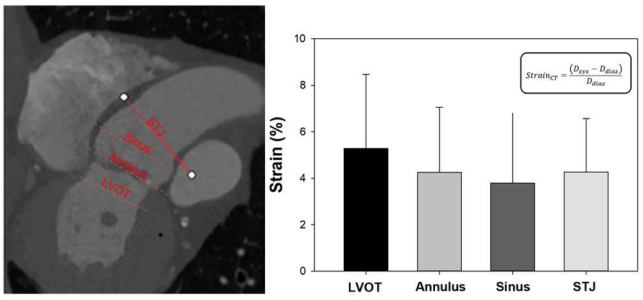

Fig. 2: Systolic strains at different anatomic levels derived from post-CT

Table 1 summarizes the material properties for both the aortic wall and orifice area as well as the good-of-fitness. Fitting results suggests a stiff behavior of the aorta as compared to literature data when the aortic wall is assumed as linear elastic [22]. The biomechanical behavior of the orifice area is very stiff, and this may be the results of the calcifications linked to the aortic valve leaflets or the severe stenotic condition.

	E (MPa)	SD	R	RMSE	p
Aorta	5.91	3.03	0.74-0.86	0.0068-0.0274	0.008-0.019
Valve	10.85	3.06	0.72-0.84	0.0041-0.0382	0.009-0.023

Once the optimal material parameters were achieved, a new analysis was carried out for each patient using the optimized material properties. For the aortic wall, the deformed shape was exported and compared to that from the CT images at

systole. The root mean square error (RMSE) representing the summatory of the Euclidean distance between corresponding point on the predicted surface and the correspondent point on the CT-based surface was used to quantify the difference between model predictions and CT images. The relative errors were in the range of 8.6% to 13.6 % for the n.20 patients with more marked differences in the distal LVOT than in the sinus and ascending aorta (see Figure 3).

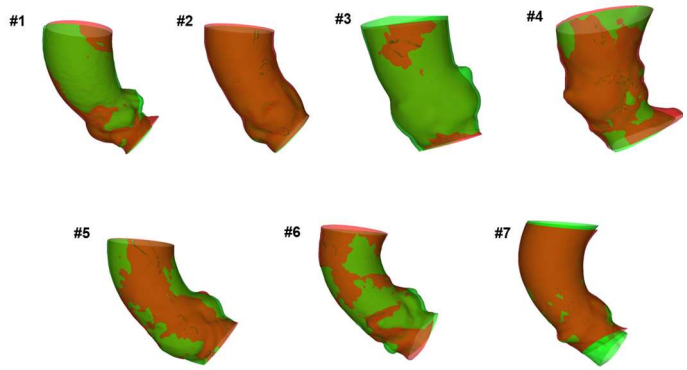

Fig. 3: Comparison between model predictions (red color) and CT-based shape (green color) of the aortic root at systole for several patients

Figure 4 shows the comparison of the CT-based measurement of orifice area versus the numerical predictions when the optimal material parameter values are used for the aortic valve. Not any statistical difference was observed between predictions and CT-based measurements (p=0.145). The relative errors between predictions and CT-based measurements were in the range of 0.08% to 11.86%. This suggests a realistic evaluation of the biomechanical response of the stenotic aortic valve.

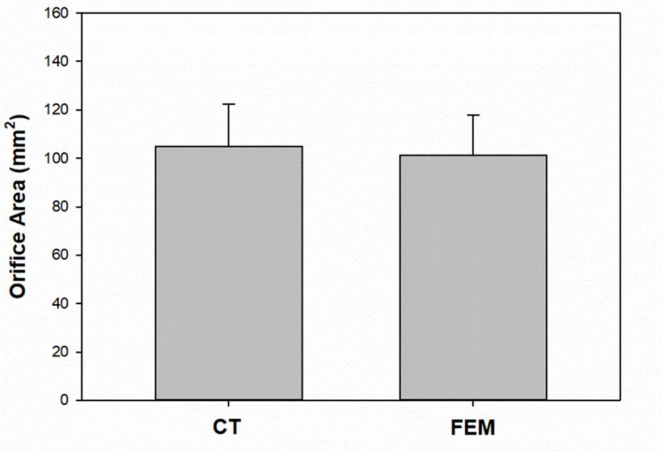

Fig. 4: Comparison between predicted and CT-based measurements of orifice area for all patients

Figure 5 shows the calcific valve leaflets at opened configuration using the optimal material parameter set. The stiff aortic valve behavior remarkably reduced the valve opening with diastolic orifice area of 92 mm^2 and systolic orifice area of 113 mm^2.

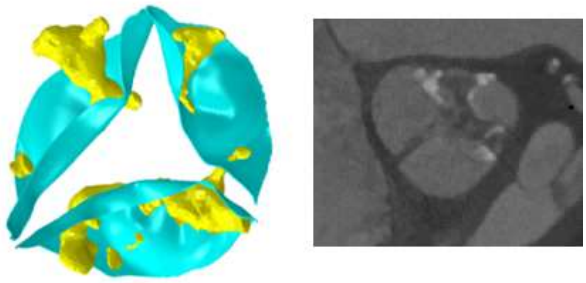

Fig. 5: Shape of calcific valve leaflets from simulation (left side) with the optimal elastic modulus and the CT-based image (right side)

IV. Discussion

The major novelty of this study is the development of a non-invasive inverse approach for the assessment of reliable material properties for the aortic root of patients with severe aortic valve stenosis. The approach used pre-TAVI ECG-gated CT images at two cardiac phase to optimize the material properties using a regression model for the minimization of the difference in the aortic wall strain and orifice area between predictions and CT-based measurements. These findings can be considered relevant as patients undergoing TAVI are very elderly so that the current *ex-vivo* material descriptors reported in literature are not suitable. Though a linear elastic material behavior was assumed, the present inverse analysis can be extended to the assessment of multiple materials descriptors and thus complex constitutive relationship. In this context, Trabelsi at al. [23] demonstrated that the potential of inverse analysis for determining the two-term Demiray's constitutive model. As compared to our approach, they adopted three cardiac phases (i.e., the systole, mid-cycle and diastole) to quantify the two-term material model using the aortic wall volume as the output parameter. Since ECG-gated CT imaging procedure is usually based on n.10 cardiac phases in the R-R interval, the present inverse approach can be extended to complex constitutive law using different parameters as aortic volume or strain at different cardiac phases or anatomic locations.

The fact that we adopted a simple linear elastic model to capture the biomechanical response of the aortic wall is based on recent findings using computational modeling and mechanical characterization [9, 10, 12]. In a large cohort of TAVI patients, a validated computational model demonstrated a good agreement between predictions and imaging measurements when the aorta is assumed linear elastic. The value of Young's modulus was 7.78 MPa as compared to our mean value of 5.91±3.03. Overall, these studies suggests a very stiff behavior for the aortic wall as compared to the physiological normal compliance of the ascending aorta reported in literature [22]. It should be also noted that a linear elastic model facilitates the springback seen once the transcatheter heart valve is numerically deployed. However, more complex constitutive models were used to model the aortic root. Several studies adopted fiber-reinforced constitutive models of the human aorta when simulating TAVI [1, 4]. Morganti et al. [7] considered the difference between the material properties of left-coronary sinus, non-coronary

sinus and right-coronary sinus using a six-term polynomial constitutive model. This model relies on biaxial testing data reported by Martin et al. [12] on eight human aortas from patients with 90.1±6.8 years underwent surgical valve replacement. Experimental data revealed the stiff material properties of the aortic root, with not any statistically significant difference among sinuses. Green strains were reported in the range of 4-6% as found in this study using ECG-gated image data.

There is a lack of information on the material properties of stenotic valve leaflets, and this is mainly caused by the impracticality of developing *ex-vivo* mechanical testing. It is clear the difference in the material properties between the healthy and calcific aortic valve. We found that the aortic valve leaflets had a stiff behavior with elastic modulus of 10.8±3.0 MPa, and this is likely caused by the constraining effect of embedded calcifications. Thus, the value of elastic modulus here found should be considered that of the combined effect (i.e., valve leaflets plus calcification) rather than the effect of valve leaflets only.

V. Conclusion

Using ECG-gated CT images of patients undergoing TAVI, we developed and applied an inverse analysis for the non-invasive identification of material properties of the aortic root and calcific aortic valve. Specifically, the inverse analysis minimized the difference in the aortic wall strain and orifice area between prediction and CT-images. Once the optimal material properties were obtained, simulations revealed a good agreement of numerical and CT-related aortic root shapes, with value < 13.6 % in all cases. The utilize of reliable estimations of material parameters could greatly enhance the prediction of numerical simulations of TAVI and thus improve the pre-operative planning.

***Abstract*— Current challenges in tissue engineering are aiming for the realization of materials that can be used for the replacement of damaged tissues/organs and that are able to integrate with the host organism. To this purpose, a hybrid membrane was made by coupling a decellularized tissue, e.g. porcine pericardium, with a commercially available polycarbonate urethane. The hybrid material was characterized from the biomechanical point of view and a constitutional model was formulated considering the hybrid material as the coupling of the two materials, pericardium and polymer. The model was then validated experimentally.**

***Keywords*—Hybrid membrane, tissue engineering, mechanical characterization.**

I. Introduction

TISSUE engineering is a field of research that proposes potential solutions to overcome the shortage of donor tissues/organs and aims at repairing or replacing damaged or diseased tissues/organs using a combination of cells, biomaterials, and growth factors [1].

The current challenge is to create a material that can perfectly integrate with the host body without evoking any adverse reaction: to this purpose, one of the most promising approaches is the use of hybrid materials.

Hybrid materials can be obtained by entanglement or interpenetration of at least two different types of materials, combining the advantages of both to create new and improved tissue constructs: they exhibit unique properties that are not found in either of the individual components [2], [3].

Hybrid materials can be divided into two main categories: those that combine organic and inorganic materials, and those that combine different types of organic materials. Examples of the first materials include scaffolds made of collagen or poly(lactic-co-glycolic acid) (PLGA) with hydroxyapatite for the substitution of natural bone tissue and cartilage [4], [5]. Examples of the second materials include hybrid hydrogels, e.g. collagen-poly(ethylene glycol) (PEG) hydrogels and polycaprolactone-collagen scaffolds [6], [7], which combine different types of synthetic polymers to create new materials with improved mechanical and biological properties.

The aim of the present work is the realization of a hybrid material, called hybrid membrane (HYME), involving the combination of a decellularized biological tissue, i.e., porcine pericardium, with an organic synthetic polymer, a commercially available polycarbonate urethane (Chronoflex ARLT). Synthetic materials provide mechanical support and other properties like impermeability and patency for the hybrid membrane; biological tissues give a natural extracellular matrix (ECM) able to support cell adhesion and proliferation, thus encouraging cell recruitment, attachment, growth, and differentiation, consequently guiding tissue regeneration *in vivo* [8], [9]. In the present study, HYME was assessed from a biomechanical point of view and a mechanical constitutive model was implemented.

II. Materials and methods

A. Pericardium decellularization

Fresh porcine pericardial tissues were collected from a local slaughterhouse, following EC regulation 1099/2009 protocols regarding animal health and protection, and treated within 3 hrs. The portion corresponding to the right anterior ventricle was isolated from the whole pericardium, and pre-pericardial fat was removed. The pericardium was decellularized using the Tricol method [10], which is based on the use of hypotonic and hypertonic solutions, a non-ionic detergent (Tergitol, code 15S9), and an ionic detergent (Sodium Cholate, code C1254). Removal of residual DNA was carried out with Benzonase® (cod. E1014). All reagents were supplied by Sigma Aldrich (Saint Louis, MO, USA).

B. Membrane production

Hybrid membranes were realized as described by Todesco et al. [11] by coupling decellularized porcine pericardium (DPP) with a polycarbonate urethane, Chronoflex AR-LT (AdvanSource Biomaterials Wilmington, MA, US).

DPP was laid into a custom-made aluminum frame and the polymer, supplied as 22% (w/v) solution in N,N-dimethylacetamide (DMAc), was gently poured onto the fibrous part. The membranes were dried for 24 hours at 38°C in a vacuum oven (Raypa, Barcelona, Spain). DPP and membranes made with only polymer were used as controls.

C. Mechanical tests

DPP, the hybrid membrane (DPP ARLT), and the membrane made with Chronoflex only, were cut into dog-bone-shaped specimens with a gauge length of 5 mm and 2 mm width using an in-house designed cutter [12], [13]. With regard to DPP and DPP ARLT, specimens were cut along the prevalent direction of the collagen fibres during visual inspection.

All samples (n = 9 for each material) were tested for stress–relaxation at room temperature using a customized apparatus (IRS, Padua, Italy) consisting of four linear actuators, each equipped with a 50 N load cell. During each test, samples were kept hydrated with saline solution. Before each type of test, samples were pre-loaded up to 0.1 N. Stress–relaxation tests were realized by elongating DPP and DPP ARLT samples until

10, 20, 30, 40, 50, 60, and 70% strain, whereas CFARLT samples until 10, 20, 30, 40, 50, 100, and 200 % strain, with an elongation rate of 1 mm/s, with 600 s holding time after each elongation. Force and elongation were measured during each test and stress curves over time were calculated as the ratio of the force to the cross-sectional area of the sample in gauge length. Thickness samples were measured with a digital calliper (Mitutoyo, ID-C112XB) and reported in Table I. Data analysis and graphs of the three materials were obtained with an in-house developed Matlab® script (Mathworks, Natick, MA, USA).

The stress–strain curves were obtained considering the different strain levels tested and the corresponding stress values at the end of the relaxation process, whereas the stress–relaxation graphs were obtained by normalizing the stress–relaxation curves of the materials.

TABLE I: THICKNESS OF TESTED SAMPLES OF DPP, DPP ARLT AND CF ARLT. DATA ARE REPORTED IN MEAN ± STANDARD DEVIATION.

Sample	*Thickness [mm]*
DPP	0.19 ± 0.09
DPP ARLT	1.18 ± 0.18
CF ARLT	0.80 ± 0.08

D. Mechanical constitutive model

A constitutive model is a mathematical tool that describes the general mechanical behaviour of a material; the mathematical formulation of the model includes constitutive parameters, which characterize the specific properties of a material.

Hence, a visco hyperelastic constitutive model of the membrane (DPP ARLT) has been formulated and validated. It was decided to consider the hybrid membrane as the coupling of the two materials separately (DPP and ChronoFlex ARLT), therefore the sets of hyperelastic and viscoelastic constitutive parameters were obtained for both materials: the polymer and the biological tissue. Finally, the constitutive parameters of the two materials were validated by developing a computational model of the hybrid membrane, simulating tensile tests, and comparing numerical results with experimental data.

Regarding the identification of the two materials' hyperelastic parameters, it was decided to use the one–parameter incompressible Ogden model, implemented in the simulation software *Abaqus/Standard* (Dassault Systèmes, Simulia Corp., Providence, RI). A specific tool of the software is provided for the parameter's identification by means of the inverse analysis of tensile tests, obtaining the hyperelastic parameters for the polymer and the tissue. The parameters obtained are μ_i and α_i, which are the material constants, and are reported in Table II.

A MatLab routine has been used to obtain the set of viscoelastic parameters (Table III) for both materials, by fitting the stress–relaxation experimental curves (showed in Fig. 1) with the Eq. (1), which illustrates the normalized stress depending on the relative stiffness and the relaxation time, and describe the viscoelastic phenomena:

$$\sigma_{norm} = (1 - \gamma_1 - \gamma_2) + \gamma_1 exp\left[-\frac{t}{\tau_1}\right] + \gamma_2 exp\left[-\frac{t}{\tau_2}\right] \quad (1)$$

The parameters obtained are γ_i and τ_i, which represent the relative stiffnesses and the relaxation times, respectively.

III. RESULTS

In Fig. 1 experimental stress–strain and stress–relaxation curves of each single material, i.e. DPP, CFARLT, and DPP ARLT, obtained from the mechanical tests, are reported. Figures A, C, and E represent the equilibrium stress–strain behaviour of DPP, CFARLT, and HYME. They were obtained considering results from stress relaxation tests at different strain conditions: for each strain value, the last point of relaxation curve defined the equilibrium stress. Mean data from experimentations on different samples were assumed.

Figures B, D and, F, which represent the stress relaxation behaviour, were obtained by normalizing the mean of each relaxation process (at the different strain rates) of each sample of the three investigated materials.

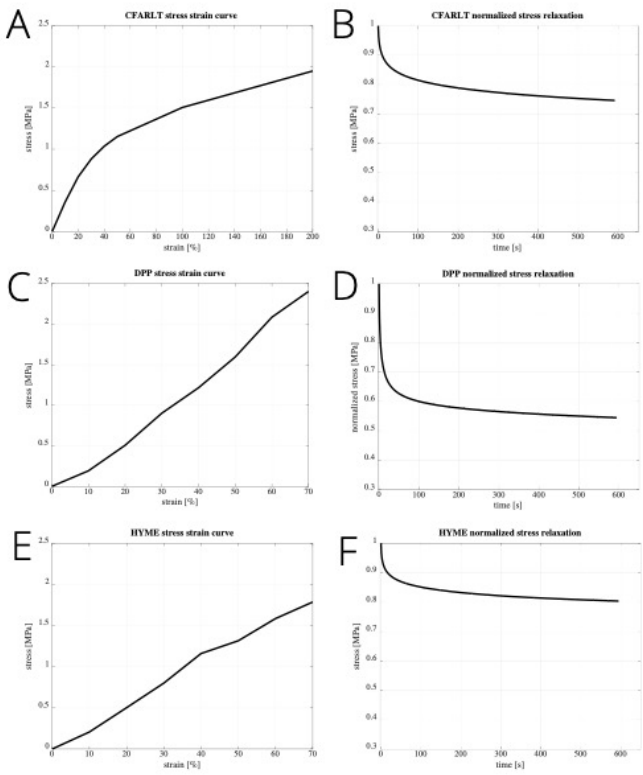

Fig. 1: Experimental DPP (A), CF ARLT (C) and DPP ARLT (E) stress–strain curve and DPP (B), CF ARLT (D) and DPP ARLT (F) stress–relaxation curves.

Table II shows the sets of hyperelastic parameters, whereas Table III shows the sets of viscoelastic parameters of the two materials.

TABLE II: HYPERELASTIC PARAMETERS

Samples	$\mu_i\ [MPa]$	α_i
Chronoflex ARLT	1.36	0.64
DPP	0.75	5.24

TABLE III: VISCOELASTIC PARAMETERS

Samples	γ_1	γ_2	$\tau_1\ [s]$	$\tau_2\ [s]$
Chronoflex ARLT	0.13	0.12	8.33	201.76
DPP	0.33	0.12	4.89	128.19

As mentioned above, the validation was carried out by comparing the experimental and computational data; the lasts were obtained by creating an Abaqus numerical simulation of the hybrid membrane sample, using the same experimental protocol and the constitutive parameters (for the two materials) presented above. The results demonstrated the reliability of the model, capable of correctly describing the mechanical behaviour of the hybrid membrane (Fig. 2).

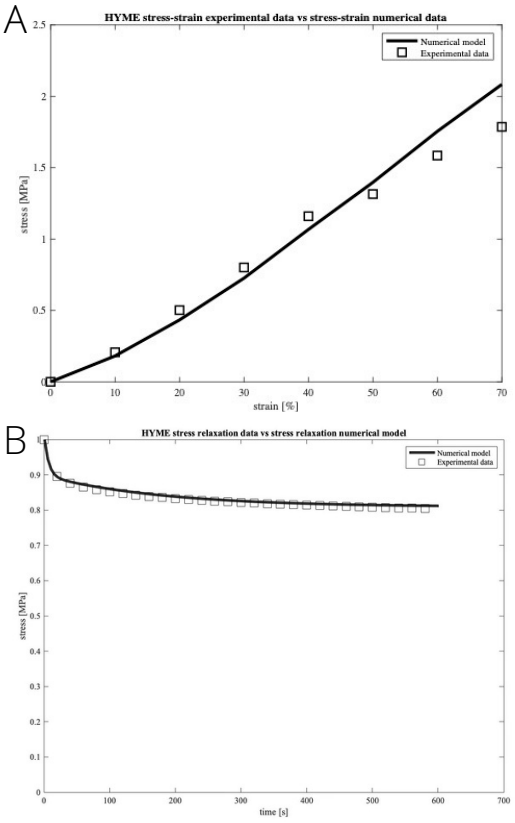

Fig. 2: Stress–strain (A) and stress–relaxation (B) validation curve of the membrane (DPP ARLT). Data obtained from the numerical model (continuous blue line) and experimental data (black squares) are overlapped.

IV. Conclusion

The development of new biomaterials that can integrate with the host body without causing adverse reactions is still very challenging. This work aimed at characterizing a hybrid membrane obtained by coupling a decellularized biological tissue and a synthetic polymer, able to provide blood compatibility and mechanical resistance. The membrane was mechanically characterized to formulate a constitutive model able to generally describe the material's behavior.

A visco hyperelastic model was then developed through stress–relaxation tests, and Abaqus and Matlab® software were used to obtain the sets of constitutive parameters of the two single materials composing the HYME. The validation was carried out with a numerical simulation of the hybrid membrane and comparing the simulation results with experimental data.

The proposed constitutive model shows to be reliable and able to describe the mechanical performances of the hybrid membrane.

The use of these hybrid membranes to replace damaged cardiac tissues, for vascular grafts, or as material to realize mechanical devices will be a big step towards the cure of cardiovascular diseases through regenerative medicine and tissue engineering.

***Abstract*— Hemophilic arthropathy (HA) is a frequent complication of Hemophilia A and B, being caused by repeated episodes of joint bleeding which lead to the degeneration of the articular cartilage (AC). The current management of this side pathology can only slow down the osteo-chondral damage, with no effect on cartilage regeneration. Tissue Engineering (TE)-based approaches represent a valid and poorly investigated option to replace the cartilage in HA patients, restoring the continuity of the osteochondral interface. Thus, in this project we developed a composite scaffold combining synthetic polyvinyl alcohol (PVA), which assures for the mechanical support, with decellularized human AC matrix, which increments the bioactivity of the hydrogel. Composite scaffolds in PVA at two different concentrations (15 % and 20 %) were fabricated by cross-linking a thin layer of decellularized, homogenized and lyophilized cartilage on hydrogel disks. Scaffolds were mechanically investigated by indentation and consolidation tests to define their compressive mechanical behavior in relation to hydrogel concentration. Subsequently, PVA/AC scaffolds were tested for their ability in promoting HM1-SV40 mesenchymal stem cells adhesion and proliferation, showing an increment of cell interaction capacity in comparison with the hydrogel alone. In conclusion, our preliminary evidence showed some promising mechanical and biological properties of PVA/AC composites for cartilage restoration in hemophilic patients suffering from HA.**

***Keywords*— hemophilic arthropathy, cartilage regeneration, polyvinyl alcohol, acellular cartilage matrix**

I. Introduction

Hemophilic arthropathy (HA) is a complication of Hemophilia A and B, which occurs as a consequence of repeated episodes of joint bleeding (hemarthrosis) and resulting exposure of the cartilage to blood [1]. Specifically, the chondrocytic metabolism is disrupted and consequently the proteoglycan synthesis is inhibited, causing the deterioration of the cartilage matrix. Therefore, HA has long-term consequences for bone health, causing chronic pain and functional disability. Generally, replacement therapy (i.e., prophylaxis with the missing coagulation factor) and conservative orthopedic approach (e.g., physiotherapy, hyaluronic acid injections, joint arthroplasty, and osteotomy) are the treatments of choice. Nevertheless, these therapies can only slow down the osteo-chondral damage [1].

Thus, the identifications of new strategies based on Tissue Engineering (TE) could represent a valid therapeutic approach to promote tissue regeneration in patients suffering from HA. Revising the literature, it can be noted that the main target of TE osteochondral repair techniques are patients suffering from osteoarthritis due to trauma, obesity and aging. On the contrary, the application of advanced TE strategies for the focal repair of early cartilage damages in hemophilic patients has been poorly considered so far [2].

In TE strategies, scaffold design needs to take into consideration that it has to highly mimic the target-tissue, presenting similar bioactivity and mechanical properties. Hydrogels represents a promising class of material as cartilage substitutes. Among them, polyvinyl alcohol (PVA) stands out for its peculiar characteristics: high-water content, good viscoelastic and compressive mechanical properties, well-established atoxicity and high biocompatibility [3]. Remarkably, its suitability is confirmed also by the satisfactory outcomes given by PVA-based medical devices which are already used in the clinical practice (e.g., CARTIVA®, marked CE in 2002) [4]. Nevertheless, PVA is not capable to sustain cell adhesion and proliferation, likely due hydrophilic moieties (i.e., hydroxyl groups) present on the polymer backbone [5]. For this reason, different studies combined the hydrogel with specific biomolecular components of the cartilaginous extracellular matrix (ECM) and other natural biomaterials [6].

Based on the above considerations, this work investigated the fabrication and characterization of a bioactive composite scaffold, consisting of a hydrogel support made of PVA at different concentrations (15 % and 20 %), which was cross-linked to a superficial layer of acellular AC matrix of human origin (Figure 1). In this composite, the synthetic PVA component, placed towards the inner layers of hyaline cartilage, assures for the adequate structural and mechanical support, whereas the biological counterpart, facing the synovial fluid, guarantees for scaffold bioactivity. In particular, the AC matrix was obtained by decellularization, homogenization and lyophilization of the native cartilage, removing the immunogenic component of the tissue (i.e., cells, DNA), while preserving the plethora of ECM biomolecules, that can provide specific biological cues for tissue regeneration. On the other hand, the original structural features of the cartilaginous tissue was not maintained.

In this work, the mechanical properties of PVA hydrogels at different concentrations were investigated in order to find the material that could better mimic the cartilaginous tissue. In fact, different studies in the literature proved that the concentration of PVA into the hydrogel influences the

properties of the material [3]. Moreover, the ultrastructural features and cell-interaction abilities of the composite PVA/AC scaffolds were assessed to demonstrate their enhanced bioactivity in comparison with PVA alone.

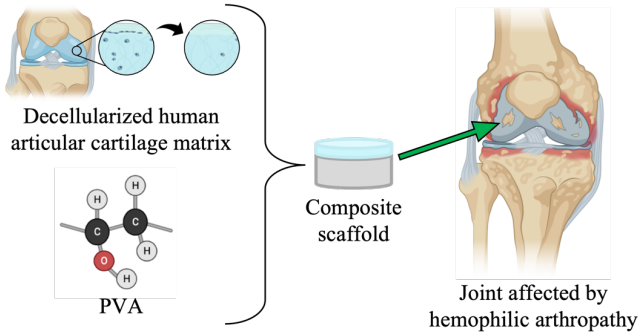

Fig. 1: Schematic representation of scaffold structure and application.

II. Materials and Methods

A. Scaffold manufacture

The composite scaffolds (PVA/AC) were fabricated using a PVA discoidal support as the bottom layer and combining it with a thin surface layer of decellularized cartilage matrix. Regarding PVA, two different polymer concentration were considered (i.e., 15 wt% and 20 wt%). Hence, the aqueous solutions of 15% and 20%PVA (Mw 146,000–186,000Da, 99+% hydrolysed) were obtained by heating the polymer suspension for 8 hours (h) at 90°C under stirring, until complete dissolution. The different PVA samples will be named as 15%PVA and 20%PVA, according to the polymer concentration they contain.

In parallel, for the AC matrix preparation, human cartilage samples (n = 3) were harvested from cadaver donors enrolled by the Body Donation Program of the Section of Human Anatomy, University of Padova [7], in compliance with European, Italian and regional guidelines [8].

Specifically, the tissue samples were rinsed several times in a 2% penicillin/streptomycin solution in PBS in order to remove any residual blood. After grinding the cartilage into small fragments, they were decellularized by a detergent-enzymatic method according to Stocco et al. [9].

