[3] *BiomimX s.r.l. Milan, Italy*

***Abstract*— Absorption of orally administered therapeutics occurs at the gastrointestinal tract level and its efficiency is paramount for their success through the drug development pipeline.**

Current methods used to assess drugs absorption lack in recapitulating 3D physiological microenvironment of intestinal epithelium. Organs-on-chip (OoC) models have been lately proposed to overcome this limitation. We developed an *in-vitro* model of intestinal epithelial barrier in an OoC able to mimic peristaltic motion by providing a controlled mechanical stimulation. The created barrier functionality was assessed through immunofluorescence analyses and permeability tests.

***Keywords*— Gut on chip, OoC, ADME, Drug discovery.**

I. INTRODUCTION

DEVELOPMENT of new therapeutics is an expensive and risky process: success rate of candidate drugs is lower than 0.1% with severe waste of investments, in terms of money, time and human safety [1].

The main reason for such high failure can be ascribed to the poor efficacy and safety predictive power of preclinical studies. Animal models, despite their intrinsic ability of replicating systemic responses, often fail in faithfully recapitulating human biology due to interspecies mismatch. On the other hand, *in-vitro* human models such as standard 2D cultures, although based on human-derived material, often fail to properly mimic the *in-vivo* biological complexity [2], [3]
Development of accurate human *in-vitro* models is thus crucial to speed up translational processes and better predict the outcome of clinical trials [4].

In the last ten years increasing attention has been dedicated to the Organs-on-Chip technology (OoC). OoCs are miniaturized *in-vitro* culture systems able to mimic the *in-vivo* microenvironment by controlling cell-cell and cell-matrix interactions as well as biochemical and mechanical cues [5]. Despite their recent introduction, worldwide scientific community and regulatory agencies are collaborating to speed up the adoption of OoC. For instance, Food and Drug Administration (FDA) has recently signed memorandums of agreement with commercial companies to start adopting the OoC technology [6]

In this scenario, the study of absorption, distribution, metabolism and excretion (ADME) processes is crucial to assess the efficacy of drug candidates. The greatest share of newly developed compounds is orally administered, and their absorption mainly occurs at the gastrointestinal tract level, making the intestinal epithelium absorption of paramount relevance for drug candidates' success [7].

Current 2D methods used to assess gut absorption exploit monolayer structures made of gut epithelial immortalised cells (mainly Caco-2 line) cultured on porous membranes (transwell systems) that are used as a model of intestinal barrier. However, such model lacks in recapitulating the 3D and dynamic microenvironment of intestinal epithelium characterized by crypts and villi structures and peristaltic motion. OoC models have been lately proposed to overcome this limitation [8].
The purpose of this work was to develop an *in-vitro* model of intestinal epithelial barrier in an OoC capable of mechanically stimulate the cultured cells. In this regard, a stimulation with sinusoidal pattern was adopted in order to best replicate the phenomenon of peristalsis and induce the functional maturation of the tissue.

II. MATERIALS AND METHODS

In order to create a functional 3D intestinal epithelium on chip, the commercial device *uBeat® Stretch Platform* from BiomimX® was used to mimic the mechanical stimulation that the tissue undergoes during peristalsis.
The device is endowed with two microstructured layers separated by a thin membrane (**Fig. 1A**). The first layer is the one dedicated to the 3D cell culture, it has a chamber with two arrays of hanging pillars. Pillars were designed to divide the space of the chamber in three channels and confine a prepolymer hydrogel solution in the central channel one. The lateral channels, in the gut model, are intended to be perfused with medium or seeded with cell suspension. (**Fig. 1B**).
The second layer has a chamber that can be pressurized to deform the membrane and induce the controlled mechanical conditioning of the construct(**Fig. 1C**) [9].
The mechanical stimulation is finally tuned by the cross-section shape of the pillar and by their height that define the maximum displacement of the membrane.
Furthermore, an electronic control system (*uBox*) was designed to produce pneumatic stimulation patterns with complex waveforms resembling peristaltic movements.
The deformation obtained in the OoC was characterized as previously described [10]

After technical characterisation, the intestinal epithelial barrier was recapitulated by seeding Caco-2 and HT29 cells mixed in a 9:1 ratio ($8x10^6$ cells/mL) in one of the later channels and allowed them to adhere to a central fibrin

hydrogel matrix. 10% uniaxial strain stimulation at 0.2 Hz was exerted for 9 days to induce tissue maturation and epithelial monolayer formation.

The effects of an impulse-wave stimulation and a sine-wave stimulation were compared to the cells cultured in static conditions.

As readouts, brightfield and fluorescence microscopy analyses were performed in order to compare cell proliferation (Ki-67), epithelial integrity (ZO-1), and specific protein production (villin, mucin) among groups. Moreover, fluorescent dextran (4 kDa) diffusion studies from epithelial compartment to the empty channel were performed to assess the integrity of the epithelial barrier.

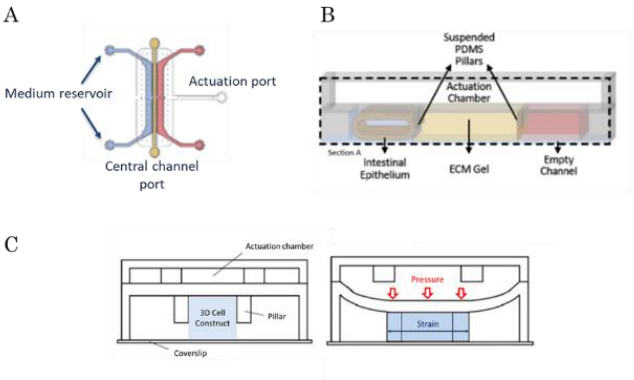

Fig. 1 *:* Gut on chip model. (A) Top view of the chip showing the ports for medium change and cell seeding, and for ECM (fibrin hydrogel) injection. (B) cross-section of the device showing the biological experiments configuration. (C) Stimulation on the gut on chip through the pressurisation of the pneumatic chamber located on top of the cell culture compartment

III. Results and Discussion

The mechanical stimulation pattern provided by the uBox electronic control system to the OoC platform was characterised before biological experiments. The stretching applied to a 3D-beads laden hydrogel seeded in the central channel of the culture layer was proved to faithfully follow complex waveform such as sinusoidal ones (**Fig. 2**). In fact, the deformation pattern reached a maximum of 11 ± 1.1% and was synchronous with the applied pressure wave frequency, therefore proving that the stimulation exerted on a 3D constructs can be finely modulated.

As a result, the characterization has proved that the device is able to reproduce complex physiological-like stimulation waves within microfluidic devices: deformation curves and strain magnitude are strictly dependant from the pressure value over time, proving that the setup is able to provide for mechanical stimulation of cell populations seeded in Organ-on-a-chip devices with any desired pattern.

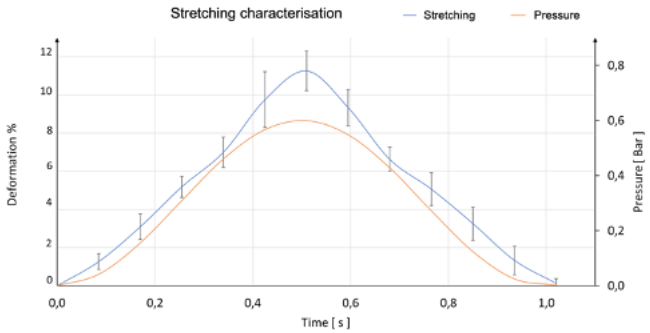

Fig. 2 :Deformation acquired in dynamic conditions (blue) and a sine pressure wave 0.6 bar, 1 Hz (orange).

Cells were seeded in the device and cultured with different mechanical conditioning (impulse-wave vs. sine-wave stimulation) for 9 days. At the experiment endpoint, brightfield microscopy images showed the presence of cells proliferating and forming a uniform epithelial barrier in both mechanically stimulated conditions. Cells self-assembled in 3D villi-like structures during culture period. Specifically, the amount of such structures was higher in both stimulated groups while the static control mainly showed a 2D cells monolayer (**Fig. 3**). This behaviour confirms the relevance of mechanical stimulation in the *in-vitro* recapitulation of functional gut morphology as already proved by literature [11].

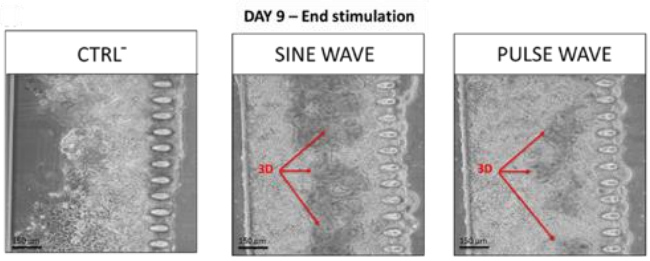

Fig. 3 *:* Comparison of the intestinal epithelium on chip after 9 days of culture. Cells subjected to two different patterns of stimulation were compared to unstimulated constructs showing that physiological mechanical cues are able to generate 3D villi-like structures (red arrows). Scalebar= 150 µm

At the end of the culture period, immunofluorescence analysis was performed to compare the stimulated groups and static control, by assessing specific markers production (ZO-1, Villin, Mucin), cells arrangement and proliferation (Ki-67).

After 9 days of culture, cells proliferated in all conditions as evidenced by the positivity for Ki67. Mechanically stimulated conditions exhibited an abundant expression of villin, a protein related to brush borders of epithelial cells, and mucin, involved in mucus secretion (**Fig. 4**). Positive expression of ZO-1 staining proved that cells formed a closed epithelium characterized by cell-cell tight junctions. Notably, expression of these proteins was enhanced within the 3D villi-like structures found mostly in stimulated constructs, as already displayed in bright field images.

The amount of the expressed proteins was also quantified to compare the experimental groups (**Fig. 5**): mechanically stimulated tissues feature a higher ZO-1 level as compared to static ones. Sine-wave stimulation was responsible for an increase in villin-positive zones and exhibited larger areas hosting 3D-structures, with a statistical difference with respect to both other experimental conditions.

Furthermore, the application of a stimulation characterized by impulse waves promoted the activity of mucus secreting cells, presenting higher levels of mucin expression than sinusoidal stimulations and static devices. This suggests that

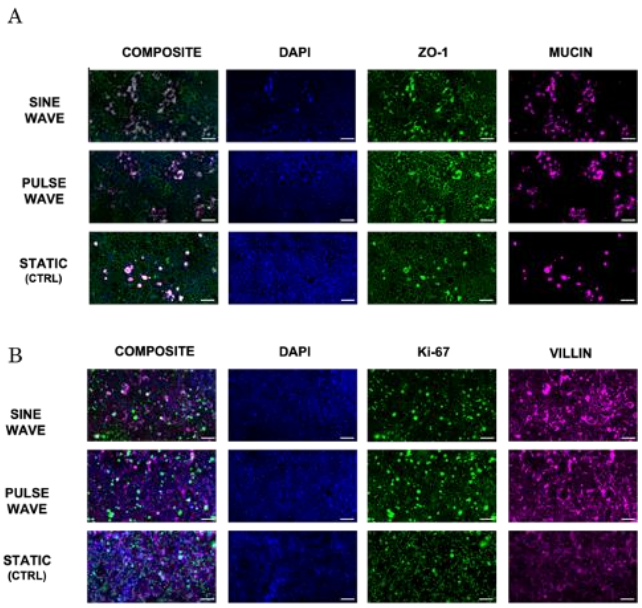

Fig. 4 : Immunofluorescence microscopy images of the epithelial barrier cultured on chip with sine stimulation, pulse stimulation and no stimulation (CTRL). A) Nuclei (blue), morphology of the tight junction between cells (ZO-1, green) and the amount of produced mucin (magenta) were stained to assess the physiological reliability of the model. B) Nuclei (blue) and Ki-67+ cells were counted to assess proliferation while villin (magenta) was stained to highlight villi-like structures.