The decellularized cartilage was soaked with a 10% acetic acid solution (2.5 M) in dH_2O and homogenized at 0°C in iced bath using Ultra-Turrax homogenizer (Janke & Kunkel GmbH, Staufen, Germany) 8 times/20 sec with intervals of 5 minutes (min). Thereafter, 400 μL of matrix solution were casted into each well of a 24-well cell culture plate, frozen at -20°C and finally lyophilized by a freeze-dry system (FreeZone, Labconco Corporation, Kansas City, USA).

For mechanical testing, 15%PVA and 20%PVA scaffolds were fabricated by pouring the hydrogel solutions into cylindrical molds (internal diameter 22 mm, height 7 mm) and performing physical cross-linking of the polymer through freeze-thawing (FT) cycles (24h at -20°C/24h at 4°C for three cycles). These samples were kept at -20°C until use.

Moreover, the two types of PVA/AC composite scaffolds were fabricated by pouring a layer of 15% or 20%PVA solution at 40°C into each well of a 24-well tissue culture plate. After that, a thin matrix layer of lyophilized AC matrix was carefully placed upon each hydrogel solution. The physical cross-linking of the hydrogel and the embedding of the matrix occurred through a FT treatment, as described before. The scaffolds were then stored at –20°C until use.

B. Mechanical tests

Indentation and consolidation tests were carried out on the PVA scaffolds only by Bose® ElectroForce Planar Biaxial TestBench (TA instruments, New Castle, USA), in accordance with the test protocol previously described by Todros et al. [10]. The samples were immersed in phosphate buffer saline (PBS), let unfrozen at RT for 1 h before the testing and maintained in submerged condition for the entire duration of the tests.

Samples were kept in the cylindrical molds they were fabricated in, which served also as sample holders. Indentation tests occurred using a rigid, spherical indenter with a diameter of 28 mm. The contact of the indenter with the hydrogel surface was assumed when measuring a compressive force equal to −0.05 N. According to the physiological range of maximum compressive strain for human cartilage, indentation tests were then carried out at a depth rate of 10 mm s^{-1}, up to −1.4 mm, corresponding to 20% of the overall sample height. Consolidation tests were performed by keeping constant compressive strain for 5400 s.

Each sample was used for a single test and five samples were tested for each material.

C. Ultrastructural characterization of composite scaffolds by Scanning Electron Microscopy

The ultrastructure of the composite scaffolds was assessed by SEM. Samples were fixed with 2.5% glutaraldehyde in 0.2M phosphate buffer (pH 7.2) for at least 24 h. Following dehydration through ascending graded ethanol series, critical point drying and gold sputtering, the samples were observed using a Scanning Electron Microscope (JSM-6490LA, JEOL, Eching b. München, Germany).

D. HM1-SV40 culture

For seeding experiments on the composite PVA/AC scaffolds, the immortalized human bone marrow cell line HM1-SV40 was used. This mesenchymal stem cell population was cultured at 37 °C, 95% relative humidity and 5% CO_2, using a proliferation medium containing Alfa-Modified Eagle Medium (α-MEM) Without Nucleosides (ThermoFisher Scientific), 16.5% fetal bovine serum (FBS) (ThermoFisher Scientific), 1% L-Glutamine 200 mM and 1% penicillin/streptomycin solution (100 mg/mL) (P/S; Life Technologies, Paisley, U). The medium was refreshed every 2-3 days.

E. Cell behavior on composite scaffolds

To test the bioactivity of the composite PVA/AC scaffolds, HM1-SV40 cells were seeded on the superficial cartilage layer of the supports. Briefly, 15%PVA/AC and 20%PVA/AC scaffolds were previously sterilized by soaking into 2% P/S solution in PBS under shaking for 72 h, then rinsing in PBS and finally leaving them for 1 h under UV light. To prepare the scaffolds for seeding, they were kept overnight into cell proliferation medium HM1-SV40 at 37 °C, 95% relative humidity and 5% CO_2. HM1SV40 cells were then detached by using trypsin/EDTA solution and counted with a TC20 Automated Cell Counter (Bio-Rad, Hercules, USA).

Finally, the scaffolds were seeded with 100,000 cells/support in 300 μL of proliferation medium and cultured for 7 and 14 days. In parallel, the same procedure was followed to seed 15% and 20%PVA scaffolds as controls. At the established end-points, cell viability and growth on the composite and synthetic scaffolds were evaluated by MTT assay. In brief, HM1-SV40 cells were treated with 3-(4,5-dimethylthiazol-2-yl)-2,5-dimethyltetrazolium bromide (MTT; 0.5 mg/ml) for 4 h and resulting formazan crystals were dissolved in 2-propanol acid (0.04 M HCl in 2-propanol) for 15 min under mild agitation. Finally, the optical density at 570 nm of samples was measured by using a microplate auto-reader EL 13 (Bio-Tek Instruments, Winooski, VT, USA). The results were expressed as number of viable cells detected on scaffolds by plotting the optical density values measured for each sample on the standard curve obtained by seeding defined cell numbers and evaluating them by MTT.

F. Statistical analysis

The statistical analysis was developed using the software Prism (v. 9.3.1, GraphPad Software, San Diego, USA). Mann-Whitney test was performed to evaluate differences among experimental groups, which were considered statistically significant with $p < 0.05$.

III. RESULTS

A. Indentation test

In order to design an effective scaffold for repairing osteo-chondral defects, the biomaterial should mimic the native cartilage tissue mechanical properties. It has to be able to withstand the joint loading environment, especially compressive forces, and it should have a stiffness comparable to the native cartilage, because it is known that this factor represent an important cue to regulate cell behavior during cartilage regeneration [11].

The compressive behavior of composite scaffold is expected to be mostly due to the PVA layer, due to its considerably higher thickness and stiffness. Thus, indentation tests were preliminary performed on 15%PVA and 20%PVA to assess which polymer concentration better resembles AC mechanical features. In Figure 2 a, the results of indentation tests are shown as values of indentation load as a function of indentation depth. To highlight possible significant differences among the hydrogels, a measure of the material stiffness was calculated by dividing the maximum absolute value of indentation load measured in each experimental test by the maximum indentation depth (1.4 mm) (Figure 2, b). From these results, it can be observed how the almost-instantaneous compressive behavior of PVA varies with the hydrogel concentration. At maximum penetration depth, the lower is the PVA concentration, the lower is the indentation load. Moreover, a statistically significant difference was calculated between PVA at 15 wt% and at 20 wt% (p-value = 0.0317). As expected, these results suggest an increment in material stiffness as polymer concentration increases. In perspective of in-vivo application, to choose the most suitable hydrogel, indentation tests in the same condition and setup should be performed on human AC and the results should be compared.

B. Consolidation test

Tissues at high water content like cartilage, subjected to compressive loads, undergo consolidation: the load causes the exudation of the fluid and the compaction of the solid phase. This effect, producing hydraulic lubricant, reduces friction and mitigates the impact of sudden loads [12], [13].

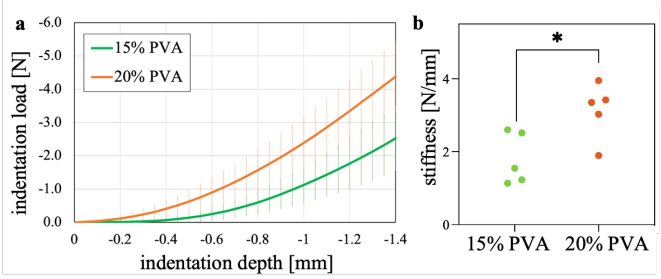

Fig. 2: Results of indentation tests on PVA hydrogels at different concentrations (15 wt% and 20 wt%): (a) Indentation load (mean and standard deviation) vs. indentation depth; (b) Values of stiffness for each concentration of hydrogel. Significant differences among hydrogels are indicated by (*) for p-values < 0.05.

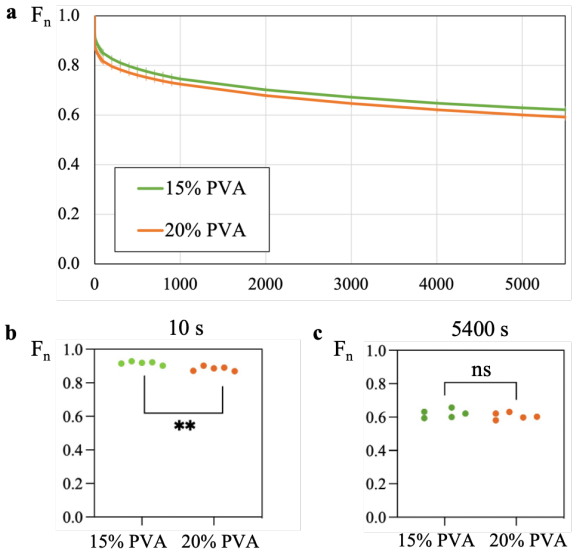

Fig. 3: Results of consolidation test on PVA hydrogel at different concentrations (15 wt% and 20 wt%). (**a**) Mean of normalized indentation force vs. time; values of F_n for each samples of hydrogel at a specific time points during consolidation tests: (**b**) at 5 s; (**c**) at 5400 s. Significant differences are indicated by (**) for p-values < 0.01.

Considering the end-use destination of these scaffolds, mechanical consolidation tests were performed to fully characterize the behavior of PVA hydrogels subjected to compressive loads. For each test, the normalized indentation force F_n was calculated dividing the force at the current time by the maximum force measured at the initial time of the consolidation process.

In Figure 3 a, the variation of F_n in time are represented for each sample at different concentration of hydrogel. It can be noticed that the 15% and 20%PVA curves are almost overlapping. To assess possible significant differences in the consolidation process, ascribable to the variation of hydrogel concentration, normalized force values for the five experimental tests conducted on each hydrogel were analyzed in the short time (i.e., 10 s) and at the end of the test (i.e., 5400 s). A significant difference was detected only at 10 s (p-value = 0.0079), highlighting a greater force reduction in 20%PVA.

C. *Gross appearance and ultrastructural morphology of PVA/AC scaffolds*

After FT, the AC matrix were firmly embedded into the hydrogel. This result confirmed F/T to be an adequate method for composite scaffold fabrication, as already proven in previous studies [2], [9].

Macroscopically, the AC matrix layer was well identifiable on each type of composite scaffold surface (Figure 4, a-d). The matrix appeared slightly darker and rougher than the hydrogel underneath. Considering the side view of the scaffolds (Figure 4, b and d), the reduced thickness of the acellular matrix layer comparing to the hydrogel can be appreciated. This data is consistent with the structural and mechanical function that the PVA layer of the scaffold has to exert.

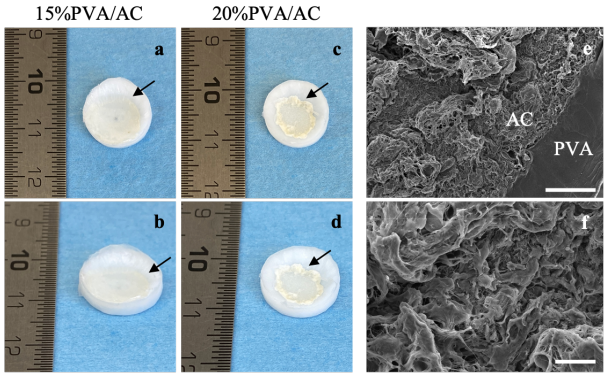

Fig. 4: (**a**-**d**) Structural appearance of composite scaffolds: (**a**, **b**) 15%PVA/AC and (**c**, **d**) 20%PVA/AC. (**a**, **c**) Top view; (**b**, **d**) Side view. In all figures the articular cartilage matrix superficial layer is indicated by a black arrow. (**e**, **f**) Representative scanning electron microscopy (SEM) micrographs of PVA/AC scaffolds: in (**e**) the interface between AC and PVA can be detected; in (**f**) the spongy appearance of AC based matrix can be observed. Scale bars: (**e**) 500 µm, (**f**) 100 µm.

The ultrastructural morphology of scaffold surface was well characterized by SEM, showing no relevant differences among the two types of composite supports, since the top layer of all scaffolds consisted of the same biomaterial. Thus, they all appeared irregular and spongy (Figure 4, e and f). The morphology was coherent with the one observed by Stocco et al. [1,3] on composite scaffolds consisting of AC derived matrices and both 16 wt% PVA and partially oxidized PVA (1%) hydrogels.

D. *Cell behavior on composite scaffolds*

Different studies in the literature proved that PVA hydrogels exhibit a low level of non-specific interaction with solutes and they do not sustain cell adhesion and proliferation [5]. Hence, the bioactivity of the PVA hydrogels was enhanced by the combination with the decellularized and homogenized AC matrix and assayed by culturing HM1-SV40 mesenchymal stem cells on the composite scaffolds for 7 and 14 days.

Comparing to synthetic PVA scaffolds, the composites acquired the capacity to effectively sustain HM1-SV40 cell adhesion and proliferation. As expected, no significant differences among the three type of composite scaffolds were calculated, because the surface that interacted with the cells consisted of the same biomaterial (i.e., AC derived matrix).

These results confirm that biological acellular matrices effectively increase the bioactivity of the PVA. Specifically, the acellular cartilage matrix can generate signaling cues that will guide the cells activity, directly binding cells to ECM components, and sequestering and regulating the access to soluble growth factors and cytokines [14]. Simultaneously, the matrix will not elicit any immune reaction due to the removal cellular component, allowing to fabricate non-immunogenic, biocompatible and bioactive scaffolds to improve cartilage tissue regeneration.

IV. Conclusion

Our in vitro model, consisting of a bilayer composite scaffold in PVA and acellular AC matrix, demonstrated to have the adequate mechanical and biological properties to support cartilage restoration in patient suffering from hemophilic arthropathy. Starting from these promising results, future studies may focus on alternative kinds of scaffolds, which could be prepared by combining the same components with different fabrication strategies (e.g., PVA/AC blend).

***Abstract*— Extracellular matrix (ECM) is the principal source of mechanical stimuli for cells in their native tissue environment. Different tissues means different stiffness: mechanotransduction signalling aims at the maintenance of specific homeostasis and function of each organs. In order to mimic different kinds of cell-ECM interaction, micropatterned polydimethylsiloxanes (PDMS) substrates were designed to feature different stiffnesses for the cells cultured in vitro. These microstructures are fabricated by soft-lithography on SU-8 molds, obtained by an optimized protocol of maskless photolithography. The different stiffness values are achieved by different geometrical, mechanical and topological features of fabricated micropillars. Preliminary results showed the ability of cells to spread on the selected substrates. This proof-of-concept optimization of the photolithography/soft-lithography protocol will allow us to test and observe cells in a wider interval of mechanical stimuli, mimicking defined physio-pathological environments.**

***Keywords*—Mechanotransduction, cell substrate interaction, modelling, microfabrication.**

I. Introduction

Cells are continuously in contact with different topographies ranging from macroscale to nanoscale in their native environment. Macroscale topographies are reflected in tissue organization, microscale in the cellular level architecture and nanoscale ones in the subcellular architectures [1]. Cells are stimulated not only by biological and chemical signals but also by mechanical stimuli. These stimuli are exerted by physiological flow [2], e.g. inside blood vessels, but also by the surrounding extracellular matrix (ECM) [3] or from neighbouring cells, and they affect various biological functions such as activation of signalling pathways that in turn control cellular differentiation, migration and proliferation [4].

The ECM features different values of stiffness within the different organs, and each one suits the function of that specific organ. These specific values usually contribute to the maintenance of tissue homeostasis via mechanotransduction signalling to the cells. However, in pathological conditions, the ECM can stiffen or soften, thus affecting the cell-cell and cell-ECM interaction [5]. Over the last years, improvements in micro- and nanotechnology have enabled the manufacturing of micro- and nanoscale sized substrates with different geometrical and mechanical features that could be exploited to mimic the environment that surrounds the cells.

The present work aims at the development of micro-pillar based substrates that can mimic different stiffnesses via geometrical and topographical features to test the mechanostransduction response of endothelial cells. In particular, we aimed at the optimization of a standard photolithography and soft-lithography protocol for for 3D PDMS (Polydimethylsiloxane, Dow Sylgard 184) micropillars substrates. The use of such SU8 and PDMS techniques helps integrate fine microstructures in microwells and microchambers, normally used in biology, exploiting the potentiality of this approach to increase testing possibilities in microfluidic devices, too [6] .

II. Materials and Methods

A. Design of geometrical patterns

Micropillar substrates were designed to obtain a homogeneous distribution of circular micropillars, arranged in a hexagonal pattern fashion. We tested cellular adhesion and spreading of cells happened on a height range 2,7 ÷ 3,7 µm, with ∅3,3 µm and spatial density of 4 µm [7]. Since spatial density might affect cell extension [5], different pattern pitches were tested ranging from 4 to 5.5 µm. Furthermore, we introduced pillars featuring an oval section to model heterogeneity versus anisotropy of the substrate stiffness. The minor axis was fixed at 3.5 µm while the major axis ranged from 7 to 8 µm. (Fig.1)

B. Photolithography for molds microfabrication

To optimize the mold fabrication (Fig.2), we used the epoxy based negative SU-8 2005 photoresist, characterized by low viscosity and suitable to produce a thickness ranging between 2 and 5 µm (spin rate 1800 rpm / 900 rpm). SU8 was spun (Spin Coater–Sawatec SM-150) directly on silicon substrate.

Based on a standard SU8 photolithography protocol, a customized protocol was set up and adapted to obtain the described micropillars. A double layer fabrication was set: the first layer acts as crucial reinforce to the pattern of the second, to avoid undesired deformations or detachments. This second layer is characterized by cavities devoted to shape PDMS pillars: the thickness of the photoresist coating will establish the depth of micro-cavities and, consequently, the maximum height of PDMS micropillars.

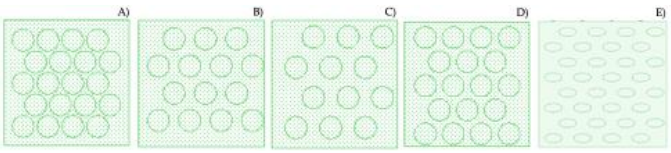

Fig. 1: Layout Editor designs of different geometrical patterns: 4 µm (A), 4.5 µm (B), 5 µm (C) and 5.5 µm (D) spacing with ∅3.5 µm and oval dimensions (E).

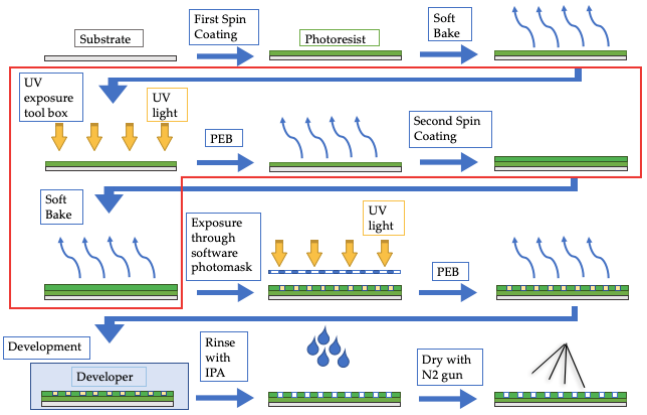

Fig. 2: Complete photolithographic protocol. The red contour includes the four steps added to improve the stability of the structures as mold for PDMS.

The design of the pattern was obtained by the selective exposure (maskless) of the coated film to a high-power LED light source (Direct Write Lithographer Heidelberg MLA100) to a pattern defined by software.

C. Optimization of microfabrication process and characterization

When the design is transferred to the coating, the critical settings of the exposure step are *dose* (exposure energy in terms of mJ/cm^2) and *defocus* (focus position of the write head for a fine tuning of the exposure focus). Starting from a series of exposure modes, different *dose*s (200 – 500, by 25 steps) and *defocus* values (-2 + 4 by 1 step) were combined and tested to achieve the best resolution and accuracy of the pattern during the exposure.

PDMS micropillars were obtained by molding DOW Sylgard 184 Silicone on the SU8 micropatterned substrates. Two ratios resin/curing agent have been tested, 9:1, 10:1 (weight ratio), targeting different mechanical properties.

Despite the affinity of PDMS to silanized mold surfaces (Chlorotrimethylsilane, Sigma–Aldrich), second degassing time with uncured polymer on the mold, in a vacuum chamber for 2 h, is necessary to allow PDMS to fill the cavities and reach the actual height of the final PDMS structures. Samples were then placed to cure in a furnace at 70 °C or 80 °C, for 15 h. Although the profilometer (3D Optical Profilm3D) seemed to read the interior shape of cavities of SU8 patterned substrates, the data was dominated by artefacts and did not reflect the actual ability to get PDMS pillars from the cavities of the molds.

The lack of information required an indirect measurement on the obtained PDMS replica to characterize the size of the related cavities. The micron scale size, the translucent aspect and the electrical insulating properties of both PDMS and SU8 needed a metallization of surface to improve the visualization and characterization of samples under interferometry profilometer and the observation via SEM. These measurements were necessary to perform a precise process control and to find the best working point for a successful photolithography. Characterization of the sample led to set out the best process settings as 275 mJ/cm^2 for the *dose* and *defocus* 3 and 4, for 900 and 1800 rpm, respectively.

TABLE: 1 PILLARS CHARACTERIZATION

	9:1	*10:1*
L = 2.7 µm	E_{eff} = 460 kPa	E_{eff} = 381 kPa
L = 3.7 µm	E_{eff} = 173 kPa	E_{eff} = 147 kPa

The evaluation of the effective elastic modulus of micropillar depending of PDMS ratio for 2,7 µm and 3,7 µm, with 3.3 µm diameter.

D. Mechanical modelling of the substrates

We used a simple Euler-Bernoulli beam theory approximation to assess the elastic moduli of micropillars (Tab.1). This approximation assumes a micropillar as an elastic spring whose constant bending k_{bend} is defined by Eq. (1) and the effective Young modulus can be assessed according to Eq. (2):

$$k_{bend} = \frac{3\pi E D^4}{64 L^3} \quad (1)$$

$$E_{eff} = \frac{9k_{bend}}{4\pi r} = \frac{18k_{bend}}{4\pi D} \quad (2)$$

where E is the elastic modulus of PDMS material [8], D the diameter and L the height of the micropillar.

Regarding the oval micropillars, the calculation of the elastic spring of the single oval post is given by Eq. (3), where *a* is the semi-major axis, *b* is semi-minor axis and α is the angle of the deflection with respect to the major semiaxis:

$$k(\alpha) = \frac{3}{4} * \pi E \frac{a*b}{L^3} * [a^2 * \cos^2(\alpha) + b^2 \sin^2(\alpha)] \quad (3)$$

III. RESULTS

A. Micropatterned substrate fabrication

A number of PDMS micropillar substrates, different in height, size, pitch and mechanical properties of the materials were realized. SEM analysis showed that the profilometer overestimated the heights of the structure by a not-negligible factor, as shown in Fig.3

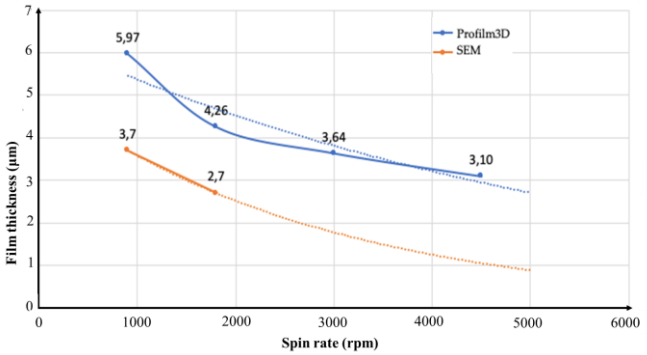

Fig.3: Plot of the relationship between film thickness and spin speed obtained from optical profiler analysis (Profilm3D in blue and SEM in orange) on the SU-8 master mold. The dotted lines indicate the exponential trend.

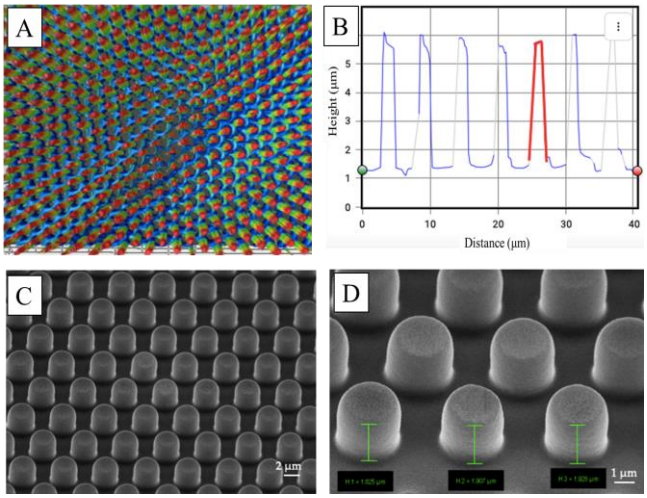

Fig. 4: Profilm3D images (A, B) and SEM images with InLens detector (C, D). Top view (A), step-height (B) of sample spin at 1800 rpm with spacing center-center 5.5 µm. SEM images tilted by 45° at scale bar 2 µm (C) and 1 µm (D) with measured tilted height in overlay.

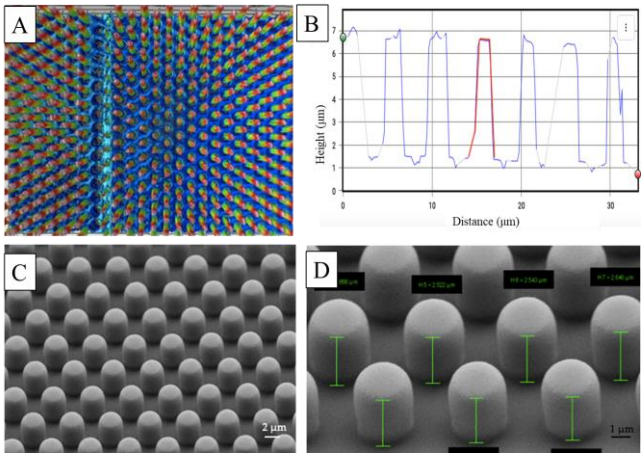

Fig. 5: Profilm3D images (A, B) and SEM images with InLens detector (C, D). Top view (A), step-height (B) of sample spin at 900 rpm with spacing center-center 5.5 µm. SEM images tilted by 45° at scale bar 2 µm (C) and 1 µm (D) with measured tilted height in overlay.

We selected sample characterized by 2.7±0.1 µm and 3.7±0.08 µm in heights (Fig.4, Fig.5).

Structures featuring a higher aspect ratio combined with tight pitches made the micropillars irreversibly stick to each other after demolding, thus generating a compact pattern of pillars that increases the overall stiffness of the substrate We identified a threshold of 4.5 µm as the limit to avoid this phenomenon (Fig. 6). Despite the fact that the mask was designed with a ∅3.5 µm, a difference in circumferential terms can be appreciated via SEM analysis (Fig.7), that shows a size of ∅3.3 µm for the horizontal section of pillars. ∅3,5 µm on the layout was been observed to be the minimum limit to obtain well-defined and empty cavities in SU8 substrates. This can be explained analyzing the functioning of the Direct Write Lithographer because high exposure dose is associated with higher polymerization, leading to a diametrical reduction of cavities.

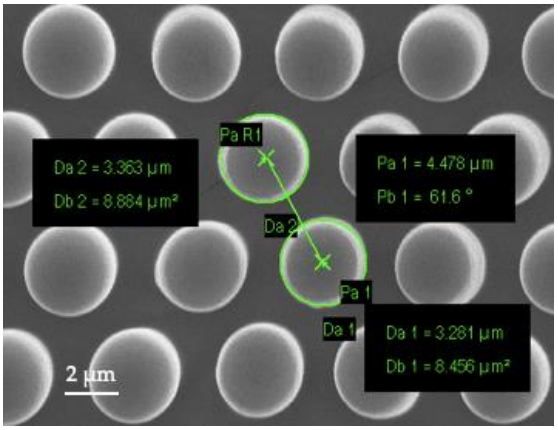

Fig. 6: SEM image with InLens detector of substrate sample with 4.5 µm spatial density (scale bar 2 µm).

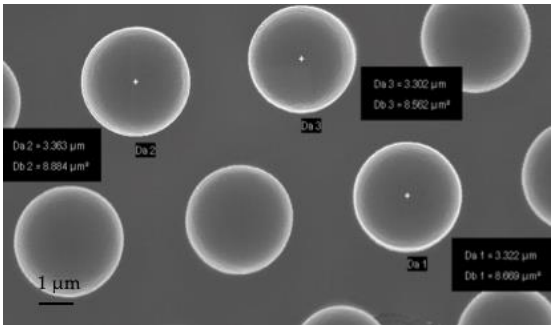

Fig. 7: Diameter measurements at SEM microscopy with InLens detector (scale bar 1 µm).

The different PDMS ratios (9:1 and 10:1), cured at temperature 70 °C and 80 °C impacted on the substrate stiffness. In addition, the spatial density among micropillars varied from 4-4.5 µm up to 5.5 µm.

B. Cell adhesion assay

We selected eleven conditions for biological testing. Each PDMS sample (11 conditions x 3 replicates) was punched with a ∅6 mm-biopsy puncher, sterilized and positioned in a standard multiplate for cell culture.

The preliminary cellular adhesion assay conducted revealed a preferential adhesion of endothelial cells on substrates featuring a stiffness in the range of 173 – 381 kPa and featuring a circular cross-section (Fig. 8).

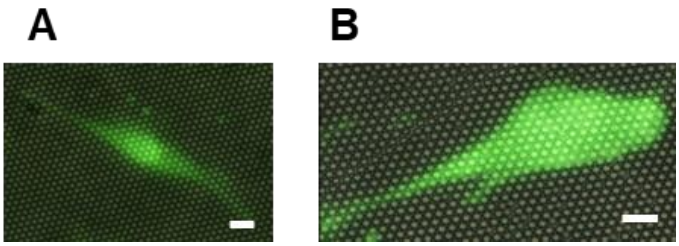

Fig. 8: Representative images of endothelial cells on 2,7 µm height pillars with 4 µm pitch made of 10:1 PDMS ratio (A) and 3,7 µm height pillars with 4.5 µm pitch made of 9:1 PDMS ratio (B) (10 µm scale bar).

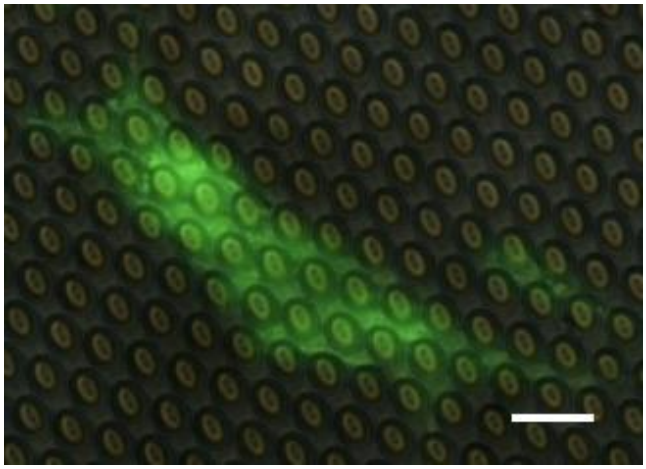

Fig. 9: Representative image of endothelial cells on oval pillars showing spreading along the major axis (scale bar 10 µm).

Interestingly, we observed that endothelial cells preferentially elongated in line with the major axis of pillars when oval-pillared substrates were used (Fig. 9).

CONCLUSIONS

Overall, this study optimized the microfabrication process of micropatterned substrates to model mechanotransduction response in endothelial cells. This proof-of-concept study allowed us to define the best size, height and pitch that promotes the adhesion of endothelial cells. Of note, we preliminary assessed how an asymmetric pillar pattern direct the elongation of endothelial cells. These results open up the possibility of study endothelial cells on substrates that features different stiffnesses and investigate their response. Further studies will be directed to investigate the cellular mechanism involved in these processes.

***Abstract*— Cell microencapsulation has been utilized for years as a means for cell shielding from the external environment while facilitating the transport of gases, general metabolites, and secretory bioactive molecules at once. In this work, we developed and characterized a novel way to obtain silk fibroin (SF) microgels (μgels) as a versatile platform to encapsulate relevant cell types for therapeutic purposes.**

***Keywords*—cell encapsulation, silk fibroin, hydrogels, cell therapy.**

I. Introduction

Cell microencapsulation is a very promising technique whereby living cells are entrapped within a biocompatible permeable membrane[1]. Such a strategy enables cells to be nourished and to secrete catabolites and paracrine factors while preventing them to exit the encapsulating device and cells and proteins of the immune system to enter[2].

In the search for the most suitable material for prolonged cell microencapsulation, natural polymer-based hydrogels have been extensively explored due to their high-water content and physical features resembling those of the extracellular matrix (ECM)[3]. Despite alginates, keratin and collagen have been exploited as starting materials for the development of microencapsulation systems, their poor mechanical properties make these materials hard to handle and process[4,5,6].

As an alternative, silk fibroin (SF) extracted from the *Bombyx mori* (*B. mori*) silkworm cocoon possesses many interesting features, such that the ease of processing, excellent biocompatibility, remarkable mechanical properties, and tunable degradability. Of note, the highly repetitive Gly-Ser-Gly-Ala-Gly-Ala (GSGAGA) motifs found in its structure enable the protein to self-assemble from its water solution into different crystalline structures, making it appealing for a wide variety of applications[7,8].

Despite being used in different material formats, a proper methodology to obtain SF hydrogel-based microcapsules is still lacking. In this context, we herein propose a clever strategy based on water-in-oil (W/O) emulsion to fabricate SF μgels obtained under mild gelation conditions and in a relatively short time to encapsulate living cells[9]. Drawing inspiration from previous works[10,11], we exploited ultrasonication as a smart way to speed up the SF gelation process. The strategy allowed the efficient encapsulation of both immortalized cells and primary myoblast cells. Encapsulated cells showed excellent cell viability and proliferation overtime. Moreover, SF μgels allowed for the release of soluble factors with paracrine activity while inhibiting antibody entry.

II. Materials and Methods

A. Preparation of SF solutions

SF solutions with different molecular weights (M_W) were obtained as previously described[12]. Briefly, 5 g of *B. mori* silk cocoons (Cantiere della Provvidenza SPA Scs Onlus) were boiled for 30 min in 2L of 0.02 M Na_2CO_3. The resulting SF solution (i.e., 30 MB) was rinsed three times in deionized water (dH_2O), dried at room temperature (r.t.), dissolved in 9.3 M LiBr at 60 °C for 4 hrs, then dialyzed for 3 days against MilliQ water. 60 mg/mL SF solutions were centrifuged to remove impurities and stored at 4 °C until use.

B. Determination of SF gelation time

The gelation time of 30 MB SF solutions was assessed by preparing 5 mL of the SF solution at different concentrations (i.e., 10, 12, 15, and 20 mg/mL) in either MilliQ water, Phosphate Buffer Saline (PBS), or cell culture medium (Dulbecco's Modified Eagle's Medium, DMEM). SF solutions underwent ultrasonication at a frequency of 20 kHz and 30 % amplitude for 5, 10, 15, and 20 s using a Fisherbrand™ Model 505 Sonic Dismembrator (Fisher Scientific). After sonication, the SF solution were kept at 37 °C and the sol-gel transition was visually monitored.

C. Preparation of cell-free SF μgels

SF μgels were prepared as illustrated in **Figure 1**. Briefly, 5 mL of sonicated 30 MB SF solution was loaded in a 10 mL syringe with a 20 G needle connected to a Tygon tube ($\emptyset = 1$ mm). The syringe was mounted onto a Landgraf LA-100 syringe pump (Colaver). The SF solution was dripped at 250 μL/min onto a 2 % (v/v) Span80-in-oil emulsion. The emulsion was next stirred at 2,000 rpm for 1 hr at 37 °C, then washed three times in PBS to separate μgels from the oil phase. SF μgels were suspended in PBS for further analysis.

D. Morphological and physicochemical characterization of cell-free SF μgels

SF μgels were analyzed using a cold field emission Scanning Electron Microscope (SEM). Briefly, SF μgels were dehydrated in graded ethanol series, then transferred into a critical point dryer and rinsed 5 times with CO_2 under supercritical conditions. Samples were mounted on conductive

tape, gold-sputtered and examined using a 10 kV accelerating voltage. SF dimension was determined by ImageJ software.

To investigate the SF µgel chemical structure, Fourier Transformed Infrared Spectroscopy (FTIR) was used. Briefly, samples were analysed with a Vertex 70 v FTIR (Bruker), and spectra were measured in the range from 400 cm^{-1} and 4000 cm^{-1}. The β-sheet content was quantified by performing self-deconvolution of the Amide I region according to literature[13].

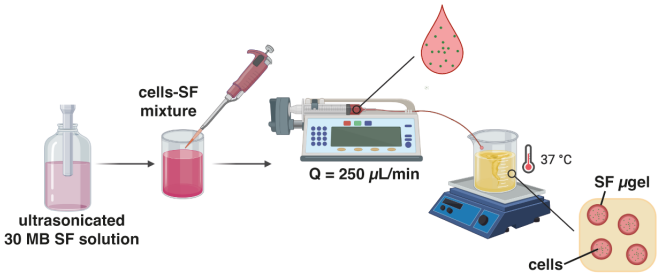

Figure 1. Schematic representation of the cell-laden SF µgels production through the water-in-oil emulsion procedure.

E. Mechanical characterization of cell-free SF µgels

SF gels fabricated as both µgels and macroscopic cylindrical samples (Ø = 10 mm, height = 16 mm) were mechanically characterized by indentation test using a Chiaro Nanoindenter (Optics11 Life) equipped with a 26 µm-SiO_2 bead tip and a cantilever with an elastic constant of 0.48 N/m. To compare the mechanical characteristics of µgels and macroscopic gels, microindentation tests (800 nm/s with an indentation depth of 2.5 µm) were performed both on the surface and in the core of the samples. The compressive modulus was determined by Hertzian best fit of the linear part of the indentation curve.

F. L929 cell encapsulation in SF µgels and biochemical characterization of cell-laden SF µgels

Mycoplasma-free L929 cells were routinely cultured in high glucose DMEM supplemented with 10 % (v/v) fetal bovine serum (FBS), 1 mM sodium pyruvate, 10 mM HEPES buffer, 100 U/mL penicillin, 0.1 mg/mL streptomycin, and 2 mM glutamine (hereafter referred to as complete DMEM, cDMEM) in a humidified atmosphere and 5 % (v/v) CO_2 at 37 °C (hereafter referred to as standard culture conditions).

L929 cells were detached with 1× trypsin-EDTA solution and resuspended in cDMEM. L929 cell suspension was next mixed 1:4 (v/v) with 30 MB SF solution to give 2.7 × 10^7 cells/mL and a SF concentration of 15 mg/mL. Next, 5 mL of the cell-SF mixture was loaded into a 10 mL syringe and µgels were obtained by batch emulsion as illustrated in Figure 1A. The resulting emulsions were resuspended in cDMEM and kept in standard culture conditions for 1, 4, and 7 days.

Cell viability was assessed at different time points by Live/Dead Cell Viability assay. Briefly, at given time points L929 cell-laden µgels were rinsed with PBS, incubated with 1 µM calcein AM and 2.5 µM propidium iodide (PI) to stain live and dead cells, respectively, and incubated for 15 min at 37 °C in dark. Samples were next washed with PBS, resuspended in cDMEM and analyzed using a fluorescence microscope.

Cell proliferation within µgels was evaluated by quantifying the DNA content. Briefly, at different time steps (i.e., 1, 4, and 7 days post encapsulation) cell-laden SF µgels were washed in PBS, resuspended in 200 µL of 0.01 % (v/v) Triton X-100 in 50 mM HEPES (homogenization buffer), and subjected to three freeze-thawing cycles. Next, samples were disrupted with a tissue homogenizer and centrifuged at 12,000 rpm at 4 °C for 5 min. Next, 20 µL of each supernatant were mixed with 10 µL of 200× SYBR Green I, incubated 15 min in dark, then the fluorescence was read with a Sinergy H1 Spectrophotometer (Biotek; λ_{ex} = 497 nm, λ_{em} = 520 nm). To determine the DNA content in the samples, a standard curve using salmon sperm DNA was used. The DNA content was normalized to the total protein content of each sample, as determined by the bicinchoninic acid (BCA) assay. Data were expressed as µg of DNA per mg of SF.

G. Primary myoblasts encapsulation in SF µgels and assessment of the release of paracrine factors

Transgenic SOD1-G93A (male) mice were purchased from Charles River, Inc and maintained and bred at the Fondazione ICCRS Istituto Neurologico "C. Besta" in compliance with institutional guidelines, international regulations (EEC Council Directive 86/609) and project approvals from the Italian Ministry of Health (ref. IMP183/2018-PR). At week 18, SOD1-G93A were euthanized with CO_2 and gastroctnemius muscles biopsies obtained[14]. Muscle fragments were seeded onto 60 mm dishes and cultured in DMEM supplemented with 20 % FBS, 100 U/mL penicillin, 0.1 mg/mL streptomycin, 2 mM glutamine, 10 µg/mL insulin, 2.5 mg/mL basic fibroblast growth factor (bFGF) and 10 ng/mL epidermal growth factor (EGF). After 10-15 days, confluent monolayers were detached and subcultured. Primary myoblasts were purified by means of pre-plating treatment.

Myoblasts-encapsulating SF µgels were prepared as described herein above and kept in standard culture conditions for different periods (i.e., 1, 4, and 7 days). At any time point, 1 mL of cDMEM containing SF µgels was collected, then µgels and supernatants were separated by gentle centrifugation.

TRIzol reagent (Thermo Fisher Scientific) was used to extract RNA from myoblasts-SF µgels. RNA quality was next assessed by means of a 2100 Nano Bioanalyzer (Agilent Technologies). The gene expression analysis was performed by means of quantitative Real-Time Polymerase Chain Reaction (qRT-PCR). Briefly, total RNA was then retro-transcribed using the SuperScript Vilo cDNA Synthesis kit (Thermo Fisher Scientific) in a thermocycler system, according to the following thermal protocol: 25 °C for 10 min, 42 °C for 60 min, 85 °C for 5 min. Next, 0.5 µL of cDNA (corresponding to 10 ng of RNA) were mixed with 5 µL of Fast Universal Master Mix, 3.5 µL of RNAse-free water, 0.5 µL of TaqMan® gene expression assay (specific for the following genes: Neural cell adhesion molecule 1 (Ncam1) for myoblast phenotype, Paired box 3 (Pax3) for myoblast proliferation, and apoptosis regulator (Bcl2)). The cDNA was amplified (in duplicate) at the following thermal protocol: 95 °C for 20 s (reverse transcriptase inactivation), 95 °C for 1 s, and 60 °C for 20 s (40 PCR cycles). The 18 S was used as the housekeeping gene. The mRNA expression levels were normalized against 18 S, and the relative mRNA expression levels were calculated using the formula $2^{-\Delta\Delta Ct}$.

To evaluate the release of paracrine factors from encapsulated myoblasts, we quantified the amount of vascular endothelial growth factor (VEGF) in undiluted supernatants. The amount of VEGF was assessed using a Bio-Plex ProTM Mouse Cytokine 9-plex immunoassay 96-well kit (Bio-Rad Laboratory). Supernatants were transferred into a 96-well plate, then the plata was read with a BioPlex 200 system (Bio-Rad), powered by Luminex xMAP technology. Data were expressed as pg of VEGF/mL.

H. Statistical analysis

Statistical analysis was carried out with GraphPad version 8 (GraphPad Software, La Jolla, CA, USA). Data were initially analyzed using the Shapiro-Wilk normality test. Comparisons between groups were performed with one-way analysis of variance (ANOVA) and multiple t-tests. Significance was retained when $p < 0.05$. Experiments were performed at least in triplicate.

III. Results and Discussion

In recent years, therapeutic strategies relying on cell encapsulation have been in the spotlight. However, open challenges related to limited cell survival and passive cell displacement have fueled much interest in the design of novel delivery vectors. In this scenario, hydrogels have emerged as a powerful solution to these quests.

A. SF µgels fabrication and characterization

In the present study, ultrasonication was used to trigger the sol-gel transition of the SF. Because the gelation time is a critical parameter for the production of hydrogels and the subsequent cell encapsulation, the kinetics of SF gelation was carefully characterized to develop a fabrication protocol for the production of µgels. We thus assessed the effect of different SF concentrations and sonication times on the ultimate gelation time. As shown in **Figure 2A**, the SF gelation time invariably decreased with increased sonication time, irrespective of the SF concentration used. We thus decided to sonicate a 30 MB SF solution at a concentration of 15 mg/mL for 15 s at 30 % amplitude for further experiments. Of note, this allows the gelation of SF solutions after 1 hr post-sonication, thus providing enough time to conveniently mix the sonicated solution with cells, while SF is in the sol state, and to create micro-sized droplets in the emulsion. The so-formed cell-free SF µgels were morphologically characterized. Optical images of the µgels confirmed the presence of spherical shaped µgels, with a diameter of ≈ 200 µm (**Figure 2B**), while SEM analysis allowed us to appreciate the peculiar microstructure of the µgels, which is characterized by the presence of a dense network of nanosized silk fibrils (Ø ≈ 20 nm, **Figure 2C**). Spectroscopic analysis using FTIR showed the presence of β-sheet content, that is typical of highly crystalline and water-soluble SF (data not shown).

The mechanical properties of SF µgels and macroscopic SF gels were assessed by using microindentation tests. As reported in **Figure 2D**, the SF µgels showed compressive moduli ranging between 15 kPa and 25 kPa, with little influence of SF concentration on the compressive modulus. Of note, when prepared at 12 and 15 mg/mL SF concentration, µgels displayed a compressive modulus 2-fold greater than the respective macroscopic counterparts (**Figure 2E**), thus suggesting a strong influence of the microstructure on the overall mechanical properties. These results suggest that the microstructure of SF in the µgels leads to a significant improvement in their overall mechanical performances, that is, one of the most critical issues when using natural polymer-derived hydrogels.

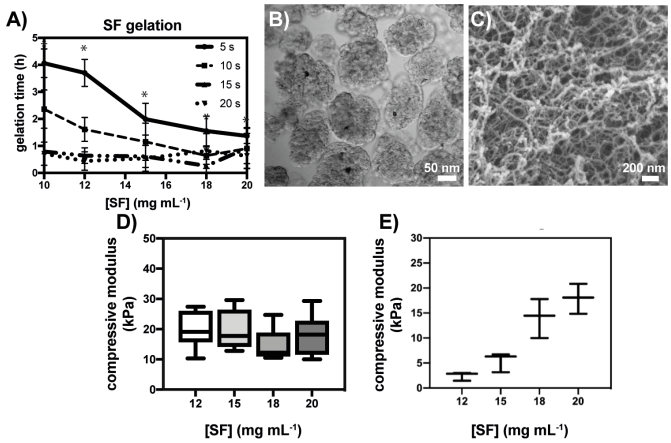

Figure 2. **A**) Gelation time of SF solutions prepared in DMEM at different SF concentrations as a function of the ultrasonication time. Data are presented as mean ± SD (n = 3), $p < 0.05$. **B**) Digital picture of the 30 MB SF µgels at 15 mg/mL SF concentration imaged through an optical microscope. Scale bar = 50 µm. **C**) SEM micrograph of the internal microstructure of SF µgels. Scale bar = 200 nm. **D-E**) Compressive elastic moduli of **D**) SF µgels and **E**) macroscopic SF gels calculated through microindentation tests. Data are presented with inter-quartile range box blots and whiskers indicating the min and max percentiles. The solid lines in the box represent the median value of each dataset.

B. Cells encapsulation and paracrine factors release

Hydrogels used for developing encapsulation systems must fulfil three main requirements, namely i) achieving high encapsulation efficiency, ii) maintaining high viability, iii) and optimizing the environment in which the cells are embedded. Therefore, all three of these aspects were tested for the SF µgels.

To evaluate the feasibility of the encapsulation process, the viability of encapsulated L929 was monitored overtime by means of the Live/Dead assay. As shown in **Figure 3A**, the number of viable cells embedded in the µgels steadily increased from ≈ 30% on day 1 to ≈ 70% on day 7, thus indicating an excellent biocompatibility of the SF µgels. Of note, a significant increase in the total cell DNA content was found in SF µgels after 4 and 7 days of culture with respect to day 1 (**Figure 3B**). Overall, these results demonstrated the reliability of our protocol to fabricate cell-encapsulating SF µgels and that SF µgels kept cells alive once encapsulated. Another extremely important aspect of cell-encapsulating hydrogels relies on their porosity, as it determines their ability to allow molecules diffusion in and out of the hydrogel while preventing the passage of cells.

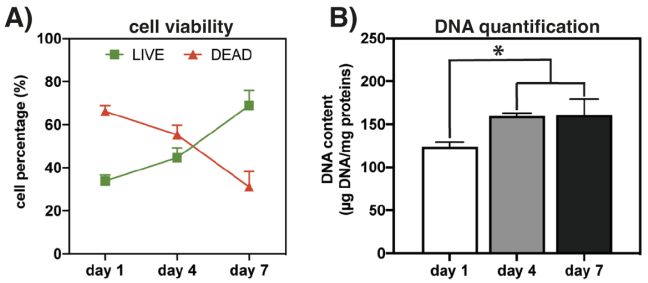

Figure 3. A) Quantification of cell viability of encapsulated L929 cells in SF µgels cultured for 1, 4, and 7 days post-cell encapsulation. **B)** Quantification of DNA content, expressed as µg of DNA per mg of protein in L929-encapsulating SF µgels cultured for 1, 4, and 7 days. Data are expressed as mean ± SD (n = 3), $p < 0.05$.

To this aim, we encapsulated extremely sensitive myoblasts into SF µgels, and investigated their proliferation and secretion of VEGF (40 kDa) outside the capsules. The expression of three regulatory messenger RNAs involved in myoblasts survival, namely Ncam1, Pax3, and anti-apoptotic regulation, namely Bcl2, was thus assessed by means of qRT-PCR. As shown in **Figure 4**, a significant increase in the expression levels of the three messengers was found after 7 days of culture, thus suggesting that the microenvironment inside SF µgels was suitable for the maintenance of myoblasts cell functions.

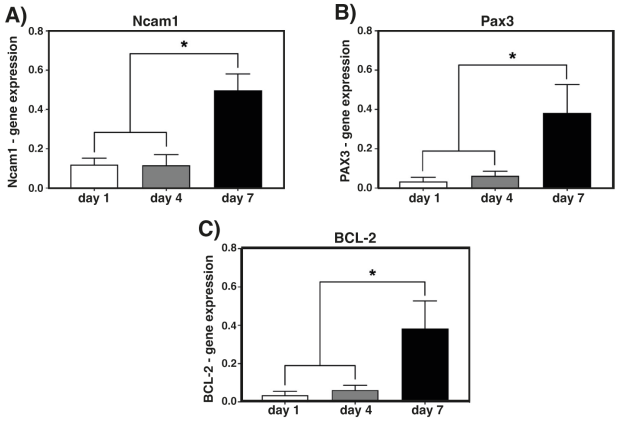

Figure 4. Gene expression levels of **A**) Ncam1, **B**) Pax3 and **C**) BCL-2 genes, as determined by qRT-PCR analysis, in total RNA extracted from myoblasts on days 1, 4, and 7 post-cell encapsulation. Relative expression data are shown as mean ± SD (n = 4) of $2^{-\Delta\Delta Ct}$ values normalized against endogenous control 18 S. *$p < 0.05$.

Moreover, we also assessed the presence of paracrine factors, such as VEGF, in the cell supernatants on 1-, 4-, and 7-days post-cell encapsulation. As shown in **Figure 5A**, the VEGF levels slightly increased from day 1 (4.5 pg/mL) to day 4 (9 pg/mL) and significantly rose further on day 7 (22 pg/mL). This implies that some signalling biomolecules and metabolites can freely diffuse out of the µgels. On the other hand, other macromolecules ($M_W \geq 150$ kDa), such as IgG antibodies, cannot enter the µgels, but stick on their surface (**Figure 5B**). Overall, such results suggest that the SF µgels possess a selective permeability to biomacromolecules, and thus represent a promising cell encapsulation system.

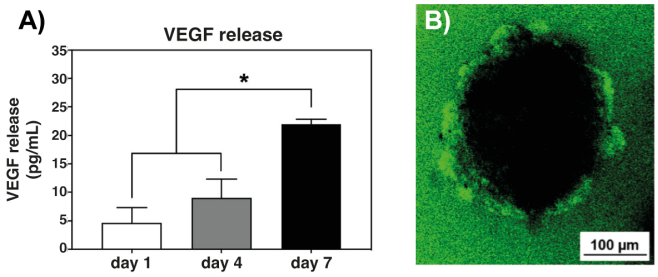

Figure 5. **A**) VEGF levels, expressed in pg/mL, quantified into the supernatant on days 1, 4, and 7 after cell encapsulation were measured by multiplex immunoassay. Data are expressed as mean ± SD (n =3), *$p < 0.05$. **B**) Assessment of the permeability of the SF µgels to FITC-donkey anti-mouse IgG imaged using fluorescence microscopy. Scale bar = 100 µm.

IV. Conclusion

In this study, we proposed a simple method for the fabrication of cell-encapsulating SF µgels. We optimized fabrication parameters to obtain µgels displaying a gelation time around 1 hr, thus allowing cell loading and cell viability overtime. The resulting cell-SF µgels were 200 µm in size and displayed a selective porosity that allowed the exchange of metabolites and gases to keep the encapsulated cells alive and proliferating, and the release of biomacromolecules such as VEGF (MW = 40 kDa) through the gel network, while restricting the entry of other molecules such as IgG. This work thus laid the ground for the development of advanced therapies.

***Abstract*—The intestinal epithelium, which consists mostly of an enterocytic monolayer, forms a physical barrier that is pivotal in the molecular absorption process. Despite the need for complex intestinal *in vitro* models to carry out predictive and reliable pharmacological investigations, cell cultures are mainly performed using standard culture systems in which cells are cultured on membranes in static conditions, thus failing in replicating the micro-physiological environment. We developed a modular bicompartmental versatile culture system, named True Tissue on Platform (TTOP) which allows to host tunable culture substrates, such as microporous membranes or scaffolds. After the biological validation with intestinal epithelial cells, we focused on the substrate's characteristics, by comparing different scaffolds and coatings, to obtain a biomimetic intestinal *in vitro* model. The results suggest that gelatin based substrates promote proliferation and better support colonization.**

***Keywords*—*in vitro* model, intestine, scaffold, microphysiological system.**

I. INTRODUCTION

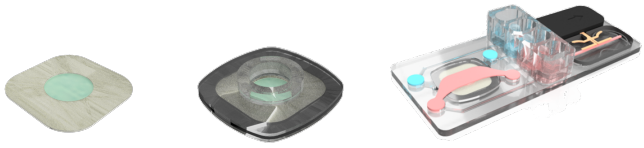
In the bioengineering field, one of the current main challenges is to develop reliable and predictive *in vitro* models which could replicate the physiological microenvironment. Indeed, the need for recapitulating the complexity of the human cell/tissue microenvironment for physio-pathological studies and assessment of new drugs and treatments, has driven the development of Micro Physiological Systems (MPSs). MPSs better mimic the key structures and functions of the biological tissues, aiming at revolutionize the pharmaceutical industry, according to the reduce, refine, and replace animal models (3Rs) principles [1]. In this scenario, the proper selection of cell sources and culture substrates plays a fundamental role in bridging the gap between *in vivo* and *in vitro* models. Indeed, *in vivo*, the function of an organ emerges from the interaction between complex cellular structures, physiochemical factors within the extracellular matrix and secreted by various types of cells, and external electromechanical stimuli [2]. The recapitulation of the tissue microenvironment opens the way to the development of new *in vitro* platforms for the investigation of the mechanisms underpinning cell behavior and tissue/organ functionality as well as pathology onset and progression, the screening of newly developed therapeutic approaches, the assessment of toxicity and the development of personalized therapies. However, despite the need for complex *in vitro* model to carry out predictive and reliable pharmacological investigations, standard cell cultures are mainly performed using standard culture systems that lack of versatility and do not allow the choice of different culture substrates, although they are crucial to enhance the biomimicry of the model and its predictive potential.