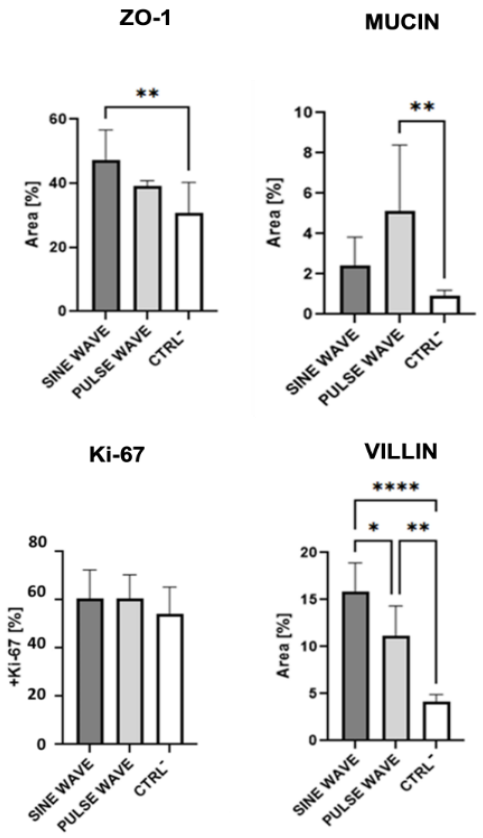

Fig. 5 : Quantitative analysis of ZO-1, mucin, Ki-67 and villin staining for sine wave (dark grey), pulse wave (light grey) and CTRL- (white) conditions. The expressions of villin, a protein related to the brush border of epithelial cells, mucin and ZO-1 were proved to be enhanced when stimulation was applied. The *, ** and **** indicate the statistic differences between conditions (P value < 0.05, P value < 0.01, and P value < 0.0001 respectively)

the two different stimulations have different effects on Caco-2/HT-29 coculture: sine wave stimulation directs cell differentiation towards villin production, while impulse wave stimulation seems to promote mucus secretion.

After biological characterisation of the developed epithelial barrier, functional permeability tests were carried out. 4 kDa Dextran was chosen as a candidate small molecule because it is not able to cross tight and functional barrier through active nor passive transport mechanisms.

The on-chip epithelial barrier developed with sine-wave stimulation was shown to be impermeable to Dextran even after 1 hour of incubation (**Fig. 6**), therefore proving the functionality of the *in-vitro* model.

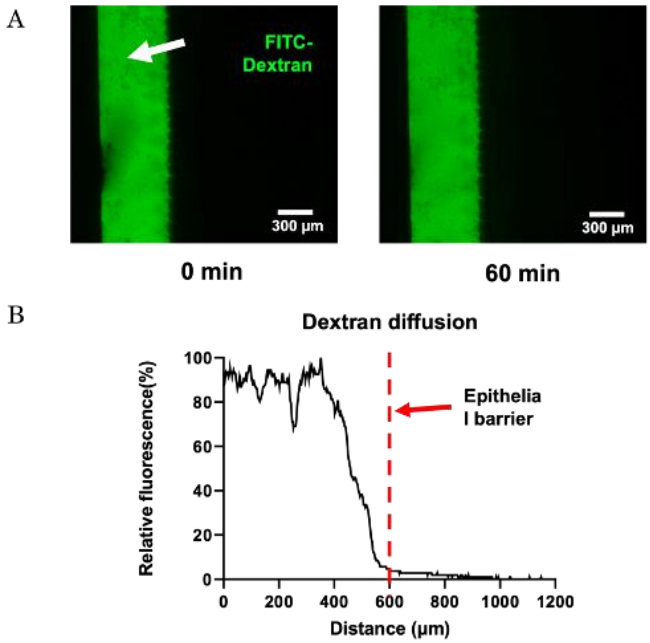

Fig. 6 : Barrier integrity analysis. (A) FITC-Dextran was inoculated in the compartment hosting the epithelial barrier and pictures were acquired over 60 minutes to assess its passage through the *in-vitro* epithelium. (B) Distribution curve of dextran across the OoC channels after 60 min: the barrier was shown to completely hinder the diffusion of dextran, proving the tightness of cell-cell junctions and the physiological relevance of the model.

IV. Conclusion

In this work, an electronic control system was designed to stimulate Organ-on-a-chip devices with pneumatic actuation, by creating customised pressure waves. In particular, we focused on sinusoidal stimulations to mimic peristaltic movements that can be exploited for the generation of an intestinal epithelial barrier model on chip.

Application of such native-like mechanical stimulation was demonstrated to be a fundamental cue to guide cell behaviour. Physiological-like stimulation led indeed to a massive generation of three-dimensional villi-like structures and improved the stability of the epithelium.

The developed gut-on-chip model represents a powerful tool for drug discovery that can provide for more accuracy and physiological relevance when it comes to ADME profiling.

***Abstract*—Electrospun hybrid scaffolds composed of synthetic and natural polymers are gaining increasing interest for tissue engineering applications. In this work, scaffolds composed of polylactic acid (PLA) electrospun fibers were coated with high molecular weight chitosan at different thickness to create a core-shell microfibrous structure. The scaffolds were fully characterized from a physical point of view and their biocompatibility was investigated by seeding mouse pre-osteoblastic MC3T3-E1 cells**

***Keywords*— Electrospinning; Polylactic acid; Chitosan; Core-shell structure.**

I. Introduction

Aiming at fabricating biopolymeric porous structures for regenerative medicine purposes, hybrid scaffolds composed of synthetic and natural biopolymers can offer superior performances [1]. Electrospun fibers with core-shell architectures composed of synthetic and natural biopolymers potentially exhibit the advantages of both kinds of materials [2].

For bone regenerative purposes, polylactic acid (PLA) is considered one of the most adequate synthetic polymers due to its interesting properties [1]. However, several studies highlighted the poor hydrophilicity of PLA that might inhibit its biocompatibility in terms of amount of absorbed proteins and cell adhesion [2].

On the other hand, Chitosan (Chi) was widely explored as a natural biopolymer suitable for bone regeneration thanks to its biocompatibility [3], [4]. Chitosan is able to improves cell adhesion, proliferation and differentiation [5] and eases hydroxyapatite formation in an osteogenetic environment [6]–[8] However, chitosan-based constructs can often lack mechanical stability or offer insufficient elastic modulus and tensile strength to be used for direct implantation [9].

In this work, core-shell PLA/Chi microfibrous hybrid scaffold were produced by direct coating of Chi on PLA electrospun scaffolds. The Chi coating affected the fibers morphology, mechanical properties, and wettability. Finally, biocompatibility of each type of scaffold was investigated by seeding pre-osteoblastic MC3T3-E1 cells and evaluating the cell proliferation via scanning electron microscopy and colorimetric assays.

II. Materials and methods

A. Materials

PLA (2002D) was supplied by NatureWorks while Chitosan, Acetone (Ac), Chloroforms (TCM), and glacial acetic acid (AA) were purchased from Sigma Aldrich.

B. PLA electrospun mats fabrication

PLA electrospun mats followed a fabrication route similar to those described in a previous work [13]. In brief, the solvent system for PLA was TCM:Ac (2:1 vol/vol). PLA was added to obtain a concentration of 10 wt% with respect to the TCM:Ac mixture and dissolved at room temperature under continuous magnetic stirring overnight. A semi-industrial electrospinning equipment (NF-103, MECC CO., Ltd., Japan) was used to prepare PLA microfibrous scaffolds. A 5-mL syringe fitted with a 19-gauge stainless steel needle was filled with the polymeric solution. The electrospinning process was then carried out using the following constant parameters: flow rate, 1 mL/h; distance between the needle tip and the collector, 13 cm; supplied high voltage, 15 kV; temperature, 25 °C and relative humidity, 40%. The microfibers obtained were collected on a grounded rotary drum (diameter = 10 cm, speed = 10 rpm) wrapped in an aluminum foil for 120 min in order to obtain membranes approximately 70 μm thick. The collected electrospun membranes were subsequently dried for at least 2 days under fume hood to remove any residual solvents.

C. Morphological analysis

The morphology of the microfiber mats was evaluated by Scanning Electron Microscopy, (SEM-FEI QUANTA 200F.). The samples (3 mm diameter) were attached on an aluminum stub using an adhesive carbon tape. Therefore, they were sputter coated with gold (Sputtering Scancoat Six, Edwards) for 60 s under argon atmosphere before imaging to avoid electrostatic discharge during the test. Fiber diameter distribution of the electrospun mats was determined using a dedicated plugin for ImageJ (DiameterJ) that permits to analyze an image obtained by SEM to produce a histogram of the fiber diameter distribution.

D. Chitosan coating

The Chitosan coating onto electrospun PLA microfiber mat was conducted via direct immersion coating. The control of the Chitosan coating thickness was carried out by changing the concentration of Chitosan/water solutions added to the PLA electrospun mats according to the following theoretical approach.

It was assumed that the whole PLA electrospun mat was composed of a single fiber with diameter equal to the mean diameter estimated via image processing. According to this hypothesis and known the PLA density ρ_{PLA}, it was possible to estimate the PLA fiber length. Then, three Chitosan coating

thicknesses were arbitrarily chosen i.e., 85, 165, and 300 nm that corresponded to three Chitosan weight amounts. Therefore, three solution concentrations were prepared by solubilizing these amounts of Chitosan in a volume of water deduced from the water uptake of the PLA scaffolds. According to these theoretical evaluations, the weight percentage of Chitosan in water were the 0.5 wt%, 1.0 wt% and 2.0 wt% to theoretically reach the Chitosan coating thickness of 85, 165, and 300 nm, respectively. The solubilization of Chitosan was carried out in an aqueous AA solution (0.5 wt%) at 60 °C for 3 hours under magnetic stirring. 4 g of Chi/water solution was dropped in 0.1 g of electrospun PLA membranes until it was completely absorbed. Then the wet membranes were let to dry under fume hood overnight at room temperature in order to allow the water phase to evaporate.

The samples were coded as follow: PLA/Chi X% where X is 0.5, 1.0, or 2.0 on the basis of the Chitosan concentration in solution used for the coating.

E. FTIR-ATR analysis

FTIR/ATR analysis (FT-IR/NIR Spectrum 400 spectrophotometer from Perkin-Elmer Inc., Wellesley, MA, USA) was performed to investigate the sample chemical surface properties. For each sample, 4 accumulations scans with a resolution of 4 cm^{-1} were collected in the range 4000–400 cm^{-1}.

F. Mechanical properties

Tensile mechanical measurements were carried out by using a dynamometer (Instron model 3365) equipped with a 1 kN load cell. The tests were performed on rectangular-shaped specimens (10 × 90 mm) cut off from the membranes along the radial direction of the rotary drum collector. The measurements were performed by using a single crosshead speed at 1 mm/min for all the samples. The thickness of each sample was measured before test (~50 μm) whereas the gauge length was 20 mm for all the samples. The representative nominal stress-strain curves were reported for each material. The elastic modulus (E) was calculated from the slope of the initial part of the engineering stress-strain curves. Seven samples were tested for each material and the average values of the mechanical parameters were reported with their standard deviations.

G. In vitro cell cultures

The scaffolds were sterilized by UV light treatment for 2 h under the laminar fume hood and all of them were pre-conditioned overnight with complete culture medium. Mouse pre-osteoblastic MC3T3-E1 cell line (ECACC, European Collection of Cells Cultures) were grown in Dulbecco's modified Eagle's-high glucose medium (DMEM, Sigma Aldrich) supplemented with 10% (v/v) fetal bovine serum (FBS) (Euroclone, Celbar), 100 units per ml penicillin G, 100 μg/ml streptomycin (Euroclone, Celbar) and 2 mM L-glutamine (Euroclone, Celbar) at 37 °C, in a humidified atmosphere of 5% CO2.