Drugs orally delivered follow a precise path starting from the mouth, and terminating in the intestine. The latter represents the major absorptive site, which consists mostly of an enterocytic monolayer that forms a physical barrier that regulates the paracellular transport of ions, metabolites, and macromolecules. Paracellular transport and barrier integrity are pivotal in drug absorption, hence in pharmacokinetic and pharmacodynamic studies. Therefore, complex intestinal epithelium *in vitro* models are required for carrying out more predictive and reliable pharmacological investigations. Previous *in vitro* models based on monocultures of intestinal cell lines (e.g., Caco-2) were successfully used as frontline assays for intestinal drug absorption/permeability but were limited as a routine screen for intestinal toxicity [3]. Although these methods have facilitated the discovery of many basic biological processes, enabling high-throughput analysis, they often fail to provide an adequate representation of key physiological characteristics.

As stated by Horvath and colleagues [4], the main limitations of current *in vitro* models can be summarized as follows:

- Most cell-based assays are based on immortalized cells, that could have lost their epigenetic and physiological fingerprint [5]
- Conventional *in vitro* approaches usually are based on static systems, not able to provide continuous medium renewal and waste removal [6]
- Cells are often cultured on planar, stiff substrates (2D), instead of 3D ECM-like microenvironments, perturbing cellular functions and differentiation [7] [8] [9]

Therefore, we aim at developing an innovative *in vitro* intestinal model, based on a novel cell culture platform, by evaluating different culture substrates in order to better mimic the physiological microenvironment, and perspectively perform dynamic cultures with human-derived biological material, thus providing a useful tool to carry out predictive and reliable pharmacological investigations.



II. MATERIALS AND METHODS

These studies were performed by using a innovative platform, designed by our research group, named True Tissue

on Platform (TTOP). First, we carried out the biological validation of the TTOP system with intestinal epithelial cells. Then, thanks to the possibility to host different substrates in TTOP, we focused specifically on the substrate's features, by comparing different coatings and scaffolds, with respect to standard microporous membranes.

A. Platform

In order to realize a biomimetic intestinal *in vitro* model, a novel bi-compartmental versatile modular culture system has been employed. The TTOP allows real time imaging and direct evaluation of viability/growth of the biological sample without affecting the culture, but also permeability changes, molecule absorption or localization.
The innovative strategy of TTOP is the cartridge-based design, that enables the easy retrieval of the biological sample without any morphological damage, to perform post treatment analyses, and the possibility to reuse the biological material, enabling to design sequential treatments and conditioning on the same sample. Thanks to the aforementioned features, two different TTOP modules have been designed, in order to perform static and dynamic cell cultures respectively.
The TTOP static module is based on an "open-well" design, compatible with standard 12-well plates, enabling the preparation of an intestinal *in vitro* model on a microporous membrane. Once the cells grow until confluence in static conditions, the "open-well" static module can be placed in the "closed-well" perfusion module, enabling continuous recirculation of apical and basolateral culture media generated with embedded piezoelectric micropumps. Bubble traps are integrated to capture flowing microbubbles. Flow rates are programmed through an Arduino-based control unit. Cells can be monitored during the culture by bright field microscopy, thanks to the optical accessibility to both sides of the sample, while at the end it is possible to retrieve the cartridge with a simple procedure and perform fluorescence microscopy to verify the expression of membrane and junctional markers.

B. Biological validation

For what concerns the biological validation of the gut model, a human colorectal adenocarcinoma epithelial cell line (Caco-2) has been used. Cells were cultured in low glucose Dulbecco's Modified Eagle's Medium (DMEM), containing 1% L-glutamine, 1% non-essential amino acids, 1% of Pennycilin-Streptomicin , supplemented with 10% heat-inactivated Fetal Bovine Serum (FBS). After the expansion of Caco-2 cells in T75 or T25 flasks, the growth rate and morphology in the TTOP static module has been monitored during long-term cell cultures. In detail, once at confluence, cells were passaged with 0.25% trypsin/1mM EDTA and seeded in TToP static preparation modules, on microporous membranes ($3x10^4$ cells/system) and cultured in static conditions in a 37°C, 5% CO2 standard incubator. In order to assess the barrier functionality of the cellular constructs, the Trans Epithelial Electric Resistance (TEER), using the EVOM3 & STX2-PLUS electrodes, was measured at different time points. At the same time, the TEER values were compared with the data obtained from the live staining of the samples, thus correlating the trans epithelial electric resistance with the confluency of the cells. Caco-2 growth was monitored every two days both with TEER measurements and Hoechst 33342 live imaging, by using a Olympus IX83 inverted microscope, until 25 days of culture, obtaining increasing TEER values over time. Immunofluorescence (IF) was performed for the presence of Villin (Rabbit/IgG anti-Human, Mouse, Rat Villin; 1:1000, Invitrogen, Eugene, OR) and ZO-1 (Mouse/IgG1 anti-Human ZO1-1A12; 1:400, Invitrogen, Eugene, OR). The antigens localization was revealed with AlexaFluor 594 Donkey anti-Rabbit IgG (H+L) and AlexaFluor 488 Donkey anti-Mouse-IgG (H+L) (1:500, 45min at RT, Molecular Probes - Invitrogen, Eugene, OR), respectively. Nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI, 0.2nM, 10min at RT, Sigma Immunochemicals, St Louis, MO) and F-actin was stained with Phalloidin–Tetramethylrhodamine B isothiocyanate (50μg/ml, 45min at RT, Sigma Immunochemicals, St Louis, MO). Sections were examined under a Olympus fluoVIEW FV3000RS confocal microscope, free projection max images were obtained from singles channel acquired Z-series.

C. Substrate functionalization

To develop a three-dimensional cellular construct it is crucial to use an appropriate culture substrate which could promote a self 3D cellular organization and differentiation. To verify the dependency of cellular behavior on the culture substrate, we carried out a comparative study by using Caco-2 cell lines cultured on bare polycarbonate porous membranes, gelatin coated membranes and various types of scaffolds, such as gelatin based scaffolds and silk fibroin based scaffolds. Up to now, investigations on gelatin based scaffolds were performed and further characterizations are still ongoing. For what concerns the coatings, since it is known that the gelatin melts over time in the incubator, we monitored if, at a fixed concentration (5 μg/ml of gelatin in PBS), different volumes of gelatin coating (50 μl, 150 μl) behave differently. Caco-2 expansion and seeding in TTOP static preparation modules was carried out as described previously, as well as Caco-2 growth rate monitoring through Trans Epithelial Electric Resistance, Hoechst 33342 live imaging, and IF analyses. IF endpoint assays evaluated the differentiation by staining

tight junctions and specific membrane proteins and the three-dimensional architecture, thanks to Z-stack imaging.

III. Results

The long-term experiments carried out with Caco-2 cells in TTOP static modules demonstrated the suitability of the device to realize *in vitro* intestinal models. Indeed, as shown in fig. 2, which represents a representative curve of TEER values over 25 days, the trans-epithelial electrical resistance kept increasing over time, meaning that the cells grew until confluence and then differentiated according to their phenotype.
During the same experiments, Caco-2 growth rate was also monitored through Hoechst 33342 live staining. According to fig. 3, Caco-2 cells reached confluence and formed a monolayer after 14 days of culture on bare polycarbonate porous membranes, as it was previous shown in studies with standard polycarbonate cell inserts [10]. Afterwards, the cells started to differentiate, therefore TEER values increase rapidly from day 14 to day 25. IF endpoint analyses, by staining the nuclei, villin and the tight junctions (fig. 4), confirmed the cell differentiation in the TTOP static module.

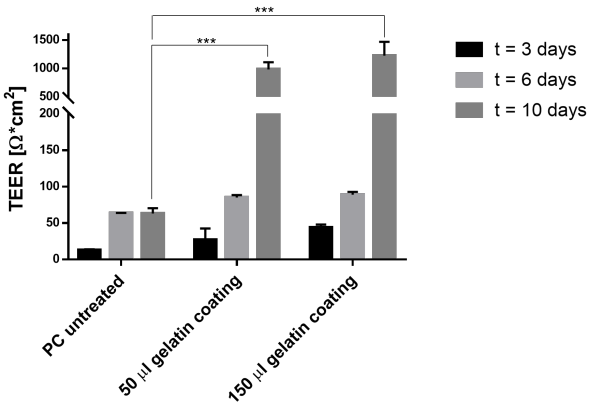
Fig. 3: Representative Hoechst 33342 live imaging of Caco-2 cells cultured in TTOP static module. (a) refers to Caco-2 cells cultured for 7 days; (b) 11 days; and (c) 14-25 days. In this case Caco-2 cells reached confluence and created a uniform monolayer

(a) Villin, DAPI **(b)** ZO-1, DAPI

Fig. 4: DAPI, Villin and ZO-1 staining on Caco-2 cells cultured in TTOP static module

For what concerns the culture substrates, the results showed that they played a fundamental role in the formation and tightness of the gut barrier. Indeed, with respect to the cells cultured on bare membranes, the gelatin coated samples and the scaffold-based cultures reached a monolayer earlier. This was confirmed also by TEER measures at different time points. Fig. 5 compares the trans-epithelial electrical resistance of Caco-2 cells cultured on polycarbonate porous membranes either untreated or with gelatin coatings. After 10 days of culture, the gelatin coated samples have much higher TEER values than the untreated ones. At the same time, no relevant differences have been observed among the samples coated with different volumes of gelatin.
Although there aren't standard TEER values for Caco-2 monolayers, previous studies have demonstrated that confluent and differentiated Caco-2 cells have TEER values ranging from 250 to 2000 Ωcm^2 [11] [12] [13]. Therefore, both data shown in Fig. 2, for Caco-2 cells cultured on bare polycarbonate membranes for 25 days, and data shown in Fig. 5, for the gelatin coated samples, are consistent with previous studies. On the other hand, Caco-2 cells cultured on untreated polycarbonate substrates after 10 days (fig. 5) have still low TEER, due to the fact the cells hadn't reached confluence yet, as shown in fig. 6.



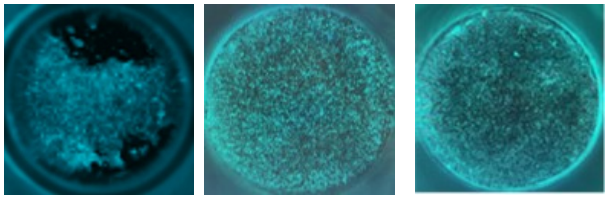


Fig. 5: Representative TEER for Caco-2 cells cultured in TTOP static module on polycarbonate porous membrane either untreated or with different gelatin coatings

Other than gelatin coatings, also gelatin-based scaffolds were tested as Caco-2 culture substrates. Fig. 6 shows Hoechst 33342 live staining images of Caco-2 cells cultured either on untreted (fig. 6a) or gelatin coated (fig. 6b) polycarbonate porous membranes or on gelatin-based scaffold (fig. 6c) after only 7 days of culture. It is evident that the presence of gelatin promote cellular proliferation, and that the cellular distribution is homogeneous within the culture surface. Indeed, with respect to the cell cultures on bare polycarbonate membranes, these results suggest that gelatin promotes an even distribution of the cells on the surface. Moreover, IF staining demonstrated that the substrate properties promote differentiation.

(a) **(b)** **(c)**

Fig. 6: Representative Hoechst 33342 live imaging of Caco-2 cells cultured in TTOP static module for 7 days. In fig. (a) cells are cultured on untreated polycarbonate porous membrane, (b) on a gelatin coated polycarbonate porous membrane, (c) on a gelatin scaffold.

IV. Conclusion

In conclusion, the TTOP can be considered a versatile system since it enables to host different culture substrates without altering other environmental conditions. Indeed, the use of the same support both for polycarbonate membranes and scaffolds makes it possible to really analyze the influence of the substrate on the culture. On the other hand, previous studies were carried out employing different devices to host different substrates, thus introducing a bias in the experimental conditions. Therefore, the unique characteristics of TTOP allow to carry out comparative studies with different culture substrates in order to tune the extracellular environments and develop a predictive intestinal barrier model.

The biological results demonstrated that the mechanical features of the gelatin based substrates promote differentiation, and suggest that the formation of three-dimensional cellular constructs is enhanced accordingly.

Up to now, the device's ease of use and tunability allowed to use different culture substrates in the same experiments. In addition, in perspective, TTOP could enable simple preparation in the static module and advanced dynamic conditions for intestinal barrier tissue in-vitro replication, by using the perfusion module. Therefore, further studies could investigate dynamic enterocytic cultures in the TTOP perfusion module. The optical access to both sides of the hosted sample also enables live imaging studies (absorption of drugs, circulating cells) under dynamic controlled conditions.

***Abstract*— Osteochondral defects are one of the most motor-disabling conditions worldwide. A limited intrinsic regenerative capability features cartilage and bone tissues involved in large osteochondral lesions and, to date, there is no clinical treatment capable of appropriately restoring them. We report an innovative injectable composite hydrogel based on gelatin methacryloyl (GelMA) loaded with dispersed fibers made of a blend polycaprolactone (PCL)/GelMA. The fibers were produced by electrospinning, and cut in stripes using a cryostat-based cutting approach. Their embodiment in the GelMA matrix improved the compressive mechanical properties of the pristine GelMA hydrogel. Specific conditions (needle size: 18G and 20G; temperature: 30 and 37°C) were found compatible with the injection of the composite hydrogel, before crosslinking, matching the criteria reported in EN ISO 7886 1:2018 standard. These preliminary results are promising in view of the optimization of injectable reinforced GelMA-based formulations to be used for the treatment of osteochondral injuries.**

***Keywords*—Osteochondral defects, injectable composite hydrogel, electrospinning, dispersed fibers.**

I. INTRODUCTION

The osteochondral (OC) unit consists of the multilayer cartilage tissue and the subchondral bone plate, characterizing the diarthrosis joints. Chondral and OC defects are lesions that result from osteoarthritis or traumatic events, leading toward an irreversible degenerative process of the joint structure. These injuries often hit elderly people in load-bearing joints, such as the knee [1]. The regenerative capacity of these tissues is limited, and the mechanisms of attempted healing and the pathophysiological mechanisms are still not completely understood [2].

Among possible clinical approaches, open surgery related to either cellular and acellular scaffolds usage for regenerative purposes, has high risks of infection and the need for hospitalization, matching site implantation issue, with related iatrogenic conditions and the high costs related to cell use and manipulation. Minimally invasive injectable materials might overcome these issues, guaranteeing the same clinical outcomes [4].

Among the approaches proposed for OC tissue applications, injectable natural hydrogels represent promising candidates given their cell-friendly properties, osteo- and chondrogenic potential, and capability to fill irregular defects. However, one of the main limitations of injectable hydrogel-based materials (especially natural ones) is the control of their mechanical properties, which is important for OC treatment. In fact, it has been shown that mechanical stimuli are crucial in maintaining a healthy OC tissue [5], as well as in promoting its regeneration (i.e., stiffness influences differentiation) [6][7].

Gelatin-based materials, particularly gelatin methacryloyl (GelMA) are attractive options in this field [8]-[10]. However, considering injectable formulations, no studies report the possibility to match the mechanical properties of OC biological tissues. To tune the properties of naturally-derived materials their combination with synthetic components (e.g., semi- or interpenetrated polymeric networks and copolymer systems) and with reinforcement fillers are under investigation [11]-[15]. Recently, fiber-based fillers have attracted interest due to their capability to provide additional features to hydrogel-based composite materials.

In this study, an injectable composite hydrogel made of GelMA as a matrix, reinforced with a fibrous filler made of a PCL/GelMA blend, is proposed, with the final aim to improve GelMA mechanical properties, in view of a future injectable solution for OC treatment, crosslinkable *in situ*. We report the optimization process for the production of the dispersed fibers (DFs) to be embedded in the GelMA solution, as well as the characterization of the composite in terms of mechanical properties and injectability.

II. MATERIALS AND METHODS

A. GelMA synthesis

Gelatin (Gel, type A, strength: 300, Sigma Aldrich, Merck) was dissolved in a pre-heated PBS at 50 °C to achieve a concentration of 10 % w/v. Methacrylic anhydride (MA, 0.6 g per Gel gram) was added and the solution was left reacting for 2 h. The solution was purified by dialyzing against deionized water (DIW) at 40 °C for 7 days. Finally, the solution was freeze-dried (FreeZone 2.5 Plus, Labconco) and stored at -80 °C.

B. Electrospun mesh and DFs fabrication

For the electrospinning solution, PCL (15 % w/v) and GelMA (5 % w/v) were dissolved separately in acetic acid and stirred at room temperature (RT) for 12 h and 1 h respectively in a sealed glass flask. Then, the GelMA and PCL solutions were mixed (ratio 1:1) to obtain PCL75:GelMA25 at 20 % w/v total polymer concentration and stirred for 1 h to achieve a homogeneous solution. The electrospinning parameters used for the fabrication of aligned fiber meshes are reported in Table I [16].

TABLE I: ELECTROSPINNING PARAMETERS

Parameter	*Value*
Rotating mandrel speed	2000 rpm/min
Electric field	16 kV
Distance (syringe-collector)	13 cm
Flow rate	0.5 mL/h
Electrospinning time	1 h

Then, the electrospun aligned meshes were cut (1x1 cm^2), rolled in a cylindrical shape, embedded in a cryomedium (PolyFreeze. Sigma Aldrich, Merk), and then perpendicularly cut using a cryostat (YD-1900, JINHUAYIDI), setting a cutting thickness of 20 µm. The frozen slices were washed in DIW and centrifugated at 4000 rpm/min for 5 min sequentially three times. The DFs were collected and then freeze-dried.

C. *Photocrosslinking of GelMA, GelMA+DFs*

Freeze-dried GelMA was dissolved in DIW to reach a 10 % w/v concentration. To obtain the DFs-loaded GelMA (GelMA+DFs) suspension, 0.5 % w/v DFs was added to the GelMA solution. Irgacure 2959 (Sigma Aldrich, Merk) was used as photoinitiator (0.5% w/v), and added to GelMA solution and GelMA+DFs suspension. They were poured into a cylindrical mold (diameter: 7 mm, height: 5 mm) for the photo-crosslinking by a UV light source (l = 365 nm, 3.5 $W/cm^{2,}$ Lightninningcure LC5 lamp, Hamamatsu) for 2 min.

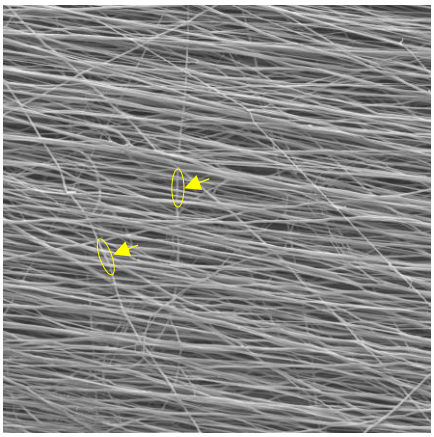
D. *Morphological analysis*

Aligned electrospun mesh, DFs and lyophilized UV-crosslinked samples (GelMA+DFs) were observed by Scanning Electron Microscope (SEM, Phenom XL, Thermo Fisher Scientific) to evaluate the fiber size, orientation and directionality distribution (ImageJ), the surface morphology and the interaction of DFs with the GelMA matrix.

E. *Injectability*

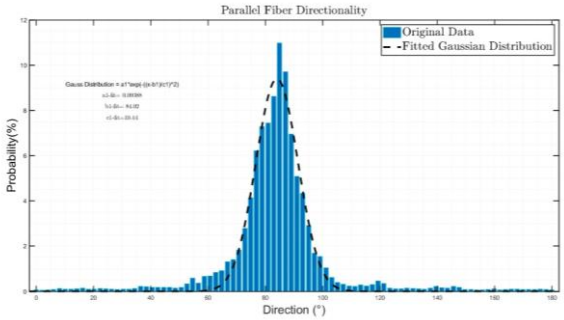
Injectability tests (n = 3) were performed on solutions of DFs-free GelMA and GelMA+DFs using a custom-made set-up adapted to an MTS electro-mechanical machine (MTS, 1/MH), equipped with a thermostatic chamber and a 5 kN load cell. The test was carried out at different temperatures (20, 25, 30, and 37 °C) and needle diameters (18, 20, and 22G). The test speed was set at 1.6 mm/s, corresponding to a 0.2 mL/s flow rate [17]. All the parameters selected (needle types and injection velocity) were based on those used for intra-articular [18] and *in-vivo* injections [19], following the EN ISO 7886 1:2018 standard.

F. *Mechanical characterization*



An Instron 5965 machine (1 kN load-cell) was used to perform compressive mechanical tests on photo-crosslinked GelMA and GelMA+DFs samples (n = 3). A 1 mm/min compression deformation rate was applied. The following mechanical parameters were considered: compressive modulus (slope of the curve in the strain range of 0-10 %), toughness (area under the curve), and maximum deformation and stress.

III. RESULTS AND DISCUSSION



A. *Morphological analysis*

The electrospun GelMA/PCL meshes showed no aggregated beads and a diameter of 724.9 ± 159.4 nm (Fig. 1a), which is comparable with the diameter size of collagen fibril bundles in the native chondral tissue [20]. The fibers were highly oriented along a preferential direction (Fig.1b). Increasing the mandrel rotation speed can improve fiber orientation reducing the presence of transversal fibers. However, an optimal match between the percentage of oriented fibers and fiber diameters was set at 2000 rpm/min to maintain adequate mechanical properties.

As shown in Fig. 2a, cutting the electrospun matrix with a cryostat, the corresponding length of the obtained strips is 51.96 ± 18.6 µm, a value dimensionally comparable with those reported in [13]-[15]. The DFs, once embedded in the GelMA matrix, showed a 3D organization (Fig. 2b). For DFs, it was hypothesized that the interaction between the DFs and the GelMA matrix determined a reinforcing mechanism. Indeed, the presence of GelMA in both DFs and matrix could generate a surface chemical affinity, qualitatively evaluable (Fig. 2b, yellow arrows). The interaction between the filler of fibers and the matrix material was hypothesized in another study [20]. Future analyses will be performed to assess the chemical interaction between these components.

(b) DFs within the GelMA matrix act as web structures. Yellow arrows indicate the adhesion point between the matrix and DFs. Scale bar= 20 μ*m*.

B. Injectability

For 20 and 25 °C, the DF-free GelMA solution was not injectable with the selected needle sizes due to the proximity of the sol-gel transition temperature ($T_g \approx 20$ °C, data not shown). Therefore, the GelMA+DFs solution was not tested at 20 and 25 °C. At 30 and 37° C, both DFs-free GelMA and GelMA+DFs were injectable and the injection force profiles were lower than the upper limit value of 10 N [17] with smooth profiles and well-defined plateau regions for 18G and 20G needles (Fig. 3a-c). The plateau region indicated a homogeneous and continuous extrusion of the material. The lowest injection force value (F = 2.3 ± 0.4 N) was found at 37°C using an 18G needle for DFs-free GelMA solution (Fig. 3c, red line). The presence of DFs did not significantly affect the injectability at 30°C by using both the 18G and the 20G needles and at 37°C with the 18G needle (Fig. 3b). However, using a 20G needle at 37 °C, the maximum peak force was higher (F = 5.6 ± 0.4 N) compared to the bare GelMA (Fig. 3d).

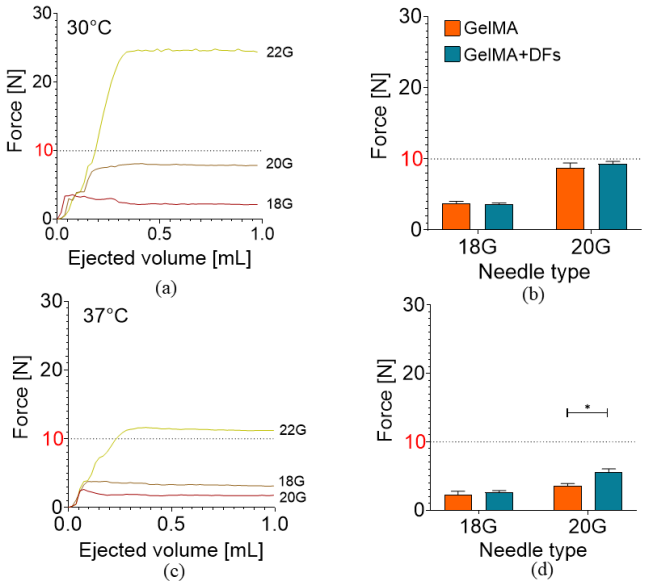

Fig. 3: (a) Representative force profiles showed by DFs-free GelMA and GelMA+DFs solutions at 30°C. (b) Maximum peak force of GelMA and GelMA+DFs for 18G and 20G at 30 °C. (c) Representative force profiles showed by DFs-free GelMA and GelMA+DFs solutions at 37 °C. (d) Maximum peak force of GelMA and GelMA+DFs for 18G and 20G at 37 °C. (*p< 0.05).

The results obtained at different test temperatures suggest that 30°C represents the minimum suitable temperature to inject both DFs-free GelMA and GelMA+DFs solutions homogeneously (reaching a well-defined plateau zone), while keeping the force needed below the threshold value (F<10N). A focus was placed on understanding the best temperature and parameters configuration to inject the formulation. For a GelMA solution concentration such as ours and equal to 10 % (w/v), to the best of our knowledge, a study for chondral and osteochondral applications has never been carried out to determine configuration in terms of parameters and temperatures of injectability.

C. Mechanical characterization

The mechanical characterization results (Table II) show that the composite GelMA+DFs achieved a higher maximum stress value and compressive modulus (150 and 75 kPa, respectively), increasing the values by 100% compared to DF-free GelMA. The composite formulation exhibited an increase in the maximum deformation (corresponding to the one at break) and toughness as well (Fig. 4a). The DFs acted within the GelMA matrix as reinforcing fillers. This feature can be related to the intrinsic characteristic of PCL in addition to the random distribution DFs, which might bear part of the load, guaranteeing a strengthening of the GelMA+DFs composite. Compared to one of the most similar casted GelMA scaffold (degree of functionalization ≈ 60%, 10 % w/v polymer concentration, photoinitiator concentration= 0,5 %, $D = 10$ mm, thickness = 1 mm, UV irradiation time= 60 s [10]), fabricated for bone tissue engineering, which was shown compressive modulus values around 10 kPa [10], the proposed GelMA+DFs composite showed higher compressive mechanical properties.

Compared to other works in which a dispersed PCL-based fiber filler was used for not bearing application [22]-[24], our work focused on exploiting the dispersed fibers to increase the mechanical properties of a GelMA+DFs injectable composite, with the aim to be used for load-bearing applications (e.g. OC).

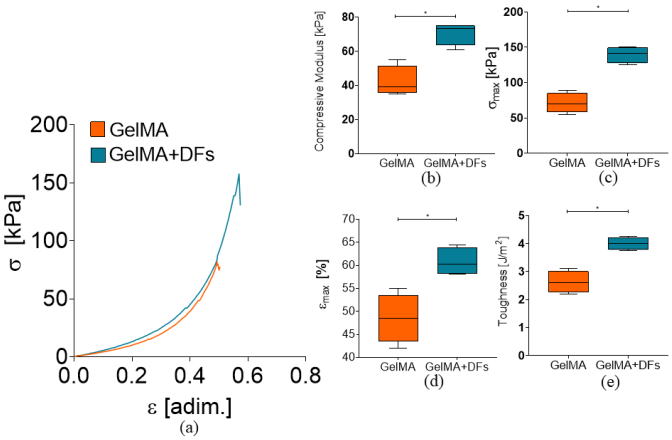

Fig. 4: Mechanical parameters. (a) Stress-strain curves. (b) Compressive modulus. (c) Maximum stress. (d) Maximum deformation. (e) Toughness. (*p<0.05).

TABLE II: MECHANICAL PARAMETERS

Parameter	*DFs-free GelMA*		*GelMA+DFs*	
Compressive Modulus	42 ± 8.9	kPa	70.8 ± 5.8	kPa
Maximum stress	71 ± 14	kPa	139.3 ± 10	kPa
Maximum deformation	48.5 ± 5.3	%	60.8 ± 2.6	%
Toughness	2.63 ± 0.39	J/m^2	4 ± 0.19	J/m^2

IV. CONCLUSIONS

In this study, we propose a composite formulation with enhanced mechanical properties, as injectable material cross-linkable *in situ*, for the potential treatment of OC injuries. A cryostat-based cutting technique was applied to obtain DFs from electrospun-aligned meshes. GelMA and GelMA+DFs were injectable using a force lower than 10 N at 30 and 37 °C, using 18 and 20G needles. The mechanical compression performance for the composite GelMA+DFs increased, supporting the hypothesis that a dispersed fiber-based filler can enhance the mechanical properties of the GelMA matrix.

A relevant aspect of our GelMA+DFs formulation lies in its possible usage with a minimally invasive approach, exploiting an *in-situ* cross-linkable natural-based GelMA material, which, compared to many other natural hydrogels proposed for this type of application, although not designed as injectables, has comparable if not superior mechanical properties.

In future work, a broader range of DFs concentrations will be investigated to find the concentration that guarantees optimal mechanical performance while still ensuring injectability below the imposed force limit. The use of such dispersed fibers might be further engineered to enable their controllable orientation once embedded. This strategy might lead to a biomimicking process in which the DFs would mimic the fibrous structures of collagen arranged in different ways in the layered natural tissue, giving different levels of anisotropy to the different composite layers.

Abstract— Nosocomial infections or healthcare associated infections (HAIs) refer to a set of infectious diseases acquired in a health facility. These infections are mainly due to the spread of a pathogen agent into a vulnerable host and pose an important cause of mortality, morbidity, prolonged hospitalization, and increased treatments with antimicrobial agents. Among the pathogens involved in HAIs, it has been observed that bacteria can adhere to surfaces and aggregate, forming a complex structure, called biofilm, which makes them much less sensitive to external agents. This structure mainly consists in extracellular polymeric substances (EPS) composed of water, proteins, nucleic acids, and provides a fully secured and functional environment for the formation of microcolonies, their sustenance and recolonization of sessile cells after its dispersal. From this scenario, the urgent need to explore innovative strategies for the treatment of biofilm infections arises. The goal of this work is to develop a multitarget nano-platform capable of degrading bacterial biofilm and killing dispersed cells to reduce diverse types of infection, allowing safer treatment paths. More in details, modified PCL-based nanoparticles have been prepared and conjugated to bioactive molecules having antibiofilm activity and deeply characterized by Dynamic Light Scattering (DLS), Zeta potential (ZP), and Atomic Force Microscopy (AFM), showing a good stability over time with a mean diameter of 200 nm, that increases to 800 nm after enzyme conjugation. The effectiveness of this nano-formulation can be investigated by AFM, monitoring, at the nanoscale, the morphology, and the Young Modulus of *Staphylococcus aureus* biofilms before and after treatment.

Keywords— **Nosocomial infections, *Staphylococcus aureus*, Antimicrobial Resistance, Biofilm formation, Atomic Force Microscopy, Nanoformulation.**

I. Introduction

Nosocomial infections or HAIs are the most common adverse event in health care that affects patient safety. HAIs affect 3.2% of all hospitalized patients in the United States, 6.5% in the European Union/European Economic Area, and worldwide prevalence is likely much higher [1]. It has been shown that over the next 30 years, infections related to antimicrobial-resistant microorganisms could cost up to US$ 3.5 billion annually [2]. These infections can be caused by the presence of viruses, fungi, and bacteria on both biotic and abiotic surfaces. Although pathogen transfer from a colonized or infected patient to a susceptible patient most commonly occurs via the hands of healthcare personnel, contaminated hospital surfaces and medical equipment can be directly or indirectly involved in the transmission pathways [3]. As a relevant example, methicillin-resistant *Staphylococcus aureus* (MRSA) strains are one of the best known at the global level. *Staphylococcus aureus* is an opportunistic, gram-positive, nosocomial bacterium causing different infectious diseases. When considering *S. aureus*, drugs are increasingly becoming partially or fully inactive due to the presence of a biofilm surrounding the bacterial cells [4]. Such biofilm is impenetrable by the drug and therefore, the concentration of antibiotics needed to eradicate the bacteria in the biofilm is up to 1000-fold higher than the concentration needed to kill planktonic cells [5]. Nowadays, antibiofilm strategies are mainly of two types:

- Inhibition or prevention of new biofilm formation, using material and coatings that exhibit chemical or structural antibacterial properties [6], [7].
- Dispersal or eradication of existing biofilms, i.e. treatments such as heat, cleaning regimens, low-power laser, sonication, and chemical treatments, also through the use of vectors that allow the transport of bioactive molecules within the biofilm [8], [9].

Traditional approaches that aim to eradicate bacterial biofilms include antibiotics treatments and antifouling agents. However, the therapeutic effect of antibiotics strongly depends on their concentration. Moreover, antibiotics need to penetrate the bacterial membrane and accumulate until a sufficient therapeutic concentration is reached. This process can also be dependent on bacterial structure [10]. It has been shown that bacterial biofilms show more tolerance than bacteria in planktonic form to antibiotics treatments, because cells enter dormancy [11]. Nevertheless, recent studies show that biofilm-associated *S. aureus* cells can have different metabolic states: they can be growing aerobically, be fermentative, dormant, or dead [12]. Treatment of *S. aureus* biofilm infections is further complicated by the existence of different phenotypes of clinical MRSA and MSSA strains, resulting in mixed-strain biofilms. For these reasons, research has been focused on the use of nanoformulations, including polymeric and metallic nanoparticles, capable of hindering the formation of the biofilm, thus reducing bacterial activity, and improving the bioavailability and targeted delivery of antibiotics/drugs. Having a high surface-to-volume ratio, these nanoformulations can be loaded with a high amount of antimicrobials, increasing the stability and avoiding burst release associated problems. Moreover, it has been shown that the effectiveness of the antibacterial treatment depends on both

the shape and size of the NPs. As the size decreases, the penetration inside the bacterial membrane becomes easier, increasing the effectiveness of the treatment [13]. It has also been observed that the bare application of nanoparticles does not allow to obtain effective results, precisely due to the presence of the biofilm. For this reason, many studies aimed at the decoration of nanoparticles with bioactive molecules to confer them antibiofilm activity [14]. Numerous biodegradable polymers such as polycaprolactone (PCL), polylactic acid (PLA), polyglycolic acid (PGA), and polylactide-coglycolide (PLGA) are being used to formulate biocompatible nano/microparticles as carriers of bioactive molecules [15], [16]. From this scenario, it is evident that there is an urgent need to explore innovative strategies for the treatment of biofilm infections [11]. This work focuses on the limitation of the transmission of nosocomial infections by setting up efficient and totally green strategies for surfaces disinfection, to be safely used in different environment. PCL, chemically modified with the addition of carboxylic groups was used. Thanks to this modification, the polymer chain assumes a star shape, increasing the surface/volume ratio of the nanoparticles, and favoring the covalent coupling with the selected enzyme thank to the carboxylic groups' enrichment. Specifically, the selected bioactive component is the Alpha amylase enzyme, capable to hydrolyze α (1,4) glycosidic linkages of the polysaccharidic part of *S. aureus* extracellular matrix, exhibiting dispersal of mature biofilms and showing the capability to prevent and disrupt biofilm formation at nanomolar concentrations when added exogenously in solution [11]. The enzyme can be conjugated to biocompatible and biodegradable polymeric nanoparticles that confer increased stability and bioavailability [4].

II. METHODS

Nanoparticles were prepared by "nanoprecipitation method" [17]. Briefly, 2% Poly viny alcohol (PVA) was dissolved in pure water, stirred at 50°C for 2h, then 1h at room temperature and filtered. Then, 5 mg/mL of modified PCL solution in acetone was added dropwise, using a syringe pump, in an equal volume of PVA solution, and kept under stirring at 650 rpm for 2h. Finally, after organic solvent evaporation, pure water was poured into the so formed NPs dispersion, to restabilize the initial PCL concentration, and kept under stirring at 250 rpm overnight for their stabilization. The next day, the nanoparticle dispersion was first centrifuged at 1500 rpm at 4°C for 20 min to allow eventual micrometric aggregates to precipitates. Then, two final washings at 11000 rpm for 20 min were carried out to remove any solvent residues. After washings, nanoparticles were stored at 4°C for subsequent analysis.

An accurate morphological characterization of PCL NPs before and after enzyme conjugation was carried out. The size distributions of nanoparticles and the surface potential of plain and functionalized nanoparticles were measured by DLS and Zeta Potential with a Zetasizer Nano ZS (Malvern Instruments, Worcestershire, U.K). AFM topography images were obtained using a Nanowizard JPK Bio-AFM (Bruker) and a Zeiss optical microscope (Axio Zoom V16). MSCT-AUHW cantilevers, with a nominal spring constant K=0,159 N/m, was used for acquisitions.

III. RESULTS

AFM characterization on PCL NPs was carried out by letting them precipitate and adsorb on a functionalized mica surface. Single nanoparticles with diameters between 70 and 150 nm were found, along with large aggregates.

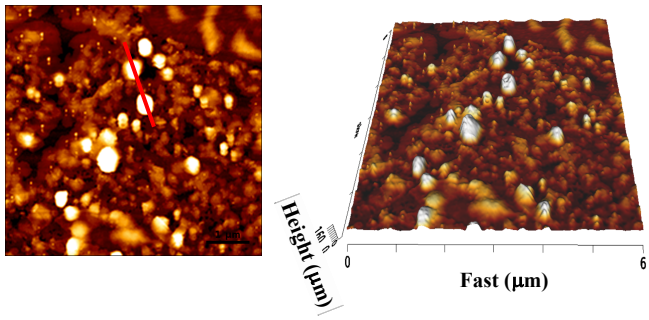

Figure 1: AFM images of PCL NPs and 3D overview. Samples from three different production batch processes were analyzed in Quantitative Imaging mode (QI) with a MSCT-AUGH tip (spring constant k = 0.159 N/m), set-point of 0.7 nN.

Fig. 1 shows the synthesized PCL NPs with spherical shape, and some material in the background. This could be due to PVA residues or non-reacted PCL.

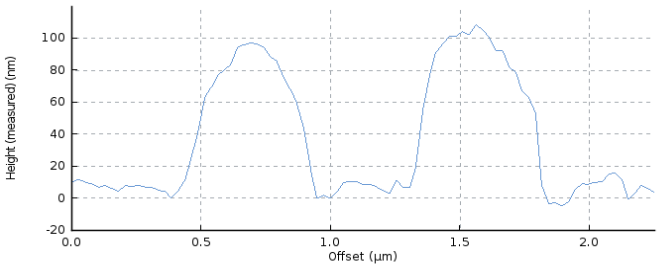

Figure 2: Cross-section of PCL NPs (red line in Fig.2).

In Fig. 2 a cross section of two NPs (corresponding to the red line in Fig.1) is represented. It is important to point out that topography obtained by AFM can affected by artifacts arising from the convolution of sample topography with the tip shape that limit the lateral resolution that can be achieved [18].

Table I reports the results obtained by DLS and ZP analyses. Plain PCL nanoparticles diameter was found to be around 230 nm, with a polydispersity index (PDI) of 0.16 which confirms the presence of a narrow distribution. The same analysis was repeated after 1 month of storage and no significant differences were found.

	DLS (nm) ± st. dev.	**ZP (mV) ± st. dev.**	**PDI**
PCL NPs	235.6 ± 76.71	-41.6 ± 7.67	0.16
PCL NPs + E	807.2 ± 137.7	-23.5 ± 4.55	0.25

Table I: DLS and ZP results.

The average of functionalized NPs diameter increased to a value of about 800 nm, with a PDI of 0.25. Trying to give an explanation to these results, ZP analysis was performed.

PCL NPs also showed differences in ZP values before and after the conjugation with the enzyme, with a mean of -41.6 ± 7.67 mV and -23.5 ± 4.55 mV respectively. This parameter shows the degree of repulsion between the charged particles in a suspension. A Zeta Potential value greater than −30 mV to +30 mV is considered to have enough repulsive force to attain better physical colloidal stability. On the other hand, a small zeta potential value can result in particle aggregation due to the van der Waals attractive forces. Overall, it can be assumed that the synthesized NPs are sufficiently charged to generate repulsive forces, and this explain the absence of aggregation phenomena. After the conjugation process, ZP value decreased, resulting in an increase in the mean particle size. Furthermore, it should be noticed that the differences in diameter obtained using DLS and AFM can be ascribed to the fact that AFM measures the physical height of the sample spread on a substrate, while DLS reports its hydrodynamic diameter.

For characterization of S. aureus biofilm, bacteria were cultured in a petri dish for 24h. Fig. 3 shows a high-resolution image of a community of bacterial cells, with the typical spherical shape and a mean diameter of about 0.8 µm. As can be seen from images, some of them have a smooth and clean surface, while others were embedded within the EPS, displaying the non-homogeneity of biofilm structures.

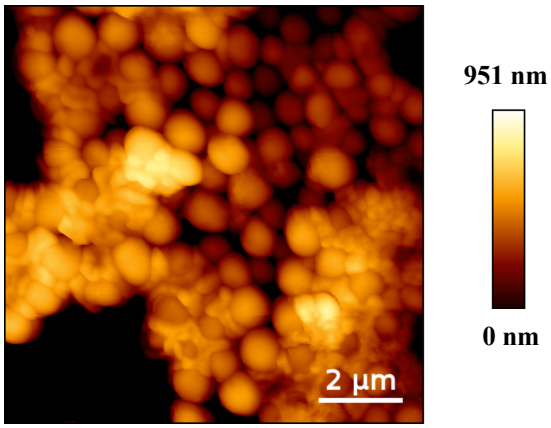

Figure 3: AFM image of *S. aureus* 24h biofilm.

The height of the biofilm was also evaluated and confirmed the observed heterogeneity, showing an irregular height ranging from few nm to 1-2 µm.

Finally, in Fig. 4 is shown an optical characterization of a 24h *S. aureus* biofilm before and after treatment with PCL NPs + E for 2.5h. After several washes it has been notice a huge reduction of the biomass.

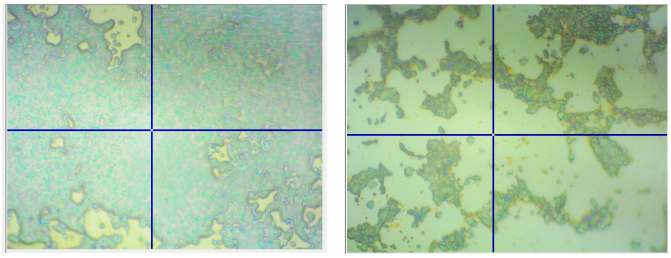

Figure 4: optical characterization of 24h *S. aureus* biofilm before (left) and after (right) treatments with PCL NPs for 2.5h.

This is only a preliminary result that shows the effectiveness of these treatments. It should be considered that the bacterial residues that has been removed are still virulent so they should be killed using some antimicrobial, to avoid the spread of these pathogens.

IV. Conclusion

We have shown the successful synthesis and characterization of a novel anti-biofilm formulation. This nano-platform has displayed a narrow size distribution and good stability over time, together with high retention of enzyme. AFM characterization on *S. aureus* biofilms was also performed. This technique has proven to be a powerful tool for investigating the antibacterial effects. AFM not only allows high-resolution images under ambient air or fluid conditions, but it can also probe the nanomechanical characteristics. The mechanical properties of bacterial cells play an important role in crucial bacterial processes such as cell growth, colonization, and biofilm formation. For these reasons, AFM will be used to calculate the Young Modulus of *S. aureus* biofilm before and after treatment with the nanoformulation observing, characterizing, and understanding the behavior of live bacterial cells as never before.

The main innovation of the proposed strategy, when compared to the state of the art, resides in the mutual action of biofilm-degrading enzymes with plant extracts having antibacterial activity. Once the biofilm has been dissolved, the use of antibacterial plant extracts together with the nanoparticles should allow the elimination of the exposed planktonic cells. The developed formulation is highly promising for removing bacterial biofilms in healthcare facilities, medical devices, and, ultimately, even for fighting infections in patients. The success of this project would pave the way for the search of new innovative strategies useful for reducing contamination and therefore nosocomial infections, making the treatment path safer and, above all, saving time, money, and, possibly, lives. Interestingly, this platform could be also in other scenarios where biofilms are associated with microbial fouling and corrosion, such as in terrestrial water-distribution systems and extended spaceflight missions [19].

***Abstract*— Clinical treatments for osteochondral defects (OCD) are only palliative, therefore the development of novel tissue engineering (TE) approaches for the active repair of damaged cartilage-bone interfaces is of utmost importance. To date, the morphological and functional renewal of OCD remains an unsolved clinical challenge. Conventional 2D and 3D morphology of TE scaffolds is not yet able to reproduce the complex tissue architecture. Here, we aim to explore a novel surface technology tailored to the OCD patient, using a robotic 3D electrospinning platform (3DES) to design ad-hoc woven scaffolds that correspond to the diseased tissue surfaces.**

***Keywords*— electrospinning, cartilage, bone, resurfacing.**

I. Introduction

Skeletal pathological conditions such as cancer and osteoarthritis, directly drive the degeneration of the boundary interlayered cartilage and bone substrates leading to extensive and incurable osteochondral defects (OCD) [1]. Variations in the morphology of the joint are correlated with the localization of OCDs and develop a complex cascade of degenerative processes that lead to the impairment of the joint functionality [2, 3]. Due to the poor regenerative capacity of cartilage and subchondral bone, the current clinical treatments of OCD are only palliative effective, reducing pain and improving joint function, but failing to achieve complete repair of osteochondral (OC) lesions and reconstruction of the joint functions [4]. Thus, the development of novel tissue engineering (TE) approaches for the active resurfacing of damaged cartilage-bone interfaces is of pivotal clinical importance [5]. To date, the morphological and functional resurfacing of OCD remains an unsolved clinical challenge. The reproduction of the native anatomic morphology is mandatory to distribute and balance the load during joint movement, playing a vital role in the maintenance of cartilage function [6]. The conventional 2D and 3D structure of TE scaffolds is not yet able to reproduce the complex morphology of the tissue [7]. Here, we aim to investigate a novel OCD patient-specific resurfacing technology, harnessing a novel 3D near field electrospinning (3DES) platform robotic-guided platform, designing ad-hoc woven scaffolds to match diseased tissue surfaces. We replaced the cartesian printer configuration with a five-axis robotic arm using a non-planar surface as a fibre collector, as shown here by using a spherical collector. Additionally, we deposit the spun fibres on a spherical and irregular support, which is placed among the spinneret and the spherical collector. The combination of these techniques allows us to use the near field electrospinning (NFES) more broadly in tissue engineering where the geometric shapes of scaffold need to be expanded.

II. Materials and Methods

A custom-made robotic arm with five degrees of freedom (DOF) is used as a 3D guiding tool for the electrospinning (ES)process to fabricate woven scaffolds on complex surfaces. The ES spinneret is fixed on the appendices of the computer-aided arm and guided over a spherical collector to deposit polycaprolactone (PCL) polymeric solution, as shown in Figure 1. The trajectory is calculated with the Robotics System Toolbox of MATLAB code, while the arm movements are controlled with a custom-made LabView script. Specifically, we optimize the experimental setup and the arm trajectory with a fine negative feedback control, to increase the capacity of the system to reproduce the irregularities and to create scaffold with comparable compositional, structural, and functional characteristics of the extracellular matrix (ECM).

Figure 1. Schematic diagram of the new ES setup, where the ES spinneret is fixed on the robotic arm end-effector and the traditional planar collector is replaced with a fiber spherical collector.

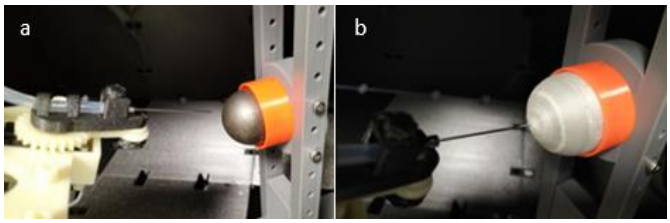

Figure 2. (a) Electrospinning setup; (b) Jet initiation phase with a spherical support fiber collector in PVA.

Figure 2a shows the ultimate setup where the collector distance of 5 mm was selected and maintained throughout. The PCL filaments were cut into short segments of ≃3 mm and solubilized in dichloromethane (DCM). The solution was used immediately after 4h of mixing. The experiments were performed at 20-40% relative humidity and at an ambient temperature of 18-19 °C. Figure 2b shows the electrospinning process of the above solution on the spherical support collector in polyvinyl alcohol (PVA). During this phase, the trajectory of the nozzle describes concentric circles while end-effector speed is kept constant during the toolpath. The PCL spun fibers were deposited on a shell support 3D printed with water-soluble polymer filament, PVA. After the deposition, the scaffold can be retrieved removing the soluble support in a

water batch. Then, spun solution was deposited on a PVA support to mimic the irregular surface of the native tissue morphology (Figure 3). The PVA supporting structure was fabricated starting from CT scan of anatomical districts (e.g., humerus epiphysis) precisely patterning PCL fibers onto a 3D collector.

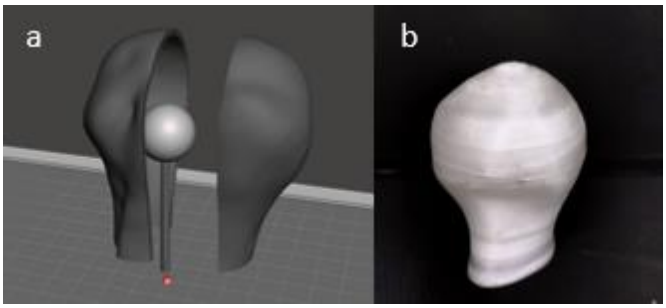

Figure 3. (a) Stl file of the shell support obtained from CT scan of humerus epiphysis; (b) Shell support 3D printed with PVA.

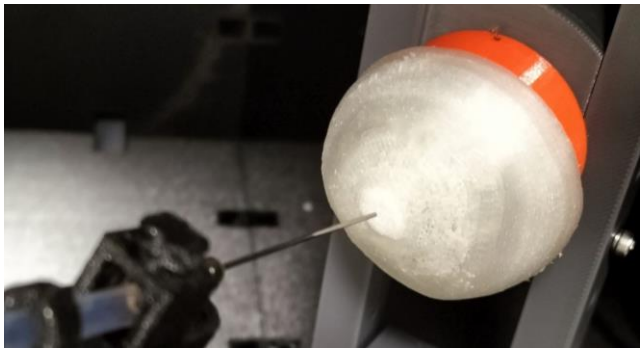

Figure 4. Jet initiation phase with an irregular support fiber collector in PVA reproducing the anatomic morphology

The PVA anatomical supporting structure was used to deposit the PCL fiber. The nozzle's trajectory follows the irregular shape of the support, and the end-effector's velocity is constant during the toolpath.

III. Results and discussion

PCL were dissolved in DMC and spun using a custom-made electrospinning apparatus. The robotically guided spinning was carried out using a custom Matlab-LabView code for precise positioning. A number of optical sensors were housed close to the spinneret to monitor the relative positioning and loop effective feedback information directly to the arm motors. The 3DES platform was optimised to reach high precision in spinning deposition. Firstly, the velocity of the nozzle along the tool path was adjusted and monitored. Particularly, the smaller portion of printed semi-sphere was found to be exposed to an over-deposition of the 3DES. This was accounted and accordingly adjusted to reach a seamless and even surface deposition in three dimensions.
Secondly, the velocity of the end-effector was found insufficient to stretch the fibers and deposit straight fibers to create aligned fibers. This issue was solved by up-scaling the hardware and software support, improving a greater ultimate higher accuracy.

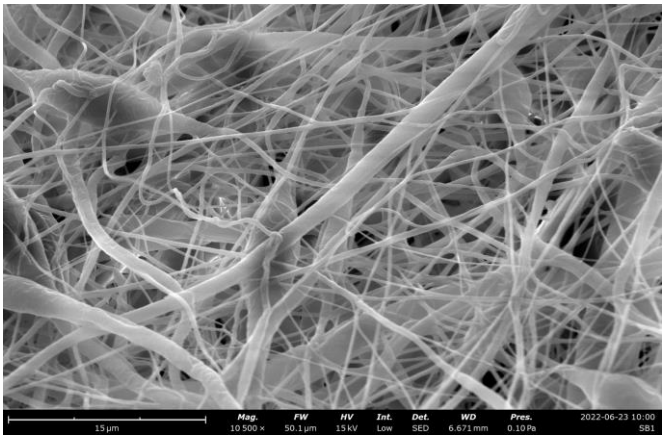

Figure 5. Scanning electron microscopy (SEM) of random fibres of 3D electrospun scaffold (scale bar 15 µm).

Figure 5 shows a scanning by SEM of random fibres deposited by 3DES, demonstrating therefore the ability of the 3D electrospinning to re-surface humerus and femur epiphysis, both of standard models and patient specific defects reconstructions. PVA water-soluble supports were found suitable to temporarily aid the fibres deposition.

IV. Conclusion

The resurfacing of OCDs is an attractive clinically relevant approach for the rapid functionalisation of skeletal defects. However, current clinical treatments are still ineffective, thus posing an urgent need for novel approaches for the resurfacing of OCD. We have reported the use of a novel custom-made robotic arm equipped with a 3D electrospinning apparatus, capable of functionalising patient-specific surfaces. In future, we will attempt to increase the efficiency and accuracy of our custom-made experimental setup to reach higher mechanical performance and improve the deposition accuracy and diameter control of the spun fibres. Then, we will validate the ability of PCL material and nanoclay-enhanced composites to retain growth factors (GFs) of interest at the site of injury, using different macromolecules to test this behaviour.

Abstract— **This paper focuses on the development of functionalized spongy chitosan scaffolds for bone tissue regeneration. Chitosan is a natural polymer that is readily available, biocompatible, and antibacterial. In this work, chitosan was covalently functionalized with two different bioactive peptide sequences, HVP (FRHRNRKGY) to improve cell adhesion, and GBMP1a (PFPLADHLNSTNHAIVQTLVNSF) to increase osteoblast proliferation and differentiation. HVP is an adhesive peptide mapped on human vitronectin, whereas GBMP1a reproduces a sequence derived from BMP-2 protein. Six different scaffolds were obtained by various combinations of both functionalized chitosan, also functionalizing the chitosan simultaneously with the two considered peptides. These matrices were then evaluated in *in vitro* biological assays with human jaw derived osteoblasts to assess their ability to induce modification of gene expression of characteristics proteins for this cell phenotype. Characterization of the matrices was completed with biomechanical tests, analysis by scanning electron microscope (SEM), and x-ray photoelectron spectroscopy (XPS).**

***Keywords*—peptide, chitosan, covalent functionalization, bone regeneration.**

I. Introduction

BONE diseases are still a clinical challenge, causing half of all chronic diseases in people over the age of 50 [1].

Nowadays, autologous bone grafting is considered the *gold standard* for bone reconstruction. However, there are still several drawbacks, such as secondary damages or donor site morbidity [2], [3]. To overcame grafts limitations, bone tissue engineering (BTE) has proposed different scaffolding materials properly enriched with bioactive molecules and cells [4].

Chitosan is a natural polysaccharide produced by deacetylation of chitin. Since it is a biocompatible and biodegradable biomaterial it has been employed for various biomedical applications. Chitosan has two specific functional groups, an amine group NH_2 in C2 and various hydroxyl groups (OH) that simplify its functionalization with peptides for engineering purposes [5]. Moreover, it can be used to obtain different shapes, such as 3D sponges, hydrogels, films, or nanofiber matrices. In particular, the porosity gained by lyophilized chitosan scaffolds allow cell migration and exchange of nutrients and waste [6].