5×10^3 cells were resuspended in 5 μl of complete medium, which corresponds to the volume of the scaffold seeded on each sample, and incubated in a humidified incubator (37°C; 5% CO2). After 30 minutes required for the cell adhesion, each scaffold was transferred to one well of 48-well plate supplemented with DMEM complete medium which was refreshed every three days.

H. Cell proliferation essay and cell morphology

At different times (1, 7, 14 and 21 days) from cell seeding, the viability and cell proliferation rate on each type of electrospinning device, were evaluated using Alamar-Blue colorimetric assay (Thermo Scientific, Foster City, CA, USA) according to the manufacturer's recommendations. Cells grown on each type of scaffold were incubated with Alamar-Blue reagent solution (10% in culture medium) in a complete medium for 2 h in a humidified incubator (37°C; 5% CO_2).

Fluorescence intensity (λ_{exc} 530/25 nm and λ_{emm} 590/35 nm), which changes according to the degree of cell viability, was evaluated through a microplate reader (Synergy HT, Biotek, Winooski, VT, USA). The fluorescence values of each type of scaffold were normalized against the same type of unseeded device, used as a blank. The assay was performed in quadruplicate for each scaffold formulation and repeated three times.

For SEM analysis, after appropriate washing in PBS, samples were fixed with 4% (v/v) glutaraldehyde at 4 °C for 2 h, rinsed with water and dehydrated with ethanol series (25%, 50%, 75% v/v and pure ethanol). Finally, samples were dried under prior vacuum gold-sputtering and analyzed by SEM at the same conditions described above.

III. Results and Discussion

A. Spectroscopical and morphological analysis

The presence of Chitosan molecules on the PLA electrospun microfibers was evaluated via FTIR-ATR spectroscopy (Fig. 1). According to the literature, the ATR-FTIR spectrum of PLA showed various absorption bands usually attributed to this polyester such as the carbonyl stretch at 1747 cm^{-1}, the C–O stretch at 1180 cm^{-1}, 1129 cm^{-1} and 1083 cm^{-1} and the OH bend at 1044 cm^{-1} [10]. The FTIR-ATR spectrum of neat chitosan powder reveals main absorption bands at 3352 cm^{-1} (stretching vibration of O–H group [11]), 3290 cm^{-1} (stretching vibration of N–H [11]), 1645 cm^{-1} (stretching vibration of the carbonyl group (C=O) in amide I [12], [13]), and 1039 cm^{-1} (stretch vibrations of C–O [14]).

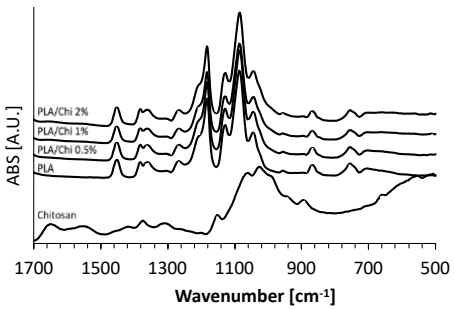

Fig. 1: FTIR-ATR spectra of PLA//Chi hybrid scaffolds as a function of the Chitosan concentration in the coating solutions.

The peaks related to PLA in the PLA/Chi hybrid scaffolds were found to be dominant although the characteristic peaks of Chitosan were visible and their intensity increased upon increasing the Chitosan concentration, thus corroborating the effective inclusion of the polysaccharide into the PLA mats (Fig. 1)

The microstructure of the scaffold was investigated via SEM analysis and the results are shown in Fig. 2. PLA fibers displayed smooth fibers morphology, randomly oriented and with a mean diameter around 1.2 µm. The addition of chitosan caused several modifications on the morphology PLA fibers. Firstly, in Figure 2 it can be qualitatively noticed an increase of the fiber diameter upon increasing the Chitosan content. This result was confirmed by mean fiber diameter quantitative evaluation via an image processing software. Interestingly, the mean fiber diameter of PLA/Chi 0.5% was very close to the expected one. Since the theoretical values of the fiber diameters were obtained by assuming that the whole volume of added chitosan increased the starting mean diameter of PLA fibers, this result corroborates the evidence that, at this concentration, Chitosan film effectively wrapped the individual PLA fibers during the water evaporation thus structuring them in a core-shell configuration.

The fiber diameters of PLA/Chi scaffolds treated with more concentrated Chitosan solutions were higher than that of PLA/Chi 0.5% but lower than the theoretical values, in particular for the PLA/Chi 2% hybrid scaffolds (Fig. 2). This result can be likely explained by observing the SEM images that reveal edges among the fibers of PLA/Chi 1% and 2% which can be presumably ascribed to an excess of Chitosan that is not able to wrap the PLA fibers during the solidification, thus being unable to increase the PLA fiber diameter up to the theoretical values. Furthermore, for those scaffolds, bundles composed of 2 to 4 fibers glued to each other were observed.

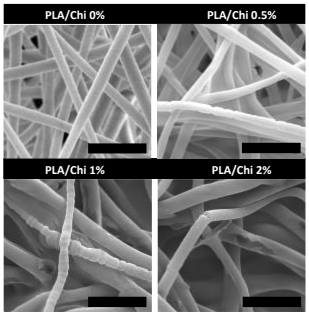

Fig. 2: SEM micrographs of PLA/Chi hybrid scaffolds as a function of the Chitosan concentration in the coating solutions. Scale bar is 5 µm

B. *Mechanical analysis*

Fig. 3 summarizes the E, TS and deformation at break (ε_b) evaluated by the nominal stress-strain curves. The elastic modulus of PLA/Chi scaffolds displayed a dramatic increase when coated with chitosan-based solutions and it increased upon raising the Chitosan concentration reaching values more than 10 times higher than PLA scaffolds.

Also TS of PLA/Chi scaffolds were higher than that of PLA, although the increase was visible up to PLA/Chi 0.5% system and then TS remained constant for PLA/Chi 1% and 2% hybrid scaffolds. As expected, the deformation at break was dramatically reduced by the addition of Chitosan to the PLA scaffolds.

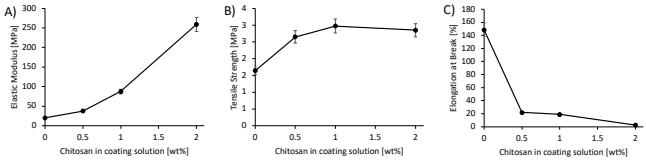

Fig. 3: A) Elastic modulus, B) Tensile Strength, and C) Elongation at break of PLA/Chi electrospun scaffolds as a function of the Chi content.

C. *Scaffolds biocompatibility*

The biocompatibility of the different types of PLA scaffolds was investigated by seeding mouse pre-osteoblastic MC3T3-E1 cells and analysing their viability and proliferation rate after different times (1, 7, 14 and 21 days). PLA/Chi hybrid scaffolds present good biocompatibility and the capability to be substrates for cells. After 7 and 14 days, there was no significant difference in proliferation rate on PLA/Chi scaffolds, which appeared more evident after 21 days in a chitosan-dependent way. According to literature that reported the chitosan effect on attachment and proliferation of many types of cells including osteoblast [15]–[17], the addition of chitosan increases the cell viability compared with PLA, and the PLA/Chi 0.5% sample presents the highest value.

These data were confirmed also by SEM investigation in which was evident an increase in cell density over time (Data not shown). After 14 days of culture, cells started to contact each other and to form a dense cell layer until the entire scaffolds were completely overgrown with cells after 3 weeks, Fig. 4. The identification of cells within it suggests a complete colonization of the scaffold.

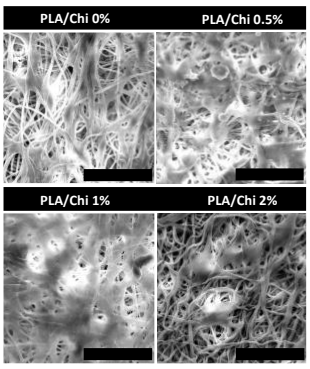

Fig. 4: SEM micrographs of MC3T3 E1 cells grown for 21 days on PLA/Chi hybrid scaffolds as a function of the Chitosan concentration in the coating solutions. Scale bar is 50 µm.

IV. CONCLUSION

In this work the physical and biological properties of hybrid PLA electrospun scaffolds coated with Chitosan were assessed. Spectroscopic and morphological investigations confirmed the effective formation of a thin Chitosan layer wrapped on the PLA fibers with controllable thickness up to 0.15 µm. From a mechanical point of view, the Chi coating on PLA fibers caused a strong increase of the elastic modulus, a slight increase of the TS and a steep decrease of the elongation

at break.

Alamar-Blue colorimetric assay and SEM analyses confirmed the biocompatibility of the scaffolds investigated by seeding mouse pre-osteoblastic MC3T3-E1 cells for different times (1, 7, 14 and 21 days).

***Abstract* — Microgels represent a versatile sub-class of hydrogels enabling new functions in biomolecule detection thanks to the highly tuneable chemistry. The microgels-based platform is composed of multifunctional particles which possess multiple components and properties to fulfil the requirements of the biodetection applications. Indeed, from the synthesis to the final read-out microgels prove advantageous and unique in overcoming issues in detection and quantification directly in biofluids. The chemical flexibility of hydrogel microparticles and microgels allows to embed several building blocks into their structure during the synthesis. Anchoring groups on particles are used to immobilize probes of diverse natures such as antibodies, enzymes, or oligonucleotide strands. In such a way particles active for the detection of a target or more than one biomarker can be obtained. Moreover, the high biocompatibility and antifouling properties of hydrogels make possible to use microgels in biosensing directly in biofluids overcoming washing and separation steps. As for the read-out steps, microgels can be easily manipulated in flow with simple microfluidics making the detection more efficient and sensitive in multiplex context.**

Here we are presenting a PEG-microgel platform for the detection of oligonucleotides and other biomarkers by using barcoded particles for multiplex analysis. In the final part of the presentation, we discuss on the use of easy microfluidics for the interrogation of microgels in-flow.

***Keywords*—Biosensing, Microgels, Detection of Biomarkers, Microfluidics.**

I. Introduction

MICROGELS are small, crosslinked polymer particles that can range in size from a few nanometers to a few micrometers. They have both liquid and solid properties due to their crosslinked structure, which allows them to swell and shrink in response to changes in their environment, such as temperature, pH, or the presence of certain chemicals. They can be synthesized using various methods and can be used in a wide range of biomedical applications, such as drug delivery, and bio-sensing [1]. In that context, microgels can be used as a chemical toolbox for the on-demand synthesis of polymer particles with different characteristics useful for the final application by using combinatory approaches and microfluidic devices.

Microgels for assays must respond to specific requirements that have been tested towards oligonucleotides and other biomarker [2,3]. The flexibility of such platform materials allowed to produce multifunctional particles that provide unique properties in the bulk and on the surface. Indeed, such kind of particles can be used in multiplex assays to detect and quantify multiple biomarkers in the same run and in the same vessel at once [4]. This feature is enabled uniquely by barcoded microgels that are univocally encoded in fluorescence and with a core/shell architecture in a limited space of sub-micrometer particles. With this kind of microgels the bulk properties are modulated differently by the surface chemical functionalities. The surface of microgel can be tailored with different number of functional groups to accommodate specific probes for the capture of targets [5]. The high surface hydration of PEG ensures antifouling properties so that particles can be used for assays directly in native biofluids reducing manipulations and addressing low LOD sensitivity [6,7]. The advantageous properties of soft and highly hydrated microgels enables the integration of the assay inside miniaturized devices so that increasing the possibilities to address high demanding assay in terms of sensitivity. Assays for small oligo sequences that are circulating in bodily fluids are represented by microRNAs (or miRNAs). Such small sequences are promising in the so-called liquid biopsies where circulating biomarker are the potency of diagnosis and prognosis in different diseases like cancer. In this context miRNAs can act in panels to allow the stratification of the disease [3,8].

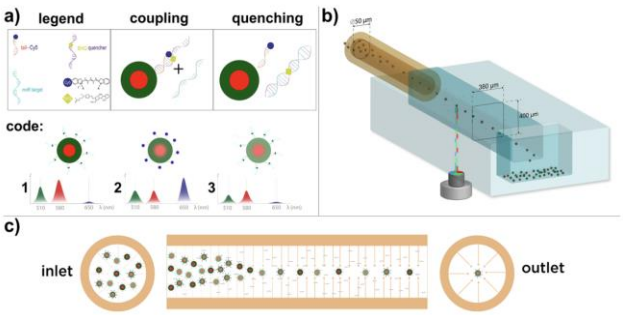

Fig 1 - The microgels platform for miRNAs sensing. In a) oligoprobes conjugated to encoded PEG-Microgels for miRNA sensing. b) and c) the straight channel with focusing microgels inside. (Reprinted from [9])

Here, we present a comprehensive platform based on PEG-microgels for the detection of circulating biomarkers with a quasi-real-time fluorescence detection of single microgels in microfluidic flows using non-Newtonian fluids at a low concentration level (Fig1) [9].

The advances made by our group will be reviewed widely highlighting the versatility of the material platform in terms of chemical functionalities, target detection and automatized read-out by using miniaturized devices for quasi-real-time acquisition and identification of signals [10-15].

II. Materials & Methods

Microgels Synthesis

Microgels were prepared by free-radical precipitation polymerization, using 1% (w/v) total monomer concentration. Polymerization was carried out in a three-neck, 100 mL round-

bottom flask to which a filtered, aqueous solution of all monomers and 1% (w/v) PVA and KPS (30mg) were added and bring to 65°C for the initiation. The monomer used was PEGDA (550Mn, Polyethylenglycoldiacrylate, SIGMA) with Acrylic Acid. The encoding was realized by the incorporation of Atto-532 dye (Atto-tec, Germany) derivatized as maleimide. The dye was added after 10 minutes of initiation and left to react for about 6 hrs. Afterward the reaction product was washed by centrifuge and left to dialyze for one week in deionized water. The characterization of microgels was performed by measuring the size and surface charge (Zeta-sizer, Malvern UK) and by fluorescence spectra and imaging. Potentiometric titration was used to assess the amount of carboxyl groups incorporated in the mircogels, while the viscometer titration (Hubbelode) for microgels concentration in the solution.

Probe design

The molecular Beacon (MB) probe was designed to specifically detect the miR-21 target. The thermodynamic parameters (melting temperature, stability, and folded fraction at the dosage conditions) were calculated using appropriate tools (OligoAnalyzer 3.1; IDT-Integrated, D.N.A. 2014 and UNAFold). Briefly, the length of the probes was carefully evaluated to allow stable hybridization between the probe strand and the target at physiological ionic strength, and the free energy (ΔG) of folded MB and opened MB hybridized to the target, were calculated.

MB conjugation to microgels.

Bioconjugation was optimized by coupling 0.1 nmol of MB with 1 mg of microgels; after 5 hrs of incubation in MES pH 6, the carboxylic groups on the microgel were activated using the coupling agent EDC, subsequently; MB solution was added to the microgels by incubating overnight at room temperature. MB microgels were washed 3 times to remove the unreacted MB and suspended in PBS buffer.

Microgels-assay

Microgels at a concentration of 0.5 ug/mL (corresponding to $1.45 \cdot 10^7$ microgels) conjugated with 0.1 nmol miR-21 MB probe were used for the microgel assay that was easily performed by mixing the microgels to the target sequences, without preliminary steps of amplification. The samples were analyzed by confocal microscopy. A calibration curve to evaluate microgels assay dynamic range was done using serial dilution of synthetic miR-21 in PBS. For each target concentration, 20 images were collected and analyzed. Images were processed and analyzed by ImageJ software.

III. RESULTS & DISCUSSIONS

After synthesis, microgels with monomodal distribution (667,1±6,407 (PDI=0,244)) were obtained with a net surface charge of -14 mV. A uniform fluorescence, due to the incorporation of Atto-532 dye, was observed. Moreover, the fluorescence behavior of microgels is compatible with that of the free dye in solution (Fig 2).

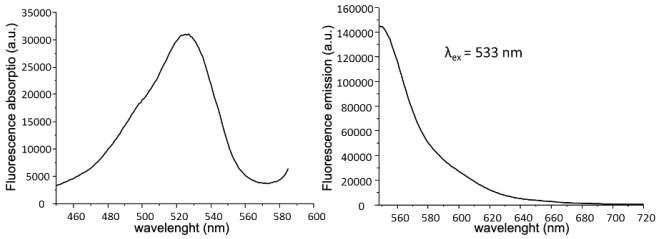

Fig 2 – Absorption (left)/Emission (right) spectra of microgels (50ug/mL) loaded with Atto-532.

As in Fig 3 A the uniform distribution of the dye molecules inside microgels enable the imaging by using fluorescence microscopy. To evaluate microgels assay performance (the working range and sensitivity), a calibration tube with tenfold serial dilution of miR-21 target concentrations was constructed tuning the number of microgels to reach the best sensitivity. We proved that the minimum amount of target distinguishable from the background noise had a concentration in the femtomolar with a limit of detection (LOD) of 17,9 fM and with dynamic range between fM and nM. Moreover, the proposed assay is easily performed with very small amount of sample (2 µL), in a volume as that of 20 µL at 25°C.

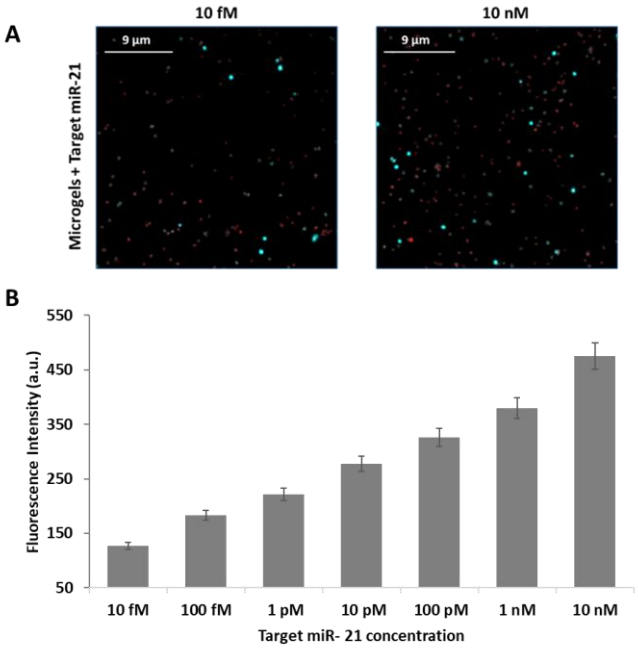

Fig 3 - Microgel assay performance. **A)** Images of microgels assay at lower (10 fM) and higher (10 nM) tested concentrations collected by CLSM. In red is rhodamine. In blue is Atto-647N. **B)** Dynamic range of 0,5 µg/mL microgels functionalized with 0,1 nmol of the molecular beacon (MB) and put in contact with the target miR-21 in a range of concentrations from fM to nM.

For an easier read-out microfluidics can be used to align microgels in the optical field-of-view of a fluorescent microscope [9, 10]. Different systems can be used for particle alignment in microfluidics generally requiring complex geometrical channel design for the focusing. Viscoelastically induced particle alignment—at low volume concentrations—permits the optical observation of target particles in a simple and cost-effective way as shown in Fig 4 [9].

In fact, particle alignment was accomplished by a viscoelastic medium (0.2wt% of Polyethylene-oxide 4MDa) and a pressure driven flow. Thanks to the resulting fluid properties, generated by viscoelastic fluid forces, particles are aligned to the centreline of the round shaped channel and subsequently remain aligned in the centreline of the microfluidic readout channel (see Fig 4). Next a routine calculated the relative fluorescence ratios (barcode *versus* target fluorescence) to detect microgel types down to the fM range. We obtained a signal to noise ratio above 20 dB for in-flow investigated microgel particles, which is comparable to quiescent miRNA investigations.

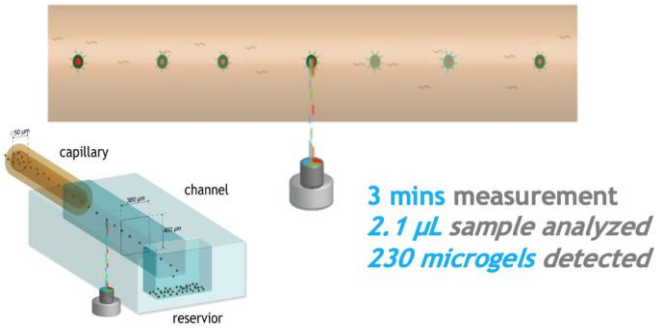

Fig 4 – Flow focusing realized by viscoelastic approach in a straight channel allows for high-throughput analysis of microgels.

IV. Conclusion

Circulating miRNAs recur at low amount (below fM) so that a sensitive method is needed for an easy detection that would overcome the enzymatic amplification and directly quantified in the biofluid. Microgels decorated by appropriate and specific oligo-probes (linear for displacement or molecular beacons) proved a wide working range down to fM in the detection of different miRNAs directly in serum without any enzymatic amplification. We tested our miRNA detection approach in microfluidic flow condition. Results show a fM detection limit, which enables the precise detection of circulating miRNA in low amounts. Next more complex samples of different miRNA subtypes will be investigated in microfluidic flow condition to highlight the therapeutic potential of this measurement approach.

***Abstract*—Oxygen consumption rates in 2D and 3D *in-vitro* cell cultures are difficult to measure accurately because of limitations in oxygen sensor technology and the challenge of identifying and maintaining initial and boundary conditions during measurement. Hence, the OCR or oxygen consumption rate of cells is usually considered as a constant. But given the importance of oxygen as the primary source of energy in living organisms and the problem of ensuring an adequate supply in non-vascularised constructs, it is necessary to develop more reliable methods for predicting the metabolic requirements of cells in culture. The aim of this study is thus to develop an experimental and computational pipeline for measuring metabolic parameters as a function of cell-density and structural complexity (i.e. dimensionality) in *in vitro* constructs.**

***Keywords*—Cell metabolic parameters, Michaelis Menten, monolayer, 3D cell-laden construct.**

I. Introduction

Oxygen utilization by cells has a pivotal role in the design of biomimetic models. In fact, oxygen is one of the key actors in cellular respiration and influences cell growth and fate, but its low solubility and diffusivity in aqueous media may result in an inadequate supply [1].
Mammalian cells adapt their aerobic metabolism to O_2 availability; traditionally, this adaptive oxygen consumption rate R $[\frac{mol}{m^3 s}]$ is described via the Michaelis-Menten's (MM) equation (Eq. 1):

$$R(x,y,z,t) = \rho_c OCR \frac{C(x,y,z,t)}{k_M + C(x,y,z,t)} \quad (1)$$

where C $[\frac{mol}{m^3}]$ is the oxygen concentration, ρ_c $[\frac{cell}{m^3}]$ is the volumetric cell density, OCR $[\frac{mol}{cell\ s}]$ is the maximum oxygen consumption rate per cell, and k_M $[\frac{mol}{m^3}]$ is the MM constant, a descriptor of O_2 cell uptake efficiency. In particular, the values of OCR and k_M, also known as the MM parameters, have generally been assumed as constants for a given cell phenotype [2].

Few reports have to date focused on O_2 metabolism *in vitro* considering the associated cell behavior as a function of construct dimensionality (i.e., 2D and 3D). Magliaro *et al.* [3] have recently shown that OCR and k_M depend on cell density, but their study is limited to 3D constructs. Hence, a systematic investigation on the effect of dimensionality as well as cell density is still lacking.
Here we established an integrated in vitro-in silico method for accurate estimation of the oxygen consumption parameters in aggregates with increasing cell density and dimensionality (2D and 3D). We focused on hepatocytes for their pivotal role of the liver in endogenous and exogenous metabolism [4].