In this work, HVP and GBMP1a peptides were covalently bind to chitosan to improve its bioactive properties. HVP is an adhesive sequence derived from fragment (351-359) of human vitronectin, and it has shown to be effective in osteoblast adhesion and in promoting cellular migration [7], [8]. GBMP1a is a 22 amino acids sequence peptide derived from fragment (48-69) of BMP-2 protein, and it is able to increase osteogenic differentiation of mesenchymal stem cells [9].

Several methods have been used to bind covalently a bioactive sequence to chitosan, such as 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) and N-hydroxy succinimide (NHS) [10], [11]. Here, a different functionalization chemistry is proposed. It consists of Schiff bases production, successively reduced, between chitosan amino groups and aldehyde groups appositely inserted in the peptide backbone during solid phase peptide synthesis [5], [12]. One of the advantages of this method is the specific anchoring of a bioactive sequence in a single-step reaction carried out in aqueous solution and mild conditions [13].

In this work, it is proposed a 3D-spongy chitosan scaffold for BTE, bioactivated with the covalently anchoring of two peptide sequences, also used in combination, to ensure faster bone healing improving osteoblast differentiation, adhesion, and proliferation.

II. Methods

A. Peptide synthesis, characterization, and purification

The S-x-HVP peptide (sequence H-Ser-x-Phe-Arg-His-Arg-Asn-Arg-Lys-Gly-Tyr-NH_2, where x represents 7-aminoheptanoic acid) and S-x-GBMP1a peptide (sequence H-Ser-x-Pro-Phe-Pro-Leu-Ala-Asp-His-Leu-Asn-Ser-Thr-Asn-His-Ala-Ile-Val-Gln-Thr-Leu-Val-Asn-Ser-NH_2) were synthesized, characterized and purified as described in [13].

B. S-x-HVP and S-x-GBMP1a N-terminal conversion in an alpha-oxo-aldehyde and purification

Both peptides were oxidized to provide the sequence with an alpha-oxo-aldehyde group at the N-terminal following the procedure described in [13].

C. Chitosan functionalization with S-x-HVP aldehyde and S-x-GBMP1a aldehyde

Seven conditions of functionalized chitosan scaffolds were prepared: pure chitosan 100% (chit); pure chitosan + S-x-HVP functionalized chitosan (50:50 w:w), (chit:chitHVP); pure chitosan + S-x-GBMP1a functionalized chitosan (50:50 w:w), (chit:chitBMP); S-x-HVP functionalized chitosan + S-x-GBMP1a functionalized chitosan (50:50 w:w), (chitHVP:chitBMP); pure chitosan + S-x-HVP functionalized chitosan + S-x-GBMP1a functionalized chitosan (50:25:25 w:w:w), (chit:chitHVP:chitBMP); pure chitosan + chitosan functionalized with both S-x-HVP and S-x-GBMP1a (50:50

w:w), (chit:chitHVP-BMP); 100% chitosan functionalized with both S-x-HVP and S-x-GBMP1a, (chitHVP-BMP).
The functionalization of chitosan with S-x-GBMP1a was carried out by dissolving 21.89 mg of chitosan in 1404 µL of 0.2 M acetic acid solution under magnetic stirring. Then, 815 µL of ethanol were added and the pH was adjusted to 5.1. 19.96 mg of peptide were dissolved in MilliQ water (1 mg/mL solution). The two solutions were then mixed, and 21.89 mg of $NaCNBH_3$ were added under magnetic stirring. The reaction was stopped after 24 h adding NaOH until the pH reached 7. The solution was then precipitated with cold ether, mixed under magnetic stirring for 10 min and then placed overnight into the fridge. The solution was subsequently filtered and dried in a vacuum chamber for 1 hour. The same procedure was followed to functionalize chitosan with S-x-HVP, (maintaining 7.734 µmol of peptide in 40 mg chitosan+peptide) and to functionalize chitosan with both S-x-HVP and S-x-GBMP1a (3.867 µmol of each peptide).

D. Set-Up of the chitosan-based sponges

The mentioned scaffolds were prepared by dissolving 1.68 mg of chitosan (enriched with peptides or not) in 252 µL of acetic acid solution 0.2 M under magnetic stirring. 200 mg of the solution were then poured in different wells of a 48-well plate, frozen with liquid nitrogen, and freeze-dried. After the lyophilization, washes were performed by filling each well three times with ethanol and later three times with sodium phosphate buffer PBS 10X. Then, the scaffolds were once again frozen with liquid nitrogen and freeze-dried. Subsequently, the matrices were soaked in 400 µL of MilliQ water and frozen overnight at -20°C. Finally, they were frozen once again with liquid nitrogen and freeze-dried.

E. Scaffolds characterization

X-ray photoelectron spectroscopy (XPS) analysis was performed using a homemade instrument, consisting of preparation and analysis UHV chambers separated by a gate valve. All spectra were energy referenced to the C1s signals of aliphatic carbons at BE = 285.0 eV. Curve fitting of the C1s, N1s, O1s and F1s spectra was performed using Gaussian profiles fitting functions. Atomic ratio values were calculated from peaks intensities. Scaffold morphology was investigated by scanning electron microscopy (SEM) using a Stereoscan-205 S (Cambridge Instruments, Pine Brook, NJ, USA). ImageJ (National Institutes of Health) was utilized to investigate the pores dimension of each scaffold. Biomechanical compression tests were performed on the cylindrical chitosan matrices, having a radius R0 = 5 mm and a height H0 = 0.3 mm. These specimens were soaked in physiological solution at 37°C and tested using a compression machine (INSTRON 5566) at a speed of 1mm/min to a deformation of 50%. Considering the measured force F, initial specimen area ($A0 = \pi R0^2$), change in specimen height (ΔH), and initial specimen height (H0), engineering stress (σ) and engineering strain (ε) were calculated as $\sigma = F/A0$ and $\varepsilon = \Delta H/H0$. Statistical analyses were performed using ANOVA and Turkey HSD test. p-value <0.05 were considered statistically significant.

F. Biological assays

Osteoblasts were seeded on chitosan scaffolds and incubated for 2 hours at 37°C to evaluate their adhesion potential. At the end of the incubation period, the cell culture was washed with PBS and a solution of 5mg/ml MTT in PBS was added. The samples were incubated again under the same conditions for 4 hours. Consequently, a 10% (w/v) solution of sodium dodecyl sulfate (SDS), acidified with 0.01N HCl was added. Finally, absorbance values were read with a microplate reader (Thermo scientific Varioskan Lux) at 620nm on 100 µL of solution. Osteoblasts proliferation on chitosan scaffolds was assessed at 4 days from seeding using carboxyfluorescein diacetate succinimidyl ester CFSE (Molecular Probe, Invitrogen), a cell-permeable fluorescent probe equally partitioned among daughter cells. Cells were first incubated for 10 min with CFSE 25 µM at 37 °C. The reaction was stopped by adding 5 volumes of ice-cold culture media. Cells were then washed, counted using Trypan blue, and seeded on chitosan scaffolds. At the end of incubation, cellular monolayers were washed in PBS and incubated for 5 min with trypsin-EDTA. Cell proliferation was assessed using BD FACS-Calibur flow cytometer by evaluating the percentage of CFSE-positive cells in 10,000 events. Specific mRNA transcript levels coding human runt-related transcription factor 2 (Runx2), vitronectin (VTN), and osteopontin (OPN) were quantified in osteoblast cells cultured for 24 h on chitosan scaffolds. At the end of incubation, the total RNA was extracted using the SV Total RNA Isolation System kit (Promega, Milan, Italy). Contaminating DNA was removed by DNase I digestion (Omega Bio-Tek, Norcross, GA, USA). cDNA synthesis and subsequent polymerization were performed in one step using the iTaq Universal SYBR Green One-Step Kit (Bio-Rad, Hercules, CA, USA). The reaction mixture contained 200 nM forward primer, 200 nM reverse primer, iTaq universal SyBR Green reaction mix, iScript reverse transcriptase, and 200 ng total RNA. Real-time PCR was performed using the ABI PRISM 7700 Sequence Detection System (Applied Biosystems, Milan, Italy). Data were quantified by the ΔΔCT method using human GAPDH as the reference gene. Target and reference genes were amplified with efficiencies near 100%. Biological data are reported as mean ± standard error. The statistical analysis was performed using the One-way ANOVA test followed by Bonferroni's multicomparison test, using Graph-Pad Prism 3.03. p-values < 0.05 were considered statistically significant.

III. RESULTS

A. XPS analysis

XPS measurements were performed to demonstrate the anchoring of the peptides to the chitosan scaffolds.

TABLE I: N/O RATIOS OF FUNCTIONALIZED SCAFFOLDS

Sample	N/O
Chit	0.05
Chit:chitHVP	0.1
Chit:chitBMP	0.09
Chit:chitHVP:chitBMP	0.1
ChitHVP:chitBMP	0.09
Chit:chitHVP-BMP	0.1
ChitHVP-BMP	0.2

The increase of the N/O ratios of functionalized scaffolds compared to the pure chitosan shown in Table I confirmed the anchoring of both peptides to chitosan, as the increment of

nitrogen is strictly related with the peptide presence. In particular, all data are similar to each other except for ChitHVP-BMP that induce a higher N/O ratio.

B. SEM analysis

A morphological characterization of functionalized chitosan scaffolds was carried out with SEM and reported in Fig 1.

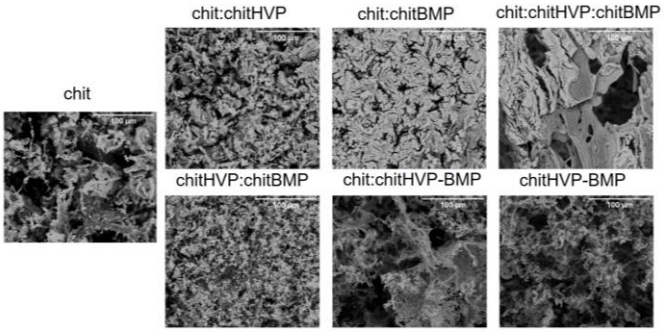

Fig. 1: Ultrastructural characteristics of the functionalized chitosan scaffolds investigated by scanning electron microscopy. Scale bar: 100µm; magnification 600x.

TABLE II: SCAFFOLDS PORES DIMENSION

Samples	Mean length [µm] ± std [µm]	Mean width [µm] ± std [µm]
Chit	22.18 ± 3.62	13.79 ± 3.58
Chit:chitHVP	16.71 ± 3.18	9.63 ± 2.79
Chit:chitBMP	14.53 ± 2.08	11.07 ± 2.89
Chit:chitHVP:chitBMP	20.46 ± 2.17	15.94 ± 2.96
ChitHVP:chitBMP	14.45 ± 3.76	10.14 ± 1.75
Chit:chitHVP-BMP	20.43 ± 5.73	12.76 ± 2.99
ChitHVP-BMP	19.52 ± 2.55	15.08 ± 3.17

Porous mean length and width reported as mean value ± standard deviation. the measures were obtained by ImageJ software.

The pure chitosan matrix shows the standard open-cell porous scaffold. Pores dimension was measured using ImageJ software, measuring both the length and the width of the pores, the results are shown in Table II. The pores dimension of pure chitosan matrices is 22.18 µm ± 3.62 µm; 13.79 µm ± 3.58 µm. Chit:chitHVP matrices are very similar structurally to the pure chitosan control; in fact, the HVP peptide is strongly basic and it is positively charged like chitosan itself. In this case the pore size is slightly smaller (16.71 µm ± 3.18 µm; 9.63 µm ± 2.79 µm). In contrast, chit:chitBMP matrix (14.53 µm ± 2.08 µm; 11.07 µm ± 2.89 µm) appears less spongy and porous, and this may be caused by a crushing effect due to the transfer of the matrix into the SEM plate. The chit:chitHVP:chitBMP matrix is morphologically very different from the control and filamentous (20.46 µm ± 2.17 µm; 15.94 ± 2.96 µm). The chitHVP:chitBMP matrix is similar to the structure of the control but with smaller pores (14.45 µm ± 3.76 µm; 10.14 µm ± 1.75 µm). Finally, the last two conditions, chit:chitHVP-BMP and chitHVP-BMP, are visually very similar to each other and to the control matrix (20.43 µm ± 5.73 µm; 12.76 µm ± 2.99 µm, and 19.52 µm ± 2.55 µm; 15.08 µm ± 3.17 µm, respectively).

C. Adhesion and proliferation assays

Biological assays were performed using osteoblasts derived from human jaw to evaluate functionalized chitosan scaffolds bioactivity. An MTT assay for cell adhesion and a CFSE assay for cell proliferation were carried out 2 hours and at 4 days from seeding, respectively (Fig 2).

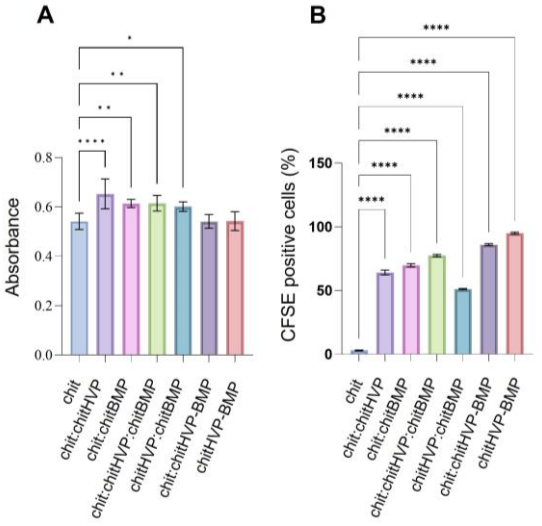

Fig 2: A) Human osteoblast cell adhesion on functionalized chitosan-based scaffolds, evaluated by MTT at 2 hours from the seeding; B) human osteoblast cell proliferation on functionalized chitosan-based scaffolds, evaluated by CFSE at 4 days from the seeding; * p <0.05, ** p <0.01, **** p <0.0001.

The results of the MTT assay are reported in Fig 2A. Chit:chitHVP is the scaffold that induces a higher osteoblastic adhesion compared to the others, with a statistical significance compared to chit ($p < 0.0001$). This is an expected result since the peptide HVP is an adhesive sequence. Other matrices with a statistically significant difference compared to chit are chit:chitBMP and chit:chitHVP:chitBMP ($p < 0.01$) and chitHVP:chitBMP ($p < 0.05$).

The results of the CFSE assay performed at 4 days from seeding are shown in Fig 2B. All functionalized scaffolds induce a higher proliferation compared to the control ($p < 0.0001$). Specifically, the highest values are obtained by chitHVP-BMP and chit:chitHVP:chitBMP, that induce a proliferation 32 and 28 times higher than the control, respectively.

D. Gene expression

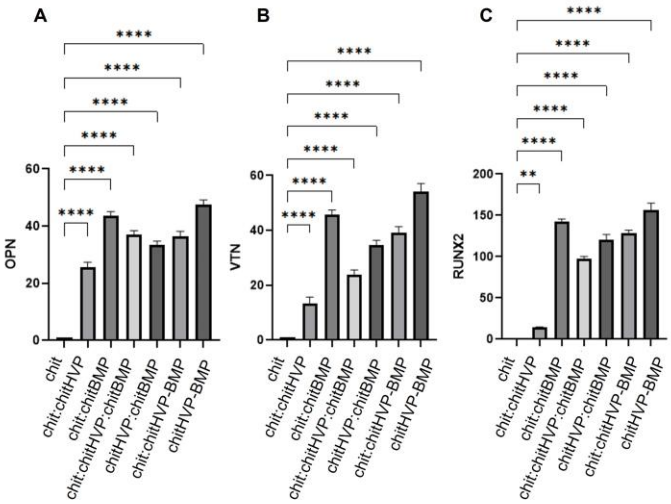

Fig 3: A) OPN expression in all chitosan scaffolds; B) VTN expression in all chitosan scaffolds; C) Runx2 expression in all chitosan scaffolds; * p <0.05, ** p <0.01, **** p <0.0001.

The results of the RNA extraction and amplification through quantitative polymerase chain reaction (qPCR) are reported in Fig 3. The expression of three genes, runt-related transcription factor 2 (Runx2), vitronectin (VTN) and osteopontin (OPN) was examined.
The most promising results are expressed by chit:chitBMP and chitHVP-BMP matrices. However, all functionalized matrices increment the expression of these genes compared to the control.

E. Biomechanical compression tests

A biomechanical compression test was carried out in all the 7 scaffolds. The Young's modulus (E) and the maximum stress (σ_{max}) with the corresponding standard deviations are reported in Table III. The general behavior is similar to that of a flexible foam.

TABLE III: MECHANICAL PROPERTIES OF SCAFFOLDS

Scaffold	E (kPa)	σ_{max} (kPa)
Chit	22.6 ± 2.0	8.9 ± 0.5
Chit:chitHVP	21.3 ± 2.1	7.3 ± 0.4
Chit:chitBMP	23.0 ± 2.3	7.1 ± 0.4
Chit:chitHVP:chitBMP	16.4 ± 1.4	5.6 ± 0.3
ChitHVP:chitBMP	10.1 ± 1.0	4.0 ± 0.3
Chit:chitHVP-BMP	22.7 ± 2.3	6.9 ± 0.5
ChitHVP-BMP	8.5 ± 0.8	4.1 ± 0.3

Mechanical properties of functionalized chitosan scaffolds: compressive modulus (E) and maximum stress (σ_{max}) reported as mean value ± standard deviation.

The maximum stress value was measured on chit (8.9 ± 0.5 kPa). However, the Young's modulus are similar among chit (22.6 ± 2.0), chit:chitHVP (21.3 ± 2.1 kPa), chit:chitBMP (23.0 ± 2.3 kPa), and chit:chitHVP-BMP (22.7 ± 2.3 kPa), and no significative statistical differences were found among these samples. Regarding the maximum stress, there were not statistical differences among chit:chitHVP (7.3 ± 0.4 kPa), chit:chitBMP (7.1 ± 0.4 kPa) and chit:chitHVP-BMP (6.9 ± 0.5 kPa). The compression modulus and maximum stress measured in chit:chitHVP-BMP (16.4 ± 1.4 kPa and 5.6 ± 0.3 kPa) were significantly higher compared to the ones of chitHVP:chitBMP (10.1 ± 1.0 kPa and 4.0 ± 0.3 kPa) and chitHVP-BMP (8.5 ± 0.8 kPa and 4.1 ± 0.3 kPa).

IV. CONCLUSION

In this work, the functionalization of a spongy chitosan scaffold with different percentage of two peptides, HVP and GBMP1a, was studied. XPS characterization of the matrices confirmed the successful anchoring of S-x-HVP and S-x-GBMP1a peptides on chitosan. The peptides' presence is proven by the increased N/O ratio in functionalized scaffolds with respect to unfunctionalized chitosan. SEM imaging showed the porous morphology of the 3D spongy matrices of chitosan and functionalized chitosan, which are necessary for BTE scaffolds, allowing cell migration and exchanging of nutrients and waste. Furthermore, the porous scaffold better mimic the extracellular matrix.
Biological assays showed an higher osteoblast adhesion in chit:chitHVP as expected by the nature of the vitronectin-derived peptide. In any case, all functionalized matrices stimulated cell adhesion. Moreover, the bioactive nature of the scaffolds is further evidenced in the four-day proliferation assays, where osteoblast proliferation is significantly higher for all matrices compared to the pure chitosan control. The powerful osteoblast differentiation factor GBMP1a is proved by the gene expression assay, where the chit:chitBMP scaffold reported the highest expression of all 3 genes. Finally, mechanical tests highlighted that chit:chitHVP, chit:chitBMP, and chit:chitHVP-BMP scaffolds showed similar compressive behavior to the pure chitosan matrix, while the remaining samples showed a reduction in mechanical properties, probably due to the more complex structure and steric hindrance due to the inclusion of both peptides in the same scaffold. These materials could be used to treat small bone defects or as a coating for implants, considering their mechanical properties that result lower than the natural bone ones.

ACKNOWLEDGEMENT

The authors would like to thank Alissa Di Giulian and Vittoria Facchin for their help in the peptide synthesis and scaffolds functionalization.

***Abstract*— Currently the main challenge of tissue engineering is the realization of materials that can replace tissues and organs and perfectly integrate with the host organism ensuring the proper functionality. Hybrid Membranes (HYMEs) were produced by coupling a decellularized tissue (porcine pericardium) with a polymeric material (polycarbonate urethane). HYMEs biocompatibility was assessed *in vitro* by direct contact cells seeding and *in vivo* by implantation in the rat model. *In vitro* no cytotoxicity was observed and cells growth was demonstrated until 7 days. *In vivo* HYMEs appeared better integrated with the host tissue than the polymer alone (control) after 4 weeks from implantation. Moreover, the polymer was not affected by degradation.**

***Keywords*—Hybrid membrane, biocompatibility, tissue engineering.**

I. Introduction

As reported by the World Health Organization, Cardiovascular diseases (CVDs) are the leading cause of death globally [1]. Among CVDs, atherosclerosis is one of the most frequent conditions: in the arterial intima, it is characterized by the formation of plaques containing cells, fragments of collagen and elastic fibers, proteoglycans and lipids. Atherosclerotic plaques generally evolve causing the reduction of the lumen and/or the damage of vascular tissues with the subsequent decrease of blood flow. This condition can cause thromboembolic events [2]-[4].

When a severe injury to cardiovascular structures occurs, the ideal therapy is the substitution of the damaged tissue with an autologous one to prevent the immune reaction. Indeed, this approach is limited by to the low availability of compatible healthy tissues due to patient's pathologies or harvesting procedures [5].

To bypass the lack of autologous cardiovascular substitutes, synthetic vascular grafts, e.g. polytetrafluoroethylene (PTFE) and polyethylene terephthalate (PET), and chemically treated biological tissues, e.g. glutaraldehyde treated pericardium, are currently used [6]. Unfortunately, these materials have shown insufficient reliability with increased risks of contamination and infections, thrombogenic reactivity and intimal hyperplasia formation [7]. Additionally, these grafts are non-viable materials and cannot be endothelialized *in vivo*, are not prone to remodeling and regeneration, hampering the process of integration with the recipient's organism [8].

Tissue engineering offers new strategies in order to minimize the drawbacks of current materials and improve patients' quality of life. The aim consists in obtaining higher biocompatibility using decellularization procedures, which allow removing cellular components, but preserving the original extracellular matrix (ECM) components, such as growth factors. Therefore, the acellular scaffold is prone to be repopulated by patient's cells and has the ability to optimally integrate with the host's body. However, mechanical performances, impermeability and patency of decellularized tissues are not completely satisfactory.

For these reasons, the present work aims at improving the mechanical features of decellularized pericardium by coupling it with a synthetic material (Chronoflex AR or Chronoflex ARLT). This novel material was named hybrid membrane (HYME). On the one side, the synthetic polymer provides mechanical resistance to the membrane, on the other side the decellularized tissue guaranties biocompatibility [9]. HYMEs cytotoxicity was assessed *in vitro* by direct contact tests and biocompatibility was investigated *in vivo* on the rat model by means of subdermal implantation.

II. MATERIALS AND METHOD

A. Pericardium procurement and decellularization

Fresh native porcine pericardia (NPP) were collected from a local slaughterhouse that followed EC regulation 1099/2009 protocols regarding animal health and protection. Tissues samples from the anterior right ventricular region were isolated and pre-pericardial fat was removed [10]. Tissue samples were decellularized in according to TergiCol methods [10], which was carried out using protease inhibitors, hypo- and hypertonic solutions, Tergitol (cod. 15S9) and Sodium Cholate (cod. C1254). Finally, samples were treated with an isopropanol based solution and endonuclease (Benzonase®, cod. E1014) was used to remove residual DNA fragments. All reagents were supplied by Sigma Aldrich (Saint Louis, MO, USA).

B. Membrane preparation and sterilization

HYMEs were made using the solution casting technique [11]. Pericardium was placed in a customized aluminium frame, and the polycarbonate urethane (ChronoFlex AR or ChronoFlex AR-LT, AdvanSource Biomaterials, Wilmington, MA, US) was poured over the fibrous face. Both polymers were supplied as 22% (w/v) solution in N,N-

dimethylacetamide (DMAc). The membranes were dried for 24 hours at 38°C in a vacuum oven (Raypa, Barcelona, Spain). Two types of membranes were made: DPP AR and DPP ARLT by coupling porcine pericardium with Chronoflex AR and Chronoflex ARLT, respectively. Two other polymeric membranes (CF AR and CF ARLT) were made and used as controls.

HYMEs were sterilized with a two-step treatment with a cocktail of antibiotics and antimycotics and peracetic acid [12]. In Fig. 1 two types of HYMEs are shown.

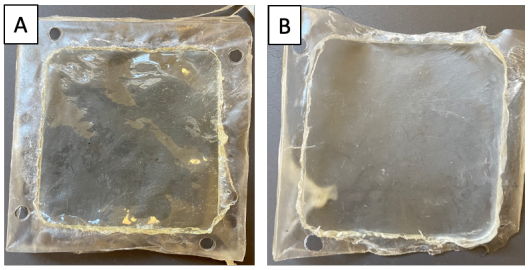

Fig. 1: HYMEs made by coupling DPP with CF AR (A) and CF ARLT (B).

C. In vitro cytocompatibility

HYMEs cytocompatibility was first assessed *in vitro* by direct contact tests, carried out by seeding HUVECs (cat. no. C12200, PromoCell, Heidelberg, Germany) on decellularized pericardium (control group 1), hybrid membranes on tissue side and polymers alone (control group 2), in accordance with ISO 10993 part 5 [13]. In order to perform direct cells seeding, DPP were cut into 2×2 cm^2 squares and mounted in aseptic conditions in inserts with a culture area of 0.5 cm^2, which were then placed in 24-well plates. Conversely, hybrid membranes and polymeric samples were cut into 8 mm diameter circular patches and directly placed into 48-well plate. All samples groups were equilibrated overnight in fresh culture medium (cat. no. C-22211, PromoCell, Heidelberg, Germany) containing SupplementPack (cat.no. C-39211) and 1% penicillin-streptomycin at 37°C in incubator. On the following day (day 0), samples were directly seeded with Huvec cells (30,000 cells/ cm^2), which were cultured for 1, 3 and 7 days. Cell viability was assessed using the Live and Dead assay (Thermo Fisher Scientific, Waltham, MA, USA), following the manufacturer's instructions: it allowed staining live cells with calcein (green) and dead cells with Ethidium homodimer-1 (red). Images of cultured tissues and hybrid membranes were acquired with an epifluorescence microscope Leica AF6000, connected to a Leica DC300 digital camera and equipped with LAS AF Software (Leica Micro-System, Wetzlar, Germany) while polymers images were acquired with an Olympus IX71 fluorescence microscope (Olympus, Tokyo, Japan). Pictures were then processed with an opensource software, Fiji.

Cells metabolic activity was measured on day 1 and 7 with WST-1 assay kit (Boster Biological Technology, Pleasanton, USA), by incubating samples with 2.5% (v/v) WST solution in culture medium at 37°C for 1.5 hrs in incubator. The amount of reduced WST-tetrazolium was calculated by absorption at 450 nm with a spark 10M TECAN microplate reader (Tecan, Männedorf, Switzerland).

Finally, samples were fixed in 4% v/v PFA for 5 min at room temperature, permeabilized with 0.1% v/v Triton X-100 for 15 min, followed by blocking in 1% w/v BSA solution for 30 min. Samples were then stained with phalloidin—Atto 647N (1:200) to counterstain filamentous actin, and with DAPI to stain nuclei. Pictures were taken with an epifluorescence microscope Leica AF6000 connected to a Leica DC300 digital camera and equipped with LAS AF Software (Leica Micro-Systems, Wetzlar, Germany). Post-imaging analysis was performed using Fiji software.

D. In vivo tests

Samples of polymers (CF AR and CF ARLT) and HYMEs (DPP AR and DPP ARLT) were subdermally implanted in rats to evaluate possible effects due to calcification and polymer degradation. Reaction of the host tissues in direct contact with the materials was also evaluated. Sixteen 21 days-old Sprague Dawley rats (Charles River, USA) with a mean body weight of 73.2 ± 11.04 g were anesthetized with inhalation of Sevoflurane in oxygen medical atmosphere (4%) and locally treated with bupivacaine. A subdermal dorsal pouch was created on each rat and a round specimen (8 mm diameter) was implanted. Each material was grafted into 4 rats and explanted after 4 weeks [14].

All experiments were carried out as stated in authorization of the Italian Ministry of Health No. 782/2021-PR (protocol number 965E9.41) and animal were treated in according to UNI EN ISO 10993-2 [15].

The weight of the animals was collected all along the observation period and considered as an indicator of animals' well-being [16].

Fourier Transform Infrared Spectroscopy Attenuated Total Reflection FTIR-ATR (Nicolet iS-50, Thermo Fisher Scientific, Waltham, Massachusetts, USA) analysis was performed on explanted materials to determine whether any chemical changes appeared on the surface of the polycarbonate urethane. Before FTIR-ATR analysis, all materials were equilibrated in deuterium oxide (Janssen, Beerse, Belgium) to reduce the contribution of interfering water.

The geometric characteristics of the explanted patches were evaluated to check possible degradation effects. A digital caliper (Mitutoyo, Kawasaki, Japan) was used to measure thickness, and area was calculated on images of the specimens processed with Fiji.

III. RESULTS

A. In vitro cytocompatibility

Live and Dead assay (Fig. 2A-E) allowed evaluating the presence of live (green) and dead (red) cells at 1, 3 and 7 days after seeding DPP, hybrid membranes and polymers alone with HUVECs. Some dead cells were detected only in DPP-ARLT on day 1 and in DPP on day 3, while in other groups very few dead cells were displayed at each timepoint. On the contrary, a significative increasing of live cells was evident both on day 3 and 7 in all groups, especially in the case of hybrid membranes, which were completely covered by live cells.

Metabolic assay using WST (Fig. 2F) performed after 1 and

7 days from seeding showed no significant difference in the case of seeded DPP; differences appeared over DPP AR and CF AR, where metabolic activity of seeded cells was found at day 7. Lastly, an increase of metabolic activity was detected at day 7 on DPP ARLT and CF ARLT, but it was not significant.

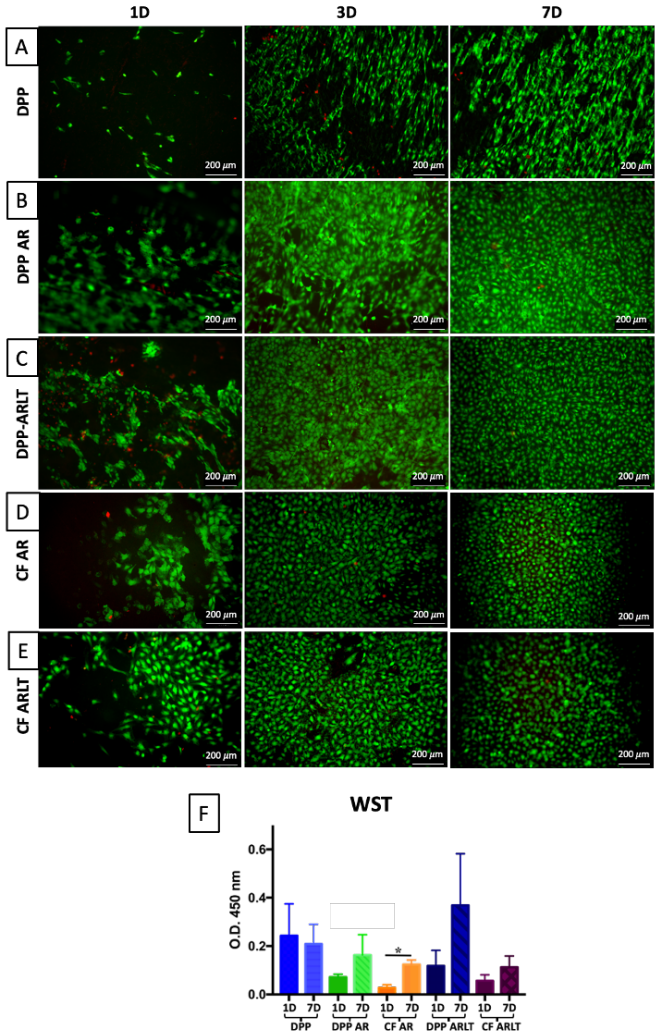

Fig. 2: Live and Dead assay of decellularized pericardium (A), DPP AR (B), DPP ARLT (C), CF AR (D) and CF ARLT (E) after 1, 3 and 7 days from seeding. Metabolic assay with WST (F) of decellularized tissue, hybrid membranes and polymers alone at 1 and 7 days after seeding.

DAPI (cyan) and phalloidin (magenta) staining highlighted the presence of nuclei and F-actin in DPP, hybrid membranes and polymers alone on day 1, 3 and 7 (Fig. 3). Evident cells proliferation was found in all groups, especially after 7 days. In the case of DPP alone, cells needed a longer time to cover the whole sample surface: on day 3 it was the only group for which cells were not completely spread, but after 7 days they completely covered the surface.

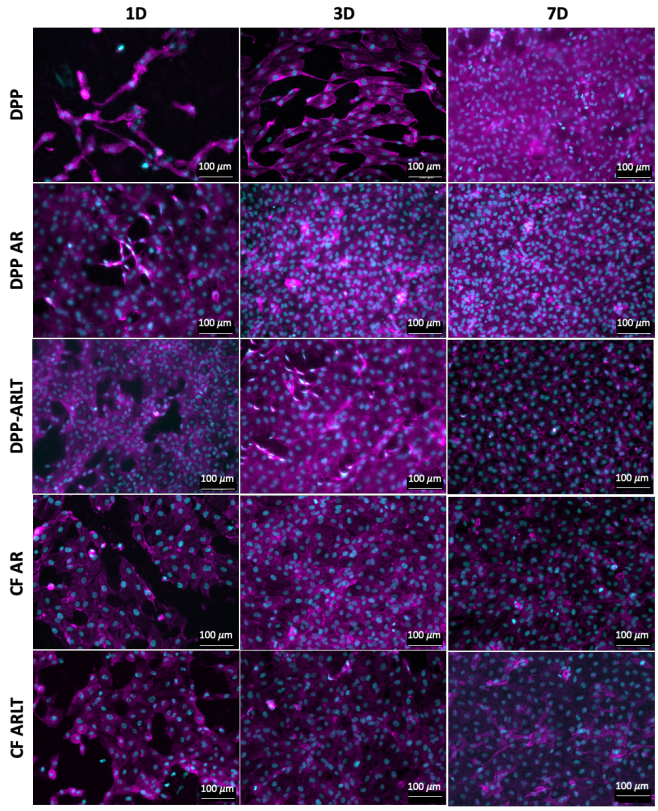

Fig. 3: DAPI (cyan) and phalloidin (magenta) staining of nuclei and F-actin, respectively of DPP, hybrid membranes and polymers alone.

B. In vivo test

All samples were explanted 4 weeks after implantation. As it is illustrated in Fig. 4A, the surgical wound has completely healed and the materials were well integrated with the surrounding tissues, which appeared vascularized: no signs of inflammation were evident.

Within 4 weeks, the rats increased in weight ~2.5 times, from 73.2 ± 11.04 g to 265.06 ± 49.54 g. Weight growth is in accordance with the characteristics of the animal reported by the supplier [17]. This aspect confirmed the good health of the animals and was considered as an index of successful biocompatibility. During surgery and subsequent clinical follow-up, any score of suffering or distress was monitored.

Analyzing the explanted materials, area and thickness of each sample were calculated and no significant difference was found before and after implantation for both polycarbonate urethane (CF AR and CF ARLT) and HYMEs (DPP AR and DPP ARLT).

FTIR-ATR spectra of CF AR and DPP AR explanted specimens, analyzed from polymer side, are reported in Fig. 4B. The spectra of the implanted materials coincided with the spectrum of the CF AR polymer used as ~~a~~ control. The characteristic peaks of the CF AR were present: peaks of urethane and carbonate groups were found at 1737 and 1251 cm^{-1}, while peaks around 1251, 956 and 791 cm^{-1} were due to carbonate groups in the soft segment. The presence of aromatic molecules in the hard segment was confirmed by the peak at 1598 cm^{-1}, while the peak at 1637 cm^{-1} was due to the presence of diamine [18].

The same results were found for CF ARLT and DPP ARLT (Fig. 4C). The composition of CF ARLT was the same of CF

AR, with the exception for the presence of micro-silica particles whose peaks were detected in the interval 1200- 900 cm^{-1}.

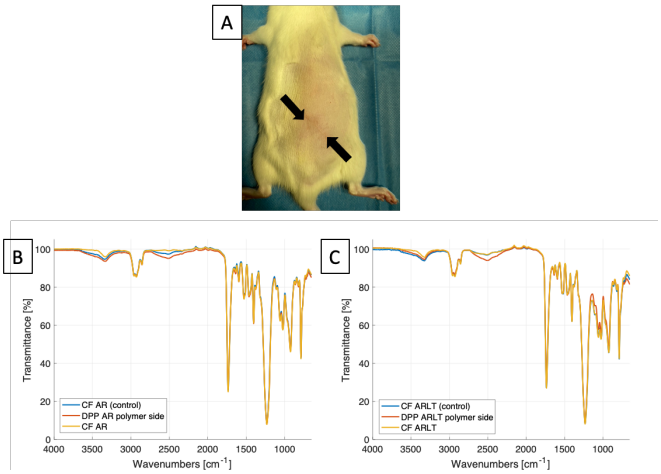

Fig. 4: View of the rat's back at 4 weeks after implantation: arrows indicate where the cutting had been made (A). FTIR-ATR spectra of CF AR and DPP AR (polymer side) (B) and CF ARLT and DPP ARLT (polymer side) (C).

IV. Conclusion

This preliminary *in vivo* and *in vitro* assessment of HYMEs confirmed their high biocompatibility. In vitro, the membranes did not show any cytotoxic effect and promoted cells proliferation 7 days after seeding. Preliminary *in vivo* results were promising as well: neither inflammation nor rejection occurred after implantation and the polymeric part did not degrade.

Further investigations are in progress to assess the ability of the hybrid membranes to integrate *in vivo* and to evaluate the effects of possible calcification. Additionally, an *in vivo* functional implantation in the long term has to be performed for a comprehensive characterization of the investigated materials in order to analyze their ability to properly interact with blood.

***Abstract*—The extracellular matrix plays a crucial role in the regulation of tissues and organ functions under both physiologic and pathologic conditions. In our body, each organ is provided with a site-specific ECM presenting to the cells the instructive molecular signals triggering and guiding organ-specific biological processes. Here we report a bioengineering method to obtain scaffold-free organotypic tissues composed of an endogenous and site-specific connective microenvironment.**

***Keywords*—modular tissue engineering, endogenous ECM, stroma, morphogenesis.**

I. Introduction

Organotypic tissues (e.g. skin, lung, cervix, gut) are composed of a connective compartment supporting the growth and the differentiation of a highly specialized epithelium. The difference between such tissues is not only represented by the epithelial cells which display different functions. The connective compartment also plays a crucial role in of developing and maintaining the whole organ [1]. Depending upon body location and tissue origin, fibroblasts elaborate and assemble different ECMs in terms of composition, mechanical, transport properties, and architecture. Such properties are tissue-specific establishing specific signaling to the corresponding epithelia. For instance, hair follicle morphogenesis occurs via the talk cross-talk between specific signals deposited in the dermis and the epithelial cells [2]. However, the dynamic reciprocity between cells and their own ECM plays a crucial role in many biological processes such as cancer progression [3], alterations in the ECM during organ diseases [4]–[6], branching morphogenesis [7], and functional epithelial development in vitro [8], [9]. The in vitro fabrication of functional organotypic tissues results of key relevance to studying the effect of both aging and extrinsic factors (e.g. AGEs, pollutant, dietary regimes, chemicals, etc..) on organ functionalities. In most in vitro applications involving barrier organs, both on-chip, and off-chip, the epithelial part is considered the only functional one. Therefore, the in vitro replication of barrier tissues is often obtained by inducing epithelial cell polarization on porous membranes, the so-called 2.5D model. More complex full-thickness 3D models, make use of fibroblasts-populated exogenous biomaterials to mimic the connective compartment. In such approaches, the mostly used ECM analogs for the in vitro fabrication of connective tissues are collagen type I or type III, mixtures of collagen and glycosaminoglycans, Matrigel, or hydrogels of either synthetic or natural origin. Although such matrices provide a suitable environment to maintain fibroblasts viability and support the differentiation of the corresponding epithelia, hold different limitations. Their exogenous origin does not allow a correct replication of spatial-temporal signal presentation necessary for the maintenance of organ functions. Often, the same material is used as a feeder for different epithelia with a clear loss of tissue specificity. At last, exogenous matrices are not able to evolve (in terms of composition, architecture, and biophysical properties) according to a specific pathophysiological status. This represents a strong limitation if one wishes to replicate, for instance, inflammatory status involving the connective compartment also. Compared to exogenous matrices, connective tissue made of fibroblasts-synthesized ECMs has been proven to be more functional [8], [9] compared to exogenous matrix-based counterparts. We previously demonstrated that an engineered full-thickness human skin composed of an endogenous dermis was able to replicate crucial biological phenomena that are not observed in the traditional full-thickness tissues: inward differentiation of human keratinocytes with subsequent formation of hair-follicle structures; (ii) rete ridge profile of the dermal/epidermal interface; (iii) replication of the ECM remodeling after a damage [8]. Also, full-thickness intestinal models possessing an endogenous connective submucosa resulted a more functional tissue compared to the corresponding exogenous one [9]. To build utissue-specific connective microenvironment, in this work, we use a modular tissue engineering approach [10] to fabricate different endogenous ECMs starting from human fibroblasts coming from different body locations (skin, lung and cervix). Fibroblasts are firstly used to build up connective microtissues (μT) having a mean diameter of 200 μm. During the μT formation fibroblasts were induced in synthesizing their own ECM. Such microtissue are then used as building blocks to form macroscopic 3D tissues (3D-Dermis, 3D-Lung and 3D-Cervix respectively) as reported in Figure 1. We will demonstrate that each fibroblast synthesized and assembled a tissue specific ECM paving the way for the building up of completely endogenous, functional and histological competent full thickness barrier organs.

II. Material ad methods

A. Cells expansion

Human dermal fibroblasts (neonatal HDF 106-05n ECACC), Human lung fibroblasts (NHLF Lonza CC-2512), and extracted Human cervical fibroblast (HCF obtained by National Cancer Institute 'Fondazione Pascale' after informed consent, were sub-cultured onto 150 mm^2 Petri dishes in culture medium (Eagle's BSS Minimum Essential Medium containing 20% fetal bovine serum, 100 µg/mL L-glutamine, 100 U/mL penicillin/streptomycin, and 0.1 mM Non Essential Amino Acids). Cells were maintained at 37 °C in humidified atmosphere containing 5% CO2. Cells in a range of passages 4-7 were used [8], [11].

B. Microtissue fabrication

Gelatin microbeads having a diameter of 75-150 µm, stabilized by 4% of glyceraldehyde were fabricated by means of a modified double emulsion technique (O/W/O) as previously reported [10]. Briefly, gelatin (type B Sigma Aldrich Chemical Company, Bloom 225, Mw 176,654 Da) was dissolved into 10 ml of water containing TWEEN 85 (6% w/v) (Sigma Aldrich Chemical Company) at 60 °C. Toluene containing SPAN 85 (3% w/v) (Sigma Aldrich Chemical Company) was continuously added to the aqueous gelatin solution (8% w/v) to obtain primary oil in water emulsion. Microbeads of gelatin containing droplets of toluene were produced through the addition of excess toluene (30 ml). After cooling below 5 °C, 20 ml of ethanol were added to extract toluene and stabilize gelatin microbeads. The resulting microspheres were filtered and washed with acetone and then dried at room temperature. To make the Dermis–µT, Lung–µT and Cervix–µT, spinner flask bioreactor (250 ml, CELLSPIN, Integra Biosciences) was inoculated with a cell density of 105 cell/ml and a gelatin microbeads density of 2 mg/ml (corresponding to $5*10^3$ beads/mg), to obtain an initial ratio of 10 cells per microbead. The culture suspension was stirred intermittently at 30 rpm (5 min stirring and 30 min static incubation) for the first 6 h post-inoculation to allow cell adhesion, and then continuously at 30 rpm for up to 10 days. All cultures were maintained at 37 °C in a humidified 5% CO2 incubator. The culture medium was replenished on the first day and every 2 days until the end of the experiments. 50 µg/ml of ascorbic acid (l-ascorbic acid Sigma A-5960) was added at each medium change Figure 1 top right).

C. Connective macrotissues fabrication 3D-Dermis, 3D-Lung and 3D-Cervix

After 10 days of culture time the Dermis–µT, Lung–µT and Cervix–µT suspension were withdrawn from the spinner flask and transferred and cultured in an assembling chamber. The assembling chamber has a sandwich-like structure in the middle of which is a silicon mold with empty spaces (1 mm in thickness, 5 mm in diameter) where the Dermis–µT, Lung–µT and Cervix–µT assembly respectively takes place [8], [11]. The silicon mold is delimited on both the top and bottom sides by two stainless steel rigid grids; the grids are posed on both sides of the system and are fastened to each other using stainless steel screws to close the assembling chamber. The assembling chamber was then placed on the bottom of a spinner flask (Bellco biotechnology code 1967-00050) and surrounded by culture medium that was exchanged every 3 days (Figure 1 bottom right). The spinner was operated at 60 rpm allowing convective mass transport across the entire thickness of the assembling chamber in which the tissue maturation process takes place [10].

Macrotissue characterization

Histology. For histological analysis, 3D-Dermis, 3D-Lung, and 3D-Cervix were fixed in a solution of 10% neutral buffered formalin for 24 h, dehydratases in in an incremental series of ethanol, and embedded in paraffin. Cross sections 7 µm thick were obtained by using a microtome (MICROM HM355S Bioptica) and stained using hematoxylin/eosin (Sigma Aldrich) following standard procedure.

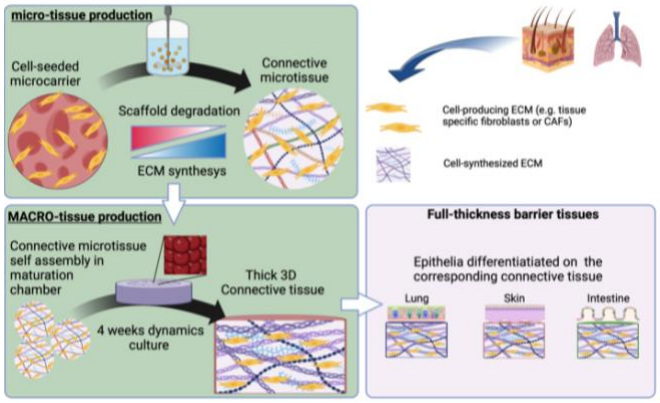

Fig. 1. Two-step bio fabrication method. Once obtained stromal cells from tissues, they were cultured in a spinner flask bioreactor in presence of porous microbeads (top left). During this step de novo synthesized ECM takes place and porous microbeads will degrade. The endogenous connective microtissues are then assembled in macroscopic structures (bottom left) to obtain 3D macroscopic tissue-specific connective tissue. In the final step o the process, each epithelial cell will be seeded on the corresponding connective to obtain full-thickness, tissue-specific and endogenous barrier tissues.

The sections were observed with a BX53 Olympus microscope and the images were acquired using an Olympus DP 21 camera.

Multiphoton imaging. The 3D-Dermis, 3D-Lung, and 3D-Cervix were fixed with 4% paraformaldehyde, and rinsed twice with PBS. The samples were imaged under multi-channeled Leica TCS SP5 II coupled with a Multiphoton Microscope where the NIR femtosecond laser beam was derived from tunable compact mode-locked titanium: sapphire laser (Chamaleon Compact OPO-Vis, Coherent). The samples were observed to induce second harmonic generation (SHG) (λex=840 nm, λem = 420±5) of unstained neo-synthesized collagen structures.

Scanning electron microscopy (SEM). The 3D-Dermis, 3D-Lung, and 3D-Cervix were dehydratases in an incremental series of ethanol (75%, 85%, 95%, and 100% twice, each step 30 min at RT. The samples place were placed on conductive stub stubs, metalized by Cressington 208HR High-Resolution Sputter Coater with 10nm of Au, and then examined by scanning electron microscopy (SEM) (Leica S400).

ECM composition. 3D-Dermis, 3D-Lung, and 3D-Cervix samples were fixed in paraformaldehyde 4% (20 min at room temperature), dehydratases in an incremental series of ethanol, and embedded in paraffin. Cross sections 7 µm were incubated for 3 h at room temperature with primary antibodies, followed by incubation with the appropriate secondary antibody for 2 h

at room temperature. The primary monoclonal antibodies used in this study included: anti-Elastin antibody (diluted 1:200; Abcam, Cambridge, UK); anti-Laminin antibody (diluted 1:50; Abcam), anti-Fibronectin antibody (diluted 1:400; Abcam) and anti-Hyaluronic acid antibody (diluted 1:100; Abcam). The secondary antibodies used were: AlexaFluor 488 goat anti-mouse (Life Techologies, Milan, Italy); AlexaFluor 568 goat anti-mouse (Life Techologies); all secondary antibodies were diluted 1:500 in PBS/BSA 3%. After rinsing with PBS, the tissue in the device was stained by 4',6-diamidin-2-fenilindolo (DAPI) 1:10000 and incubated for 10 min at room temperature. The simples were imaged with multichanneled Leica TCS SP5 II coupled with a Multiphoton Microscope where the NIR femtosecond laser beam was derived from a tunable compact mode-locked titanium: sapphire laser (Chamaleon Compact OPO-Vis, Coherent). The excitation/emission wavelengths were set as follows: λex= 500 nm, λem = 510-530 nm (single photon mode, for Elastin and Fibronectin) and λex= 580 nm, λem = 612-623 nm (single photon mode, for Laminin and Hyaluronic acid); λex = 720 nm, λem = 460 ± 10 nm (two photon mode, for DAPI). The fluorescence quantifications were obtained by dividing the green/red pixels number by the cells number. The number of pixels and the number of cells were obtained by using ImageJ software. The analysis was performed in three independent experiments.

III. RESULTS

A. *ECM architecture and composition*

ECM architecture. Fig. 2A-C shows the histological sections of 3D-Dermis, 3D-Lung and 3D-Cervix respectively. After the maturation time, no more microbeads were still detected, and compact tissues scaffold-free were obtained. In Fig. 2 D-F was showed the macroscopic collagen architecture for each proposed model; in particular, the collagen network appears to get organized in parallel fibers in the cases of 3D-Dermis and 3D-Cervix. Only in the 3D-Lung model, the fibroblasts organize the collagen network recreating the alveolar-like structures of about 50 μm. Although in this model, no pneumonocytes were added as epithelial alveolar cells, the fibroblasts still organize the ECM in order to accommodate such alveolar structures. By increasing the zoom factor in the ECM space (Fig. 2 G-I), once again the sponge-like micro/nano architecture of the lung tissue was detected. Indeed, collagen niches of 200 nm were recreated (Fig. 2M); on the contrary, for 3D-Dermis and 3D-Cervix an intricate network of collagen fiber is present (Fig. 2L, 2N).

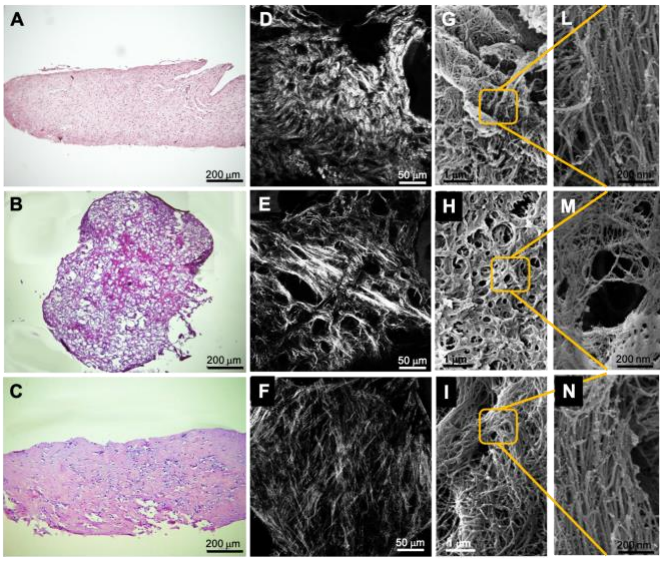

Figure 2. Architecture and organization of the 3D connective tissues. First row: histology of the 3D Dermis (A), SHG images (B), SEM images (G, L). Second row: histology of the 3D Lung (B), SHG images (E), SEM images (H, M). Histology of the 3D Cervix (C), SHG images (F), SEM images (I, N).

ECM composition. From a compositional point of view the endogenous ECMs were different in terms of HA elastin, and collagen fraction as reported in Figure 3. 3D-Cervix showed the highest amount of HA (Fig. 3, top) while 3D-Lung the lowest, the content of HA in the 3D-Dermis was in the between, with no statistical differences both with D-Cervix and 3D-Lung. The elastin fraction (Fig. 3, centre) resulted higher in 3D-Cervix if compared with the 3D-Dermis, while the 3D-Lung was in the middle, with no statistical differences with both 3D-Cervix and 3D-Dermis. The collagen fraction (Fig. 3 bottom) showed a lower collagen amount for 3D-Lung model. Indeed, both in the macroscopic and micro/nanoscopic scale, the circular shapes recreated in the ECM represented a non-collagen zone. On the contrary, in 3D-Dermis and 3D-Cervix models, higher values were reported with no statistical differences.

IV. CONCLUSIONS

Here we have reported a bioengineering method to build up scaffold-free, and tissue-specific thick endogenous ECMs. In particular, we fabricated connective tissue of the dermis, lung and cervix. We demonstrated that fibroblasts from different sites, when induced in producing their own ECM in vitro, elaborated different microenvironments resembling their native site-specific context (Fig. 2 and 3). As tissue functionalities, both in vivo and in vitro, are strictly related to the local microenvironment, we argue that this approach will have tremendous implications in the future fabrication of full thickness barrier tissue and in organotypic tissues. In fact, endogenous ECMs has been proved to be responsive and adaptive to different stimuli, by changing their composition and architecture in concert with cells' actual needs [12], [13]. This will make in vitro studies concerning aging and other pathologic conditions (e.g. cancer, inflammations, AGEs) more truthful.

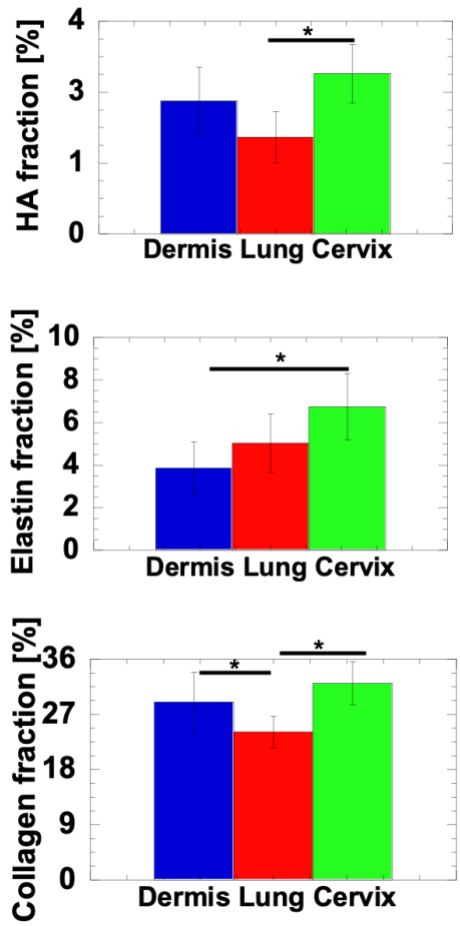

Figure 2. Composition of the three different engineered ECMs. Hyaluronic acid (HA), Elastin, and collagen fraction.