II. Materials and Methods

A. Theoretical rationale

The volume of interest is the cell culture in its well with and its surrounding media, which is in contact with a gas phase on one boundary. The O2 concentration is governed by oxygen transport, which depends on its diffusion constant, D $[\frac{m^2}{s}]$ and its consumption (from Eq. 1):

$$\frac{\partial C}{\partial t} = D\nabla^2 - R \quad (2)$$

In the case of monolayers, assuming that cells are homogeneously distributed over a boundary and that their thickness is much smaller than the total height of the system (Fig. 1), O_2 consumption by cells can be considered as a unidirectional inward flux $(J_c(0,t))$. In this situation, oxygen dynamics can be assumed as dependent on the axial direction only (Eq. 3).

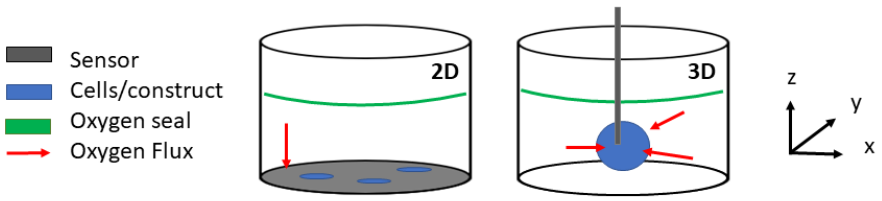

Figure 1 Schematics of 2 and 3D geometry and sensing configurations.

$$\begin{cases} \frac{\partial C(z,t)}{\partial t} = D\frac{\partial^2 C(z,t)}{\partial z^2} & (3) \\ J_c(0,t) = -\rho_c OCR\frac{C(0,t)}{km+C(0,t)} & (4) \end{cases}$$

In Eq. (3), ρ_c $[\frac{cell}{m^2}]$ is the surface cell density, and a single average O_2 concentration readout over time at the monolayer level is sufficient to characterize its consumption kinetics. Identifying the MM parameters through Eq. (2), and (3 - 4) requires performing a time dependent measurement of oxygen concentration in a fixed point in space. Furthermore, to accurately estimate km, $C << k_M$. As k_M is often much lower than ambient C, this requires that the system be brought to near-hypoxia.

B. *Experimental setup*

All measurements were conducted at 37C using a customised thermostatic chamber [3].

To establish fixed initial conditions and enable the system to attain hypoxia, it needs to be sealed to avoid O_2 infiltration from the air. We achieved this using a thick layer of silicone oil (Agilent Technologies) and, as an extra precaution an O_2-consuming chemical (AnaeroGen, Thermo Fisher Scientific) was placed in the chamber.

For the monolayer configuration, a contactless sensor spot (OXP5, Pyroscience GmbH) attached to the bottom of the well was used to monitor O_2 dynamics (Figure 1).

For cell-laden constructs we employed a needle probe microsensor (XR50, Pyroscience, GmbH, Figure 1 and 2). The needle was carefully inserted at the center of the construct using a micromanipulator and a frontal camera.

Both of the oxygen sensor systems chosen are based on quenching. The luminescence signal emitted by the spot in response to the concentration level is conveyed via an optical fiber to an oxygen-meter. Before each experiment, a two-point calibration was carried out by exposing the sensor to well-oxygenated culture medium (Dulbecco's Modified Eagle Medium), corresponding to a 100% oxygen saturation, and to a 1% w/v solution of sodium bisulphite, an oxygen scavenger guaranteeing hypoxia for the duration of the experiment. Between consecutive acquisitions, sensors were rinsed with a 70% v/v ethanol solution.

The oxygen concentrations over time obtained from the experiments were post-processed using Matlab (R2020b).

Generation of in vitro models

For monolayers, we first prepared a well of a 96 plate with sensor spots coated with a 1% w/v gelatin solution (Sigma-Aldrich) to promote cell adhesion. Human Hepatoma (HepG2) cells at different surface densities (Table I) were seeded onto the sensor spot and incubated overnight.

In the 3D experiments, hepatic spheroids were fabricated through the SpHyGa extrusion-based biofabrication platform, using a needle with internal diameter of 1.6 mm as extrusion nozzle [5]. In particular, cells were suspended at different volumetric densities (Table I) in DMEM containing 1% w/v alginic acid (Sigma-Aldrich) and 0.04% type I collagen (Life Technologies Corporation, New York, USA). Then, cell suspension drops were extruded in an electrolytic bath of calcium chloride ($CaCl_2$) 0.1 M and incubated (37 °C, 95% RH, 5% CO_2) during alginate cross-linking for 15 min. The cell-laden spheroids so-obtained were incubated overnight.

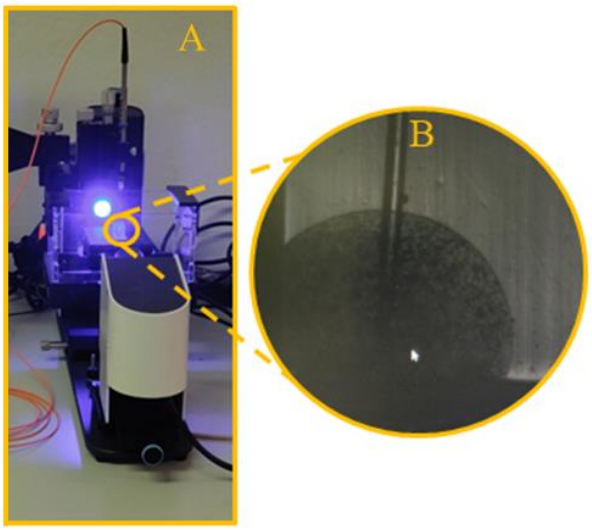

Figure 2 A) Spheroid experimental Set-up, B) Zoom showing oxygen needle sensor at the center of spheroid.

TABLE I: CELL DENSITIES IN 2D AND 3D

2D	*3D*
$\boldsymbol{\rho_{cell,s}}$ *(cell m^{-2})*	$\boldsymbol{\rho_{cell,v}}$ *(cell m^{-3})*
3.10×10^{8}	1×10^{12}
1.72×10^{9}	2.5×10^{12}
2.56×10^{9}	5×10^{12}
3.30×10^{9}	7.5×10^{12}

C. *Parameter identification*

Experimental time versus concentration data were post-processed to estimate the MM parameters characterizing cell consumption through the multiparameter identification pipeline shown in Figure 3. The model prediction is designed *ad-hoc* for each experiment exploiting the Partial Differential Equations (PDE) toolbox in Matlab (R2020b), which allows to solving a non-dimensional form of Eq. (2). Briefly, the parameters were identified by minimizing the root mean square error (MSE) between the experimental data and the model. Statistical analysis of the obtained parameters were carried out using Graph Pad Prism 7.

III. RESULTS

Figure 4 reports the results of parameter estimation for the 2 and 3D configurations as a function of cell density.

Regarding monolayers (Fig. 4 A and B), for both parameters, the Kruskal-Wallis test highlighted that medians are not constant across densities ($p < 0.0001$ and $p = 0.002$ for OCR and k_M, respectively), with significant correlations reported by means of a Spearman coefficient $r = -0.8$ for OCR and $r = 1$ for k_M. The dependency of OCR on the volumetric cell density of spheroids observable in Figure 4C could be interpreted in the same light. In fact, statistical differences (p

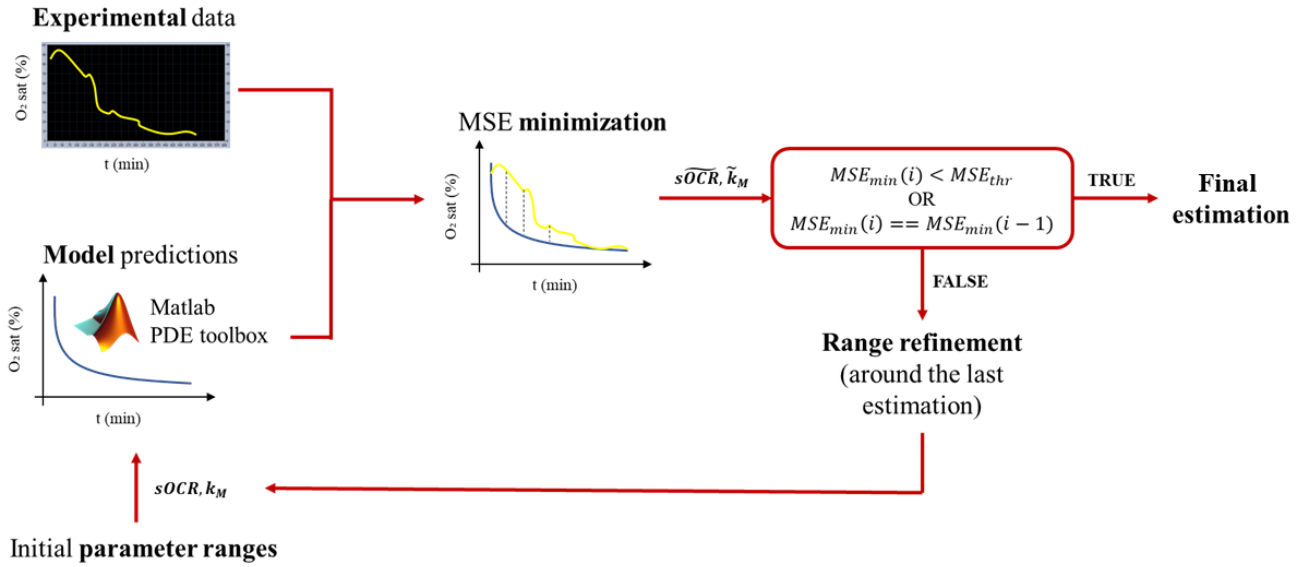

Figure 3 Pipeline of the multiparameter identification procedure for OCR and km.

< 0.0001) together with a Spearman coefficient r = -0.8 might indicate a cooperative behaviour in terms of O_2 metabolism of HepG2 cells embedded within spheroidal hydrogels, analogue to that noticed for monolayers. Neither significant differences among medians (p = 0.9030) nor correlations (r = -0.2) resulted instead for k_M in this configuration (Fig. 4D).

IV. Discussion and Conclusion

The results for 2D cultures show that OCR decreases with cell surface density (negative correlation, r = -0.8), while there is a positive correlation between k_M and ρ_c (r = 1). Our estimates for OCR are fairly close to those reported in the literature. Very few studies report k_M values – indeed oxygen consumption rates are usually considered to be constant for cells. Notably, our estimates are much higher than that reported by [6]. This could be because we took particular precautions to eliminate the passage of ambient oxygen into the medium during measurements to avoid errors due to oxygen infiltration. In the 3D case, OCR again decreases with volumetric cell density (r = -0.8). No significant differences in k_M with volumetric density were observed (r = -0.2, indicating very low correlation) and the values are similar to the few we found in the literature.

This study proposes a computational and experimental pipeline for identifying the kinetic parameters for both 2D and 3D cell constructs. The different correlation of OCR and k_M between cell density in *in vitro* constructs of different dimensionality may be evidence of a metabolic cooperation, manifested by the decrease of OCR, but also to the reduction of the O_2 uptake efficiency, explained by the increase of k_M. Future developments could include the investigation of how the kinetics parameters are dependent on the material used for both 2D and 3D cell cultures – e.g., the alginate -, as stated by Guaccio *et al.* [8]. Our current efforts are directed towards the identification of single cell consumption and the effects of fluctuations [9], coexistence and cooperation on cell metabolism.

***Abstract*—In this work, we discuss the development and antibacterial activity of bacterial cellulose/neem–hypericum oil paste for wound healing. The paste is made by mixing BC pulp with neem-hypericum oil/water emulsion. Unlike pure BC, the paste showed promising biofilm detachment properties against *Pseudomonas aeruginosa* and *Staphylococcus aureus* biofilm, laying the foundation for the development of a new strategy for the treatment of chronic wound infections.**

***Keywords*—Bacterial cellulose, neem oil, wound healing, bacterial biofilm**

I. INTRODUCTION

Cellulose is the most widely available biopolymer in nature, and it is obtained by different methods such as extraction, biosynthesis, enzymatic synthesis, and chemosynthesis [1]. Plants and microorganisms are the two main sources of cellulose production. It is well-known that bacterial cellulose (BC) is the cellulose hydrogel derived from bacteria (e.g. *Acetobacter xylinum*) by the fermentation of sugar and can produce cellulose fiber with a high aspect ratio and diameter of less than 100 nm [2]. BC has high purity, good water-holding capacity, and biocompatibility compared to vegetable cellulose (VC) derived from wood or cotton. These advantages make them extensively used in various biomedical applications such as drug delivery, tissue engineering, and wound dressing. BC is a good choice for wound healing applications because it can control wound exudate and provide a moist environment for healing. However, using BC alone is not recommended for wound healing as it lacks antibacterial activity [3].

It has been estimated that about 8 million people around the world are affected by wounds [4]. The disruption of the skin integrity enables bacteria to rapidly colonize the burn injury or the surgical incision [5]. Both commensal and pathogen microorganisms can colonize the wound site: they are Gram-positive bacteria, such as *Staphylococcus aureus*, *Enterococcus* spp., and Gram-negative bacteria like *Pseudomonas aeruginosa*, *Acinetobacter* spp., and fungi like *Candida* spp [5]. Scientific evidence demonstrates that *S. aureus* usually colonizes the top layer of wounds, while *P. aeruginosa* is localized in the deepest region of the wound bed [6]. In chronic wounds, *S. aureus* and *P. aeruginosa* react by increasing the expression level of some virulence factors that lead to the development of severe infections and antibiotic resistance [7], [8]. Moreover, chronic infections are generally associated with the development of biofilm, a polymicrobial population that adheres to the skin surface and that is difficult to eradicate because of the antimicrobial tolerance profile of the microorganisms [4]. Because of the essential role of bacterial biofilm, a major challenge is the development of new strategies that can optimize biofilm eradication in the treatment of chronic wound infection.

There are many research works reported on the antibacterial activity of bacterial cellulose incorporated with antibiotics, metal nanoparticles, microbial agents, and natural oils for wound healing applications. In most of these works, they used BC hydrogel films [9]. As an alternative to traditional hydrogel-based strategies, we optimized a BC-based paste incorporating a mix of neem and hypericum oil. Neem oil is a plant-derived product with antioxidant and anti-inflammatory properties, that has been already used alone [10] and in combination with hypericum oil [11] to promote wound healing. In this work, we try to explore the antibacterial properties of the resulting BC/neem-hypericum oil paste as a biofilm detaching agent.

II. MATERIALS AND METHOD

A. Bacterial cellulose (BC) synthesis and BC-neem-hypericum oil paste

BC pellicles were obtained by the fermentation process of the sweetened black tea with *Gluconacetobacter xilinus* strains, as reported in our previous work [12]. Purified BC pellicles were shredded into small pieces and fibrillated using a mini mixer. Finally, for making the BC paste, the pulp is made by concentrating fibrillated BC fragments by centrifugation, and the aliquot was further concentrated by vacuum pump filtration using a Whatman 41 filter. The oil mix, neem-hypericum was kindly provided by ENEA (Brindisi, Italy).

The oil-water emulsion of the neem-hypericum was prepared using the ultrasonic homogenizer (Velp OV5). Pluronic F127 was used as the surfactant and 24-weight percentage oil in water emulsion was prepared. Finally, BC/ neem oil paste was made by mixing BC pulp and emulsion in a 2:1 ratio and mixed with a homogenizer.

B. Characterization of BC pulp and neem-hypericum oil/water emulsion

The particle size of BC pulp was analyzed by laser diffraction using a CILAS 1190 multi-laser particle size analyzer. The zeta potential of the emulsion was measured using a zeta sizer (Malvern). The morphology of the BC pulp was analyzed using a Zeiss (Sigma VP, Carl Zeiss, Jena, Germany) field-emission scanning electron microscope (FESEM).

C. *Biofilm detachment properties evaluation*

P. aeruginosa and *S. aureus* were grown in Luria-Bertani (LB) medium (per liter, 10 g of NaCl, 10 g of Tryptone, 5 g of Yeast Extract, and 15 g of Agar for LB solid medium), stirring at 120 rpm at 37 °C. Bacteria were incubated overnight (ON) at 37 °C and were resuspended in the medium reaching an Optical Density (O.D.) of 0,3-0,4 measured at 600 nm. Then, each of the 12-well plates containing 20-mm square cover glasses were inoculated with 1 ml of *P. aeruginosa* or *S. aureus* suspension and were incubated at 37 °C for 24 h.

Two solutions of 10% and 1% w/v of paste were prepared in NaCl 0,9%. After 24 h of biofilm growth, cover glasses were treated with 2 ml of 10% or 1% paste solution for 5 min. To better investigate BC detachment properties, a 10% and 1% solutions of vegetable cellulose (VC) have been prepared in NaCl 0,9%, to be used as a comparative agent. Some samples were treated for 5 min with 2 ml of 1% Sodium Dodecyl Sulfate (SDS) as a standard cleaning agent.

To determine the number of Colony Forming Unit (CFU/ml), the different types of cover glass samples were put in 2 ml of LB medium and vortexed for 2 min. Then, 10 µl of the liquid phase was diluted and spotted on solid LB Petri dishes and incubated at 37 °C until the next day.

Each cover glass sample was also fixed and subjected to crystal violet staining to carry out a microscopy analysis using Leica LB30S optical microscope (*Leica Microsystems Wetziar GmbH*).

III. RESULTS AND DISCUSSION

A. *Particle size and microstructure of BC pulp and zeta potential of emulsion*

The fibrillated cellulose in BC pulp showed an average diameter of 200 microns analyzed by master sizer. The microstructure observed by SEM shows even after fibrillation, cellulose retained the nanofibrous structure (Fig 1a). A high zeta potential value of -29 mV was obtained for neem-hypericum/water emulsion indicating the stability of the emulsion. After proper mixing with BC pulp and oil emulsion, an injectable paste has been obtained (Fig. 1b).

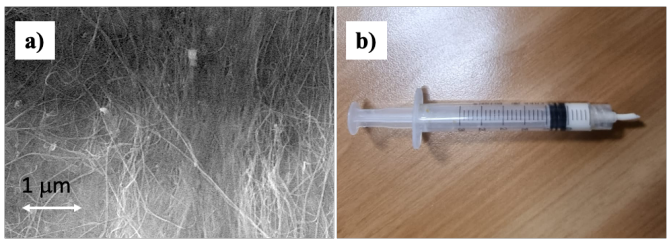

Fig. 1: Scanning electron microscopy image of fibrillated BC (a) and a photograph of injectable BC/neem-hypericum oil paste (b).

B. *Biofilm detachment properties evaluation*

In the present study, *P. aeruginosa* and *S. aureus* were chosen as common bacteria that often colonize the surface of chronic wounds. The protocol has been standardized for both species, leading to the formation of a 24 h bacterial biofilm that could be used for further investigations about biofilm detachment agents. To estimate the paste's capability to eradicate bacterial biofilms, the quantification of CFU/ml has been chosen, and these data have been confirmed through optical microscopy analysis. To conduct the biofilm detachment assay, a contact period of 5 min between the biofilm and the detachment agents was chosen as the probable application time for a cleanser agent to be used for skin lesions cleansing. Further investigations are needed to better investigate the time-response behavior of these biomaterials in the detachment of bacterial biofilms.

In this *in vitro* model, the BC/neem-hypericum oil paste shows promising biofilm eradication properties for both bacterial species that have been investigated. In particular, the application of 10% solution of BC/neem-hypericum oil paste reduced the number of CFU/ml in *P. aeruginosa* (Fig. 2A) and, more significantly, in *S. aureus* (Fig. 2B). In both cases, the use of 10% paste solution exhibits better biofilm detachment properties than SDS, which is considered a common cleaning agent capable of disrupting bacterial biofilm [13], [14]. Also, the application of 1% solution of BC/neem-hypericum oil paste exhibits biofilm detachment properties that are more evident for *S. aureus* (Fig. 2B). The use of 1% and 10% VC solutions exhibited stronger detachment capabilities against *S. aureus* biofilm than *P. aeruginosa* biofilm; however, VC detachment properties seems to be worse than that of BC/neem-hypericum oil paste for both bacterial species investigated. The greater effect of biofilm detachment that occurs with *S. aureus* compared to *P. aeruginosa* may be attributable to the different outer cell envelopes between Gram-positive and Gram-negative bacteria that can influence the strategies of surface colonization. Also, motility strategies can modulate surface colonization and biofilm formation: *P. aeruginosa* uses flagellar motility to colonize surfaces, while *S. aureus* does not possess flagella [15]. It is also necessary to consider the possible different affinity of the bacteria to the BC fibers of the formulation, which could justify the differences in the biofilm detachment capabilities of the paste. To confirm this, further investigations will be performed involving other Gram-positive and Gram-negative bacteria that commonly infect skin lesions.

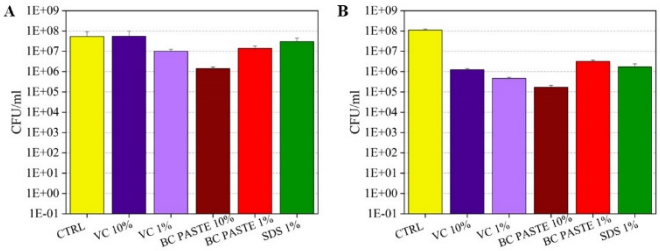

Fig. 2: Determination of the number of Colony Forming Unit (CFU/ml) for P. aeruginosa (A) and S. aureus (B) after 5 min treatment with 10% and 1% VC solution, 10% and 1% BC paste solution and 1% SDS as a standard cleaning agent.

This investigation continued by conducting an optical microscopy analysis to support the quantitative evaluation of the CFU/ml assay. The 5 min treatment with 10% solution of BC/neem-hypericum oil paste showed a significant reduction in the biofilm density for both *P. aeruginosa* (Fig. 3A) and *S. aureus* (Fig. 3B) if compared with the control. The performance obtained from the 10% solution is also higher than that of the VC solutions and of the 1% SDS (Fig. 3).

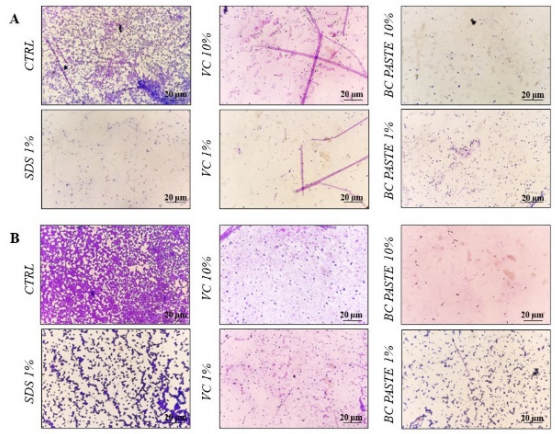

Fig. 3: Optical microscopy evaluation of the biofilm detachment properties of 10% and 1% BC/neem-hypericum oil paste solution, compared with the control, with 10% and 1% VC solutions and with 1% SDS treatments for P. aeruginosa (A) and S. aureus (B).

IV. Conclusion

In conclusion, this work highlighted the synergic effect of BC combined with a naturally derived antibacterial agent in creating a paste for wound healing application. The major result of this study is the significant reduction of biofilm formation when both *Pseudomonas aeruginosa* and *Staphylococcus aureus* bacteria are used. This feature can be further investigated in the future, especially in combination with the regenerative effect of BC.