***Abstract*—As an attempt to find alternatives to expensive microfabrication processes for polymer-based scaffolds for tissue engineering, in this work hydrogel-based photopolymers were engineered to be microstructured at high resolutions by low-cost stereolithography (SLA). To this end, both synthetic and natural/synthetic materials were blended with additives, directly affecting the SLA-printing resolution. Different formulations with tunable mechanical properties were selected for the rapid prototyping of biocompatible millimetric scaffolds with varied internal porosity, potentially exploitable for tissue engineering applications.**

***Keywords*— Stereolithography, hydrogel, tissue engineering, scaffold.**

I. Introduction

To date, 3D printing techniques are considered well-established methods in tissue engineering and regenerative medicine for the fabrication of 3D synthetic structures [1]. Among all, photopolymerization-based techniques, such as stereolithography (SLA) and two-photon polymerization (2PP), have been exploited to realize stable scaffolds with tailored geometry and porosity, which is crucial to guide cells response [2], [3]. Novel 3D photocurable materials have been developed to address specific requirements in terms of biocompatibility, biofunctionality, and stiffness [4]. Despite their rapid growth, research efforts are still needed to improve scaffolding materials. In this scenario, double network (DN) systems based on methacrylated hyaluronic acid (HAMA) and polyethylene glycole diacrylate (PEGDA) are of great interest, due to the synergic combination of natural/synthetic hydrogels whose ratio can be tuned to tailor the substrate stiffness while guaranteeing biocompatibility [5].

Here, a PEGDA-HAMA system was optimized for high-resolution 3D printing scaffolds exploiting low-cost bench-top SLA, instead of expensive and time consuming 2PP [6]. High printing speed and high printing resolution were successfully obtained by blending with additives, whose content was optimized in terms of key parameters used to quantify the SLA behaviour, namely critical energy E_c (required energy dose to cross-link the resin) and depth of penetration D_p (length of penetration of the laser within the resin, respectively) [7].

II. Materials and Methods

A. SLA-curable hydrogel double-networks

DN systems were developed by adding HAMA (20-50% substitution, molecular weight Mw 20,000-30,000) to PEGDA (average molecular weight Mn = 700), mixed with photoinitiator (PI) TPO-L (4 wt%) at varied PEGDA-HAMA ratios (Table I). In order to tune the number of photons absorbed by the PI and thus to control the laser penetration, the photons absorbing competitor Brilliant Yellow (BY) dye was added at varied concentrations to the hydrogel-based formulations (Table I). All materials were purchased from Merck. According to the procedure described in reference [7], a "wedgeplot" method adapted from the standard diagnostic WINDOWPANE technique was exploited to determine the depth of penetration D_p and the critical energy E_c of the developed formulations, when they were used with a bench top SLA printer (XFAB2500HD, Digital Wax Systems, Italy) equipped with a monochromatic actinic laser source (Solid State Bluedge BE-1500A/BE-1500AHR); the latter had an emitting output power of 30 mW at a wavelength of 405 nm and a beam diameter of 50 μm [8], [9]. Each composition was measured thrice. The SLA processing parameters were adjusted according to the D_p and E_c values obtained, so as to fabricate millimetric scaffold prototypes with pores sizes in the range 250-500 μm.

B. Characterization Techniques

Optical microscope (OM) images were taken to study the morphology of the 3D printed scaffolds in terms of pore size and geometry. A custom-made indenter equipped with a 5 N-load cell was exploited to evaluate the stiffness of the 3D-printed hydrogels at their swollen equilibrium. Swelling experiments were conducted to measure the extent of the hydrogels' mass swelling, which, according to the Flory-Rehner theory, was correlated to the mechanical strength of the crosslinked networks and to their density of crosslinking [10]. To this end, hydrogels samples were swollen at ambient temperature in phosphate buffer saline (PBS) solution. Indentation tests and swelling measurements were repeated twice.

C. Cell Cultures

In order to preliminarily assess their biocompatibility, the SLA-printed scaffolds were thoroughly washed with phosphate buffer solution (PBS), sterilized under UV-light for 25 min, seeded with primary dermal fibroblasts (FBs) extracted from human connective tissue and cultured for 1 week in a dedicated incubator. Then, the scaffolds were analysed by confocal microscopy following conventional staining protocols with wheat germ agglutinin (WGA)-594 and Hoechst 33342, for membrane and nuclei visualization, respectively.

III. Results and Discussion

The first objective of the present work was the formulation of laser-curable hydrogel-based photopolymers that could be processed with a bench-top SLA apparatus for the direct fabrication of millimetric scaffolds. To this end, starting from pure PEGDA, we investigated the effect of increasing amounts of BY on the resins' behaviour in terms of SLA processability. Table I presents D_p and E_c values experimentally determined for the developed formulations. As expected, by increasing the BY content, which competed in photons absorption with the PI (whose content was fixed at 4 wt%, following previous studies [11]), D_p progressively decreased, moving from 0.29 mm down to 0.11 mm, for a BY content increasing from 0 to 0.5 wt%. Conversely, no apparent trend was observed for the E_c values.

Blending PEGDA with natural-derived hydrogel HAMA was found to further decrease D_p values, down to around 0.08 mm (Table I), similarly to commercial high-performance SL resins taken as a benchmark (e.g. DL260 resin by Digital Wax Systems, Italy, with D_p = 0.079 mm and E_c = 9.5 mJ/cm^2). The higher E_c values obtained for these blends were likely due to the HAMA's higher molecular weight and lower methacrylates substitution with respect to PEGDA.

TABLE I: Hydrogel double-networks for SLA-processing and related values of depth of penetration and critical energy.

PEGDA:HAMA	Brilliant Yellow [wt%]	D_p [mm]	E_c [mJ/cm^2]
100:0	0	0.29 ± 0.004	1.4 ± 0.07
100:0	0.01	0.28 ± 0.005	1.7 ± 0.082
100:0	0.1	0.23 ± 0.003	1.8 ± 0.065
100:0	0.25	0.21 ± 0.001	2.9 ± 0.033
100:0	0.5	0.11 ± 0.001	1.1 ± 0.043
90:10	0.25	0.07 ± 0.001	11.4 ±1.4
70:30	0.25	0.09 ± 0.002	25.3 ± 1.3
65:35	0.25	0.08 ± 0.002	18.3 ± 1.25

The PEGDA pristine formulation with the lowest D_p value (PEGDA with 0.5 wt% BY) and the PEGDA:HAMA formulation with the average D_p value (65:35) were exploited for SLA-printing of millimetric scaffolds with micron-sized features. Circular and square scaffolds with varied micro-pore geometry in terms of size and shape (Figure 1) were successfully fabricated within 20 minutes. OM images revealed excellent physical integrity of the printed structures and confirmed that the pore shapes and sizes were consistent with the nominal values from CAD drawings. All pores were completely open throughout the millimetric scaffolds, which showed a fully interconnected pore networks and a well-defined and repetitive architecture.

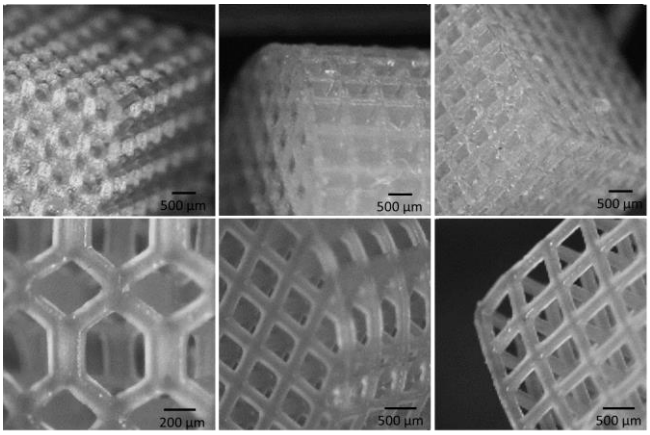

Fig. 1: OM images of SLA-printed hydrogel-based scaffolds with varied geometries.

The mechanical properties of the SLA-printed scaffolds based on the two selected formulations were characterized in terms of mechanical strength. Swelling measurements were used with the Flory-Rehner theory to calculate the crosslinking densities υ_{FR}. Data reported in Table II indicate that higher crosslinking densities were obtained for the pristine PEGDA formulation (2.4×10^{-4} mol/cm^3) relative to the PEGDA:HAMA blend (6.1×10^{-5} mol/cm^3). The decrease of mechanical strength upon blending with HAMA was confirmed by the indentation tests: the Young's modulus Y measured on the PEGDA-based scaffolds was ~688 kPa, whilst that of the PEGDA:HAMA blend was ~187 kPa (Table II).

TABLE II: Hydrogel double-networks for SLA-processing and related values of crosslinking density and Young's modulus.

PEGDA:HAMA	Brilliant Yellow [wt%]	Crosslink Density V_{FR} [mol/cm^3]	Y [kPa]
100:0	0.5	2.4×10^{-4} ± 0.1	688 ± 0.3
65:35	0.25	6.1×10^{-5} ± 5.7	187 ± 3.3

As for the E_c values, this result was probably due to the HAMA's higher molecular weight and lower methacrylates substitution with respect to PEGDA, resulting in a higher average molecular weight among crosslinks [5]. Interestingly, the Young's moduli of the 3D printed scaffolds obtained with the hydrogel formulations cover a broad range, which makes them potentially suitable to mimic a variety of physiological values typical of different soft biological tissues [12].

The biocompatibility of the scaffolds was investigated by performing preliminary cell cultures. After 1 week of incubation, cells were alive and randomly distributed within the micro-pore architecture. As visible in Figure 2, the cells showed flat and elongated spindle-like morphology, which is typical of optimal adhesion to the substrate.

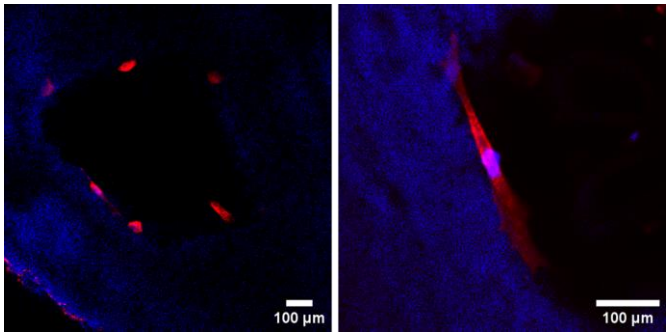

Fig. 2: FBs cultured onto the 3D scaffolds, showing typical elongated morphology.

IV. Conclusions

Synthetic and interpenetrating natural/synthetic photopolymers based on hydrogels were successfully optimized for high-resolution 3D printing of cell scaffolds, by means of a low-cost bench-top SLA apparatus. By optimizing the additive content, the SLA behaviour of the formulations was engineered for the rapid prototyping of millimetric scaffolds, with fully interconnected internal microarchitectures at high resolution, avoiding the use of expensive 2PP fabrication processes. Mechanical properties and preliminary evidence of biocompatibility of the SLA-printed scaffolds indicated their potential applicability for engineering biological tissues on substrates with physiologically-relevant elastic moduli in the 10^2 to 10^3 kPa range.

Future developments of this work will include a more systematic campaign of formulation and testing of such hydrogels network and an in-depth investigation on their possible adoption to obtain cell scaffolds actually useful for tissue engineering.

Assessment of printability on autoclaved biomaterial inks for extrusion bioprinting

E. Spessot[1], A. Battistella[1], A. Motta[1] and D. Maniglio[1]
[1] *BIOtech Research Centre, Department of Industrial Engineering, University of Trento*

***Abstract*—3D bioprinting is a powerful method to produce layered cell-laden scaffolds with complex architecture. Natural polymers, such as gelatin and hyaluronic acid, are usually exploited for this purpose. An open challenge is the sterilization of the inks before printing, since it can impact their chemical/physical properties and mechanical stability. This paper investigates the suitability of autoclaving methacrylated gelatin (GelMA) and hyaluronic acid (HaMA) blends for their use as inks in extrusion-based bioprinting.**

***Keywords*—3D-Bioprinting, Biomaterial ink, Printability, Autoclave sterilization**

I. Introduction

In the field of tissue engineering and regenerative medicine, 3D-Bioprinting is an emerging technology that allows the fabrication of cell-laden scaffolds with customized chemical composition and morphology [1]. Extrusion-based bioprinting is one of the most widely adopted technique and allows the processing of a variety of ink formulations based on high-concentrated water-soluble polymers [2] or pre-crosslinked hydrogels [3]. To achieve an adequate shape fidelity and accurately reproduce the CAD model, the formulation of the inks should be careful designed to match specific rheological and physical properties [4]. Blends of gelatin and hyaluronic acid (HA) have been widely studied showing potential applications for different tissues by tuning the chemical and mechanical properties [5], [6]. They can be chemically modified with methacrylate groups to obtain a photocurable material (i.e., methacrylated gelatin -GelMA- and methacrylated hyaluronic acid -HaMA-). Bioink formulations based on GelMA/HaMA blends have been explored [7]–[10]. One big challenge in the design of the biomaterial blends is their sterilisation, since it has a strong impact on the materials inducing chemical degradation with significant impact on the mechanical properties or triggering secondary crosslinkings [11]. The main recognized treatments comprehend gamma ray- irradiation, filtration, autoclaving and exposure to ethylene oxide (EtO) gas [11], [12]. It was demonstrated the autoclave determines significative reduction in the GelMA and HaMA properties, so some authors suggest EtO treatment as the preferred method for the sterilization of the blend [12]. However, the access to EtO is less available, especially in research laboratories, and it requires specific location for installation and special operative procedures, due to extreme gas toxicity [13], making autoclave still a preferred option.

In the present work, we used GelMA and HaMA as base matrices for the ink development and we studied the suitability of the autoclave treatment on these blends, evaluating the printability and the physico-mechanical properties before and after printing.

II. Materials and Methods

A. Materials

Gelatin (from porcine skin, powder gel strength ~300 g Bloom; type A), methacrylic anhydride and hyaluronidase (hyaluronidase from bovine testes, Type I-S, lyophilized powder, 400-1000 units/mg solid) were purchased from Sigma Aldrich. Hyaluronic acid sodium salt (m.w. 1.0-1.5 MDa) was purchased by Glentham Life Sciences. Lithium phenyl-2,4,6-trimethyl-benzoylphosphinate (LAP, >98.0% (T)(HPLC)) was purchased by TCI Chemicals. All the reagents were used as received.

B. Methacrylation of the polymers, ink formulation and sterilization

Methacrylation of gelatin and hyaluronic acid (HA) was carried out following previously reported protocols [14], [15]. Then, freeze-dried GelMA was dissolved at 20% w/v in PBS at 50°C under magnetic stirring. Freeze-dried HaMA was dissolved in the GelMA solution at the desired concentrations: 2.4%, 3.4% or 4.4% (w/v), as reported in Table 1. LAP was added at a concentration of 5% with respect to the total polymer amount. GelMA/HaMA prepolymer solutions were autoclaved for 15 minutes at 121°C under vacuum, and with slow discharge process.

TABLE I: Biomaterial Ink formulations

Sample	*GelMA %(w/v)*	*HaMA %(w/v)*
GelMA	20	0
GelMAHaMA2	20	2.4
GelMAHaMA3	20	3.4
GelMAHaMA4	20	4.4

C. Rheological evaluation on the solutions before printing

The rheological evaluations were carried out on a Discovery Hybrid Rheometer DHR-2 (TA ® Instruments, New Castel, USA) equipped with a stainless-steel cone/plate system (50 mm diameter, 2° cone angle and 100 μm truncation gap distance) and a Peltier plate for the temperature control. All the GelMA/HaMA solutions were subjected to the following tests, performed in triplicates:

Oscillatory temperature sweep: Measurements were carried out to record the storage modulus (G'), the loss modulus (G''), and the loss tangent (tan δ) at different temperatures. Tests were performed from 15°C to 40°C, with

a thermal ramp of 2°C/min, at fixed frequency and shear strain of 1 Hz and 5%, respectively. From the analysis of the resultant curves, it was possible to extrapolate the crossover point between G' and G'', which corresponds to the sol-gel transition of the solution. The test was performed on the solutions before and post-autoclave to assess the change in the sol-gel transition temperature.

Rotational shear rate sweep: The test was carried out to investigate the flow behaviour properties of the inks [16]. Samples were equilibrated at 30°C and then subjected to a shear rate sweep from 0.1 to 300 s^-1. Viscosity curves were fitted with the power-law model (Eq.1)

$$\tau = k\,\dot{\gamma}^{n} \qquad (1)$$

where τ is the shear stress, $\dot{\gamma}$ is the shear strain rate, n is the power law index, and k is the flow consistency index.

D. Printability assessment

The printability of the different inks was evaluated by means of an extrusion-based bioprinter (BIOX, Cellink) equipped with standard pneumatic printheads. The printability experiments were carried out on a polystyrene Petri dish substrate under the same printing conditions of 30° C cartridge temperature, 5° C printing bed temperature, 5 mm/s printing speed, 27G conical needle.

The extrudability of the inks was evaluated slowly increasing the air pressure until a continuous filament was extruded. The mass flow rate was determined by weighting the amount of an extruded ink in 30 second and calculating the gravimetric flow. Five different extrusion pressures were tested for each formulation selected starting from the minimum extrusion pressure and incrementing it of 5 kPa.

The quality of the printed structures has been evaluated considering the uniformity ratio (U) and the spreading ratio (S) on 5 strings 3 cm long. The parameter U is defined as the ratio between the length of the extruded strand and the length of a theoretical extruded strand, while S is defined as the ratio among the width of the printed filament and the needle diameter. The parameters were analyzed by ImageJ and MATLAB® software.

E. Swelling and mechanical characterization of the hydrogels after crosslinking

Swelling and mechanical tests were carried out on cylindrical hydrogels (diameter 8 mm, thickness 5 mm). GelMA/HaMA prepolymer solutions were extruded in silicon molds and the crosslinking was performed by means of a 365 nm UV lamp SpotLED Curing Equipment for 30 seconds at 15 cm of distance.

The water absorbency of the crosslinked hydrogels was measured gravimetrically. The as-prepared hydrogels were weighted (W0) and immersed in PBS (pH 7.4) at 37 °C. The samples were weighted every 60 minutes for 8 hours and after 24h. The wet weight of swollen hydrogels was determined at each time point by gently removing the excess of liquid with a filter paper. For each composition three replicates were tested, and the swelling degree (SD, in percentage) was determined as reported in Eq.2:

$$SD(\%) = \frac{Wt - W0}{W0} * 100 \qquad (2)$$

The mechanical properties of the crosslinked hydrogels were evaluated in compression mode. Hydrogels were kept in PBS at 37 °C for 24 h and then subjected to unidirectional compression tests with a Bose ElectroForce 3200 equipped with a 200N load cell (full scale) at a crosshead speed of 1 mm/min until sample breakage. Young's modulus (E) was calculated from the slope of the stress-strain curve in the linear range.

III. RESULTS

A. Rheological results

Rheological analysis was carried out to understand the temperature dependance and the inks flow behavior, evaluating the properties variation before and after the autoclave process.

The determination of the temperature at which the investigated materials shifted from solution state to gel state revealed an effect of the sterilization process and a dependency on the blend formulation. As reported in Fig. 1, there were no significant variations in the crossover point between different formulations before the autoclave treatment. While after the sterilization, the sol-gel transition occurred at lower temperatures depending on the amount of HaMA.

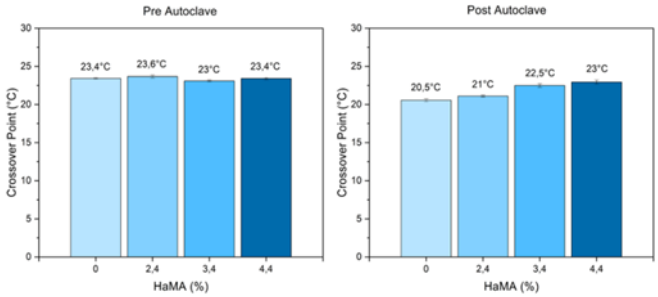

Fig. 1: Sol-gel transition of the inks pre and post autoclave

To examine the effect of different shear rate on the viscosity of the blends before and after autoclave, the properties were monitored at 30 °C, which was the temperature considered for the printing. As displayed in Table II, by increasing the amount of HA, the values of the power law index n are reduced indicating a higher degree of shear thinning, which is preferred to facilitate the extrusion. However, it is worth to notice that this effect is decreased in the autoclaved samples and the printability of these formulations was analyzed.

TABLE II: POWER LAW INDEX OF THE INKS PRE- AND POST- AUTOCLAVE

Sample	*n_pre AC*	*n_post AC*
GelMA	1.00 ± 0.01	1.01 ± 0.00
GelMAHaMA2	0.76 ± 0.03	0.97 ± 0.01
GelMAHaMA3	0.65 ± 0.07	0.82 ± 0.03
GelMAHaMA4	0.59 ± 0.05	0.71 ± 0.02

B. Printability assessment

In the design of biomaterial inks, rheological measurements are usually performed to study the flow properties of the inks and can give a preliminary information on the suitability of the

ink for extrusion 3D printing. However, they should be supported with an extended printability assessment to understand their extrudability and define the optimal printing parameters. Extrudability is the capability of the ink to produce uniform and continuous filaments when exiting the printing needle. In this work, the pressure was increased until a continuous filament was obtained and the calculated mass flow rate on different pressures is represented in Fig. 2.

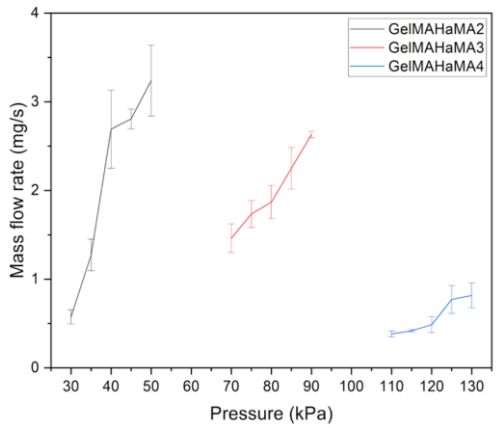

Fig. 2: Mass flow rate of the inks

Once defined the pressures, the uniformity and the width of the printed filaments was evaluated on printed straight lines, reported in Appendix. The results on the quantification of the uniformity ratio (U) are reported in Fig. 3. It is possible to observe that there are no trends correlating the printing parameter U and the increasing polymer concentration or the extrusion pressure. All ink formulations displayed a uniformity ratio that approached or slightly exceeded the unitary value. Therefore, printed strands were close to the perfect straight lines designed. This was expected since U is normally a parameter correlated to the degree of over or under crosslinking of a material. U values close to 1 indicate linear extrusion and are usually associated with polymer solutions having a fluid-like behavior [17], as in this case, since the printing temperature is higher than the sol-gel transition (Fig. 1).

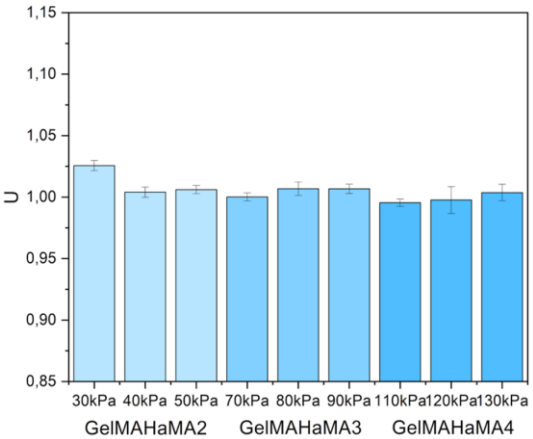

Fig. 3: Uniformity ratio (U) of the inks

The spreading ratio (S) is a useful parameter to measure the width of the printed filament considering its ability to maintain the cylindrical shape and against the spreading. As shown in Fig. 4, all ink formulations displayed S values greater than one varying from 3 to 7.5. Thus, all the tested blends largely deviated from the theoretical width due to a post-extrusion relaxation of polymer chains. Spreading ratio values higher than 2 were obtained also in other works [18], [19]. All the tested blends showed an increase of S with increasing extrusion pressure. For this reason, the selection of lower pressures must be preferred to obtain high precision printed constructs. However, even if GelMAHaMA4 was characterized by lower S compared to the other ink formulation, the printing was not completely uniform and there were problems related to needle clogging, maybe due to the high polymer concentration and the low mass flow rate.

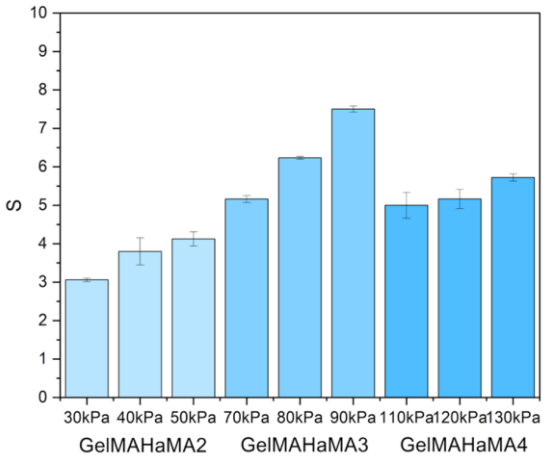

Fig. 4: Spreading ratio (S) of the inks

C. *Post-printing properties*

The swelling property of hydrogels is fundamental for cell adhesion, proliferation and nutrient exchange. The degree of swelling strongly depends on the polymer network, the interaction between the material and the solvent and the porosity. Fig. 5 demonstrates the change in the swelling degree of the hydrogels with the HaMA content. Among them, the equilibrium swelling degree of GelMAHaMA4 was the largest, as expected due to the highly hydrophilic nature of hyaluronic acid. For all the samples, the equilibrium swelling was reached within 24h after the immersion in PBS at 37°C.

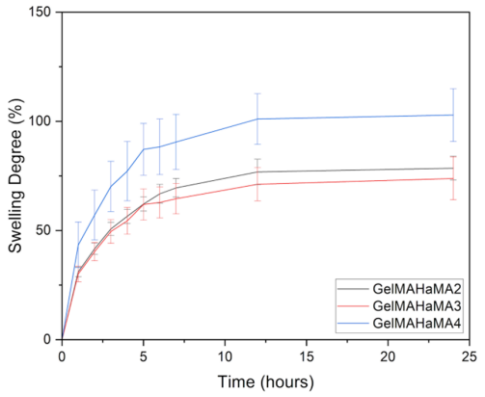

Fig. 5: Swelling degree (SD) of the inks as a function of time

The mechanical properties of hydrogels are fundamental for the stability of 3D printed structures. Compression tests were carried out to evaluate the mechanical properties of the final hydrogels after the autoclave treatment. The stress-strain curves and the compressive moduli of the different samples are

reported in Fig. 6. It can be observed that the increase of the HaMA content affects the stress-strain behaviour and can improve the compressive modulus of the hydrogel. The compressive moduli were determined to be 322±108 kPa, 361±121 kPa and 496±30 kPa for GelMAHaMA2, GelMAHaMA3, and GelMAHaMA4, respectively.

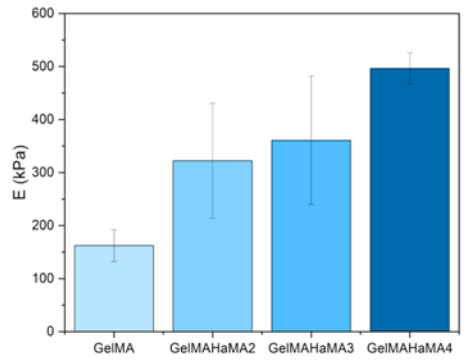

Fig. 6: Elastic moduli of the hydrogels after 24h in PBS at 37°C

IV. Conclusion

This work demonstrated the suitability of autoclave for the sterilization of a blend of GelMA and HaMA for the formulation of a sterile ink "ready to use". The autoclaved GelMA/HaMA blends displayed rheological properties suitable for extrusion bioprinting, a good geometrical accuracy on the printed structures, while maintaining good mechanical and physical properties after photocrosslinking.