***Abstract*—High incidence of thrombotic diseases worldwide, together with the variability of patients' response to antiplatelet drugs, makes the management of antithrombotic regimes of paramount importance. Platelet function testing is the most promising tool in addressing this clinical need. Here we present the first prototype of a microfluidic system for rapid, label-free, real-time functional assessment of the thrombotic risk of patients undergoing antiplatelet treatment. Our platform allows to monitor pressure drop variations on a collagen-coated microchannel under a range of blood flow conditions, and to relate these measurements to thrombus formation and ultimately to platelet functionality. The preliminary testing campaign presented in this work demonstrated the feasibility of our approach and allowed us to determine the most suitable working range of the current system.**

***Keywords*—Thrombotic risk, label-free, real-time monitoring, microfluidics.**

I. Introduction

ISCHEMIC cardio- and cerebrovascular events are the leading cause of morbidity and mortality in high-income countries, mainly caused by thrombotic or thromboembolic events. Platelets represent the main target for therapeutic treatments of thrombosis via antiplatelet medications. Yet, patients' responses to antiplatelet therapy significantly vary, with individuals showing high residual platelet activity, with higher susceptibility to thrombotic events [1]. To personalize thrombosis management and possibly predict pathological events, platelet function testing (PFT) has been suggested as a promising tool able to monitor the haemostatic impact of antiplatelet agents in real-time [2]. Most of the commercially available systems, though, are lab-based cumbersome instruments which hardly replicate physiological flow conditions [3]. Moreover, they usually allow a minimum degree of freedom, offering pre-set cuvettes and testing conditions.

To address this clinical need, we aim at developing a label-free microfluidic platform for identification of patients at risk of thrombosis. The platform performs experiments under flow conditions and can span a wide range of shear stresses. Unlike traditional immunoassays which require chemicals/antibodies, our label-free approach is low cost and more scalable for large scale patient screening, potentially becoming a point-of-care (POC) system. It also satisfies other critical requirements such as the use of a small blood volume, low-to-none blood handling and real-time analysis.

The present work presents the results obtained with the preliminary tests.

II. Materials and Methods

A. Blood sampling

The recruited healthy subjects (N=14) abstained from drugs known to affect platelet function for at least 10 days before enrolment. The study was carried out at ASST Santi Paolo e Carlo and approved by the institutional ethical committee; all subjects signed their informed consent. Blood samples were collected in the morning from an antecubital vein using a 21-gauge butterfly needle with minimal stasis. The first 3 mL of blood were collected into K-EDTA tubes (Becton Dickinson vacutainer, Australia) for a complete blood count; the following 10–15 mL were collected in 250 µg/mL INN-desirudin (Canyon Pharmaceuticals, United Kingdom), gently mixed, and allowed to rest at room temperature for 15 min before use. Platelets were marked with the green fluorescent dye DiOC6 (1 µM; ThermoFisher Scientific, Italy) for 15 min at room temperature.

B. Microfluidic device and experimental setup

Microfluidic devices featured six independent channels (1000 µm wide, 100 µm high and 3 cm long). The devices were fabricated in polydimethylsiloxane (PDMS, Sylgard™ 184, Dow Corning, USA) from silicon masters using standard soft lithography techniques (10:1 PDMS to curing agent ratio). Inlet and outlet fluidic ports were punched with a 1.5 mm diameter biopsy puncher. The PDMS layer was plasma-bonded to a glass coverslip (Figure 1, above).

Microfluidic channels were incubated at 4°C overnight with Horm fibrillar collagen type I (Mascia Brunelli, Italy) at two concentrations (10 and 100 ug/ml) [4], passivated with bovine serum albumin and finally rinsed with phosphate buffered saline (PBS).

The channels were connected to tubing for pumping system (Cellix, Ireland) and blood was perfused at two different shear rates, 950 and 1600 s^{-1}, simulating an arterial flow and a slightly pathological shear rate.

At this preliminary stage, we wanted to validate pressure measurements against the results obtained by image acquiring and processing using a platform from our previous works [3]. To this aim, all the experiments were performed under a fluorescence microscope (Axiovert A1 FL, Zeiss, Italy) equipped with a 16-bit camera (Crisel Instruments, Italy) (Figure 1, below). Images of the first portion of the collagen coating were acquired at 40x magnification every minute up to 4 min during blood perfusion through the microchannel. Mean and maximum fluorescence intensity (FI), together with

further parameters, were calculated, being FI an indicator of 3-dimensional thrombus growth in the channel lumen.

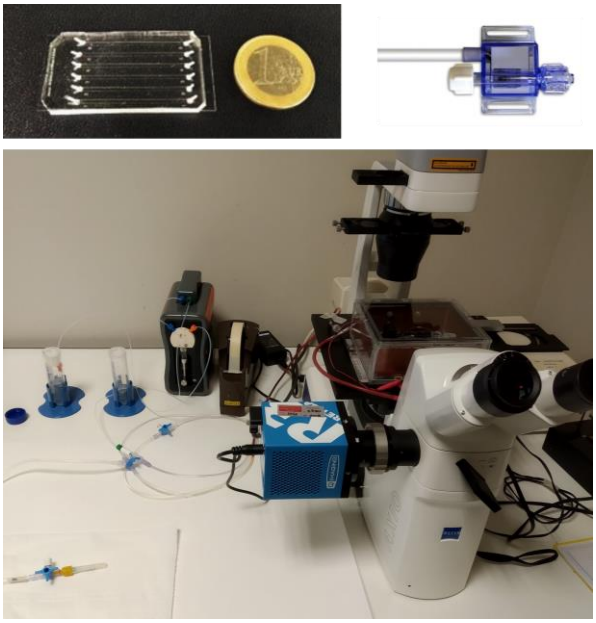

Fig. 1: Microfluidic chip and pressure transducer (above) and setup used for the preliminary testing campaign (below), comprising: an inverted fluorescence microscope equipped with a 16-bit camera, a micropump, a thermostatic chamber, the pressure transducer connected to a laptop and the microfluidic chip.

For pressure reading, an inline pressure transducer (PendoTech, USA) was placed along the circuit, to detect the pressure drop due to thrombi formation inside the channel. It was chosen for its working range, its affordability and washability. The transducer was connected to an amplifier and then to a laptop to record and visualise the pressure signal.

All the experiments were performed at 37°C thanks to a customised thermostatic chamber mounted on the microscope stage.

III. Results and Discussion

Figure 2 shows pressure drop measurements (n=14) in microchannels coated with two different collagen concentrations, 10 and 100 ug/ml, and at two shear rates, 950 and 1600 s^{-1}. A two-way ANOVA test found statistically significant differences between the pressure readings at 1600 s^{-1} with a 100 ug/ml collagen concentration and all the other conditions (****p<0.0001).

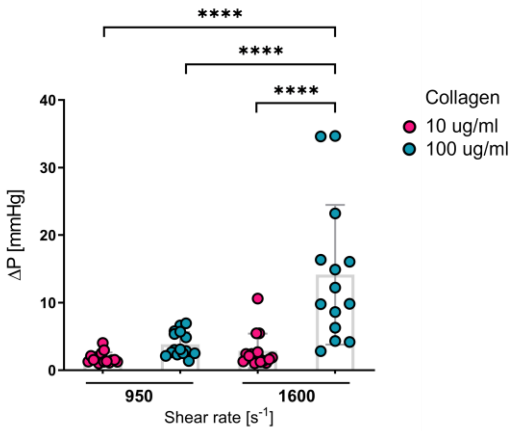

Fig. 2: Pressure drop due to thrombi formation inside the microchannel after 4 min experiments, classified for different shear rate and collagen concentration of the substrate. Bars represent mean ± standard deviation. N=14. Two-way ANOVA was applied. ****p<0.0001.

This indicates a transducer's sensitivity better working under more intense conditions. The higher collagen concentration appears to be a more suitable experimental condition, as indicated by the difference found between the data at the two different shear rates, conversely to what can be observed at 10 ug/ml. This is due to the bulkier thrombi forming on the 100 ug/ml substrate, as it works as a strong stimulus for platelets and exposes many bonding sites. The difference is more evident for increasing shear rate (Figure 3).

100 ug/ml is one of the most used concentrations in literature [5], [6], [7], while some groups employ even higher ones [8], [9].

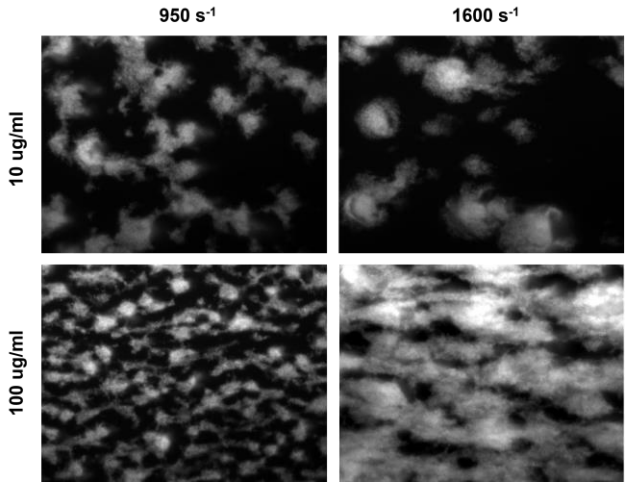

Fig. 3: Fluorescent images (magnification 40x) showing the typical thrombus formation over the two collagen substrates (10 and 100 ug/ml) at different shear rates (950 and 1600 s^{-1}).

The pressure drop results after 4 min of experiment, divided by collagen concentration, were compared with the mean and maximum fluorescence intensity computed via MATLAB from the corresponding images (Figure 4). The computed correlation demonstrated a fair agreement (R^2=0.81) between the two datasets, max FI and pressure variation, only at the higher collagen concentration, in accordance with our previous

observation. The encumbrance of the thrombi under this condition leads to partial occlusion of the channel, thus higher pressure drops.

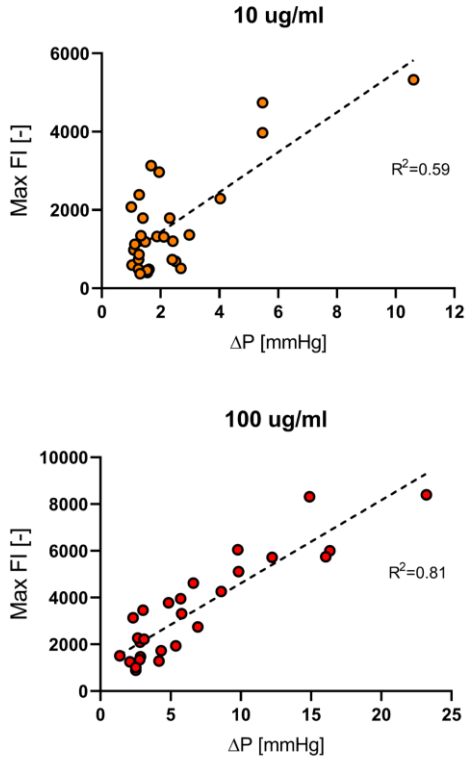

Fig. 4: Pressure drop after 4 min experiments plotted against the maximum fluorescence intensity for collagen concentration 10 and 100 ug/ml. Linear regression found R^2=0.59 and 0.81, respectively. N=14, n=28.

On the lower collagen concentration substrate, thrombi usually remain smaller and lower in height, and the employed transducer is not sensitive enough to detect low pressure variations.

Pressure kinetics was also analysed by monitoring pressure drop and fluorescence intensity throughout the experiments (4 min). Figure 5 shows a typical trend of the two parameters in an experiment carried out at 1600 s^{-1} on a 100 ug/ml collagen.

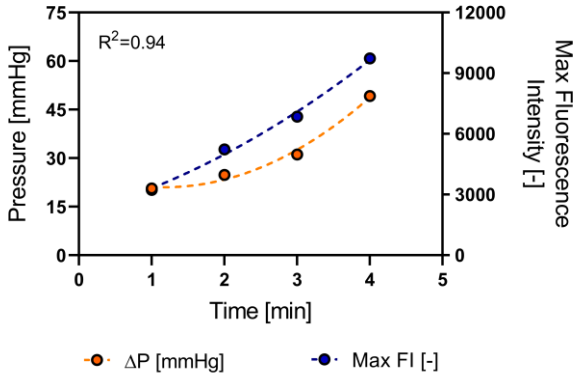

Fig. 5: Typical trend of pressure drop and max fluorescence intensity in time during an experiment conducted on collagen 100 ug/ml at 1600 s^{-1}. Dashed lines represent second order polynomial fitting. Pearson correlation coefficient R^2=0.94.

Under these conditions, platelets massively adhere to the collagen fibrils immediately after the start of the experiment and thrombi start to build up quickly. The pressure increases promptly in the first minute, then a parabolic trend can be noticed, while the channel lumen progresses towards occlusion (partial, within 4 min). A forming big thrombus is usually observed at the beginning of the coated area: it generates a hydraulic resistance which induces a concentrated pressure drop. This result shows how the pressure transducer is able to catch the kinetics of the process, especially after 2 min of experiment, displaying a trend similar to the one of the maximum FI (Pearson correlation coefficient R^2=0.94).

IV. Conclusion

Herein we presented the results of a preliminary testing campaign of a microfluidic platform for label-free, real-time functional assessment of the thrombotic risk, with the ultimate goal of a rapid monitoring of the therapeutic treatment. We demonstrated the feasibility of our approach by showing a good correlation between pressure drop and fluorescence images. These experiments allowed us to define the suitable working range of the current setup.

Future studies will investigate the correlation between pressure drop readings and occlusion rate of microchannels, obtained by confocal microscopy. Moreover, we will verify whether the pressure transducer is able to detect the detachment of thrombi from the substrate, to potentially study the patient population presenting aggregation defects.

A further improvement will be the addition of surface microelectrodes on the glass substrate, to detect platelet adhesion through electrical impedance variations.

This platform has the potential to become a POC PFT device, providing a useful tool for fast, real-time and label-free stratification of patients' thrombotic risk.

***Abstract*— During the last years, the deformability characterization of non-adherent cells like circulating tumour cells (CTCs) and immune cells gained a lot of attention since mechanical forces regulate the deformation, organization, and translocation of cytoskeleton leading to changes in T-cell mobility, migration, and infiltration. However, deformability measurements on non-adherent cells is challenging since any kind of contact between a physical probe or substrate could induce alterations into the cell state and then deformability outcome. Thus, new strategies are needed to overcome such problems. In-flow viscoelastic compression represents a straightforward way to deform CTCs and immune cells in a controlled and contactless manner. Here, we present a study of cell deformability by application of such viscoelastic compression forces on CTCs and healthy lymphocytes, eliciting a higher deformability of cancer cells with respect to healthy lymphocytes. Thus, our approach opens up to the possibility to characterize and distinguish CTCs and healthy lymphocytes depending on the resulting deformability in a rapid and versatile way.**

***Keywords*—Circulating tumour cells, microfluidics, contactless compression, deformability.**

I. Introduction

As label-free biomarker for cell phenotyping, the analysis of single cell mechanical properties has emerged as an interesting complementary approach to the well-known classical molecular biology [1]. In particular, cell deformability turned out to provide useful information about the state of a cell [2]. In fact, in cancer research, one of the most promising ways of understanding condition and mechanism of tumour metastasis, is the study of circulating tumour cells (CTCs) distinguishing them from the other circulating cells like immune cells. However, separation, classification and deformability measurement of CTCs are technically challenging, so new strategies are needed [3]. This importance of the deformability measurements justifies the interest in developing simple procedures to measure mechanical properties of these cells with easy-to-use, versatile and highly tuneable methods [4]. The current techniques for the mechanical characterization of CTCs and immune cells use different methods to apply a force and measure the corresponding deformation. For example, the micropipette aspiration technique consists of aspirating the cell by a capillary of inner dimension smaller that the cell diameter itself and analysing the aspirated length corresponding to a given suction pressure. Instead, the atomic force microscopy is based on the cell indentation into a specific location point, and it can be used also for suspended cells when fixed on a substrate. In magnetic twisting rheology, the response of a cell-attached magnetic bead is probed in response to an external magnetic field [5]. However, all of the aforementioned techniques present some drawbacks such as low cell throughput, not highly versatility in force calibration, and a mechanical contact of the used probe -atomic force microscopy and magnetic twisting rheology- with the cell which could lead to possible adhesion and active cellular responses that are crucial for CTCs and immune cells functions [5], [6].

To overcome the aforementioned drawbacks, a variety of microfluidic systems enabled alignment, deformation and/or separation of cells at high-throughput rates with precise force calibration. In particular, the combination of microfluidic based approaches like deformability cytometry, microfluidic constrictions and hydrodynamic stretching techniques demonstrated to solve the throughput problem while still lacking in the solution of the force calibration [6]. To date, viscoelastic fluids have been employed for such a kind of purposes since their intrinsic viscous and elastic properties allow to better govern in-flow cell manipulation, as deformation and separation [7]-[10].

Recently, we presented a viscoelastic-based microfluidic approach used for the in-flow compression of cells in a contactless, controlled and precise manner [11], [12]. We analysed and precisely classified breast cell lines -healthy and pathological- by coupling the classical descriptors of morphological and shape alterations with in-flow orientation angles [11].

Here, we propose to use our viscoelastic in-flow compression to deform human blood lymphocytes and immortalized lymphoid leukaemia cells as CTCs (Jurkat T-cell line) characterizing them in terms of cell deformation (CD), aspect ratio (AR) and orientation angles (φ). We demonstrate that a difference in cell deformability is present among healthy and pathological cells. Distinguishing variable deformability properties is crucial for phenotyping circulating cells since stiffer cells could be responsible of vaso-occlusion phenomena which can lead to organ failure.

Thus, our approach elicits the possibility to precisely classify Jurkat cells with respect to healthy lymphocytes in a completely label-free manner.

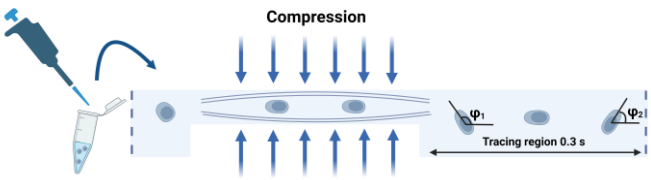

Fig. 1 Sketch representation of the microfluidic device. Cells pass through subsequent rectangular cross-sections where forces gradually change depending on the geometry. The sample arrives at the inlet capillary where it is loaded into a first section where they do not experience a deforming force. Instead, in the compression region, the deformation occurs, and it is then observed into an enlarged cross-section, conceived in order to detect in-flow deformation-dependent motion dynamics [11]. (Created with BioRender.com)

II. Material and Methods

A. Viscoelastic in-flow forces

To induce the compression of single cells under viscoelastic flow conditions, we used a highly biocompatible polyethylene-oxide (PEO - 4MDa, Sigma Aldrich). Fluid rheological

properties have been previously investigated and properly characterized [10]. We selected PEO 09 condition, which corresponds to polymer concentrations of 0.88 wt%. We calibrated the initial pressure and velocity conditions into the microfluidic device, as well as the channel geometry in order to align and deform cells in a contactless way [11].

B. Experimental setup for the in-flow measurement

The setup includes a pressure pump (P-pump, Dolomite Microfluidics), round shaped flexible fused silica capillary tubing (Molex), an ad hoc designed microfluidic chip, a fluid connector (N-333, IDEX) and an inverted microscope (X81, Olympus) with a CMOS camera (ORCA FLASH 4.0, Hamamatsu Photonics K.K.). Briefly, a pressure pump pushes the sample volume through the capillary in the microfluidic device inlet, while at the end of the chip a reservoir collects the cells. The chip is made of two separate parts made with polymethyl methacrylate, which are placed together by magnetic forces. The main part was machined using a standard CNC based micromilling technique (Minitech Machinery) to develop microfluidic duct sections. of different height, width, and length, while the cover part was simply used to close the chip. In particular, the compression section has the smallest height (W × H: 100 × 25 μm) implying that a well-defined viscoelastic compression over a certain time period on each passing cell is applied, enabling precise cell compression in-flow. Then, a subsequent enlarged section (W × H: 200 × 90 μm) is conceived for the observation and analysis of the compressed cells (Fig.1) [11].

C. Cell culture

Lymphocytes were obtained from healthy donor buffy coats obtained from the blood bank of the medical school of the Federico II University of Naples (Italy). At the time of blood donation, each donor signed an informed consent (model n. 5526 of Azienda Ospedaliera Universitaria "Federico II", Naples, Italy) in which is specified that waste parts of the blood, not useful for the medical-therapeutic purposes of blood donation, can be used for scientific research purposes. In more detail, a standard venepuncture procedure was performed using standard K 2 EDTA tubes (Vacutainer, BD) to prevent coagulation and standard density gradient centrifugation, with some adaptation to reduce a possible platelet contamination [13]. Briefly, the blood sample is gently layered on an equal volume of density gradient fluid (Ficoll) and centrifuged at 300 for 45 minutes (without brake). The peripheral blood mononuclear cell ring stratified at the interface between Ficoll and plasma is collected using a Pasteur pipette and washed twice with red blood cells lysis solution to eliminate possible erythrocyte contaminations. Next, lymphocytes are isolated by a negative selection procedure with specific Ab-coupled magnetic beads (Dynabeads Untouched kit, INVITROGEN) and suspended in phosphate buffered saline.

Jurkat human lymphoid leukaemia T cells were kindly donated by Siciliano's group (Center for Advanced Biomaterials for Healthcare@CRIB, Istituto Italiano di Tecnologia, Naples, Italy) and grown in RPMI 1640 medium supplemented with 10% FBS, 100 μg/ml l-glutamine and 100 U/ml penicillin/streptomycin.

D. Measurement procedure and data analysis

Before in-flow compression, cell diameters (d_{Static}) were measured with the inverted microscope. Then, the in-flow cell analysis was performed over the full cell tracing length(~0.3 s of measurement in the tracing region), after the compression region (Fig.1). We measured the dynamic in-flow cell parameters, such as the major axis (d_1), minor axis (d_2), circularity (c) and orientation angles (φ) in the range of [−90° to 90°], at each 0.03s. Out of such parameters, the cell deformation (*CD*), cell aspect ratio (*AR*) and angle variation (Δφ, at the beginning and the end of the tracing region) are calculated as follows (Fig. 1):

$$AR = \frac{d_1}{d_2} \quad (1)$$

$$CD = 1 - c \quad (2)$$

$$\Delta\varphi = |\varphi_1 - \varphi_2| \quad (3)$$

These parameters characterize the in-flow deformation-dependent dynamics analysis [10].

III. Results and Discussion

Firstly, we computed the compression as viscoelastic force applied on cells [11]. In order to do this, we measured the cell diameters in static conditions, before loading cells into the microfluidic device Table 1. The resulting force estimation gives 10^1 μN as order of magnitude for both the cell lines. Then, by the in-flow analysis, we collected the morphological and dynamic parameters describing the different deformability behaviour.

TABLE I: Major cell diameters before in-flow compression (N=30)

Cells	d_{Static} *(μm)*
Lymphocytes	7.1 ± 0.65
Jurkat	10.4 ± 0.75

In particular, we observed that Jurkat cells deform more than healthy lymphocytes (Fig. 2), confirming a higher deformability of lymphoid leukaemia cells with respect to the healthy counterpart [14]. As observed, both AR and CD are higher in Jurkat than Lymphocytes. In particular, looking at the ranges of CD, distinct in-flow deformation-dependent dynamics are distinguishable [11]. We observed that Jurkat cells cover Rolling (R with CD ~ (0:0.1)), Tumbling (T with CD ~ (0.10:0.21)) and Tank-Treading (TT with CD ~ (0.15:0.35)) motions, while the 81 % of Lymphocytes move as Rolling. Thus, our approach reveals a cell heterogeneity in deformability properties within the same line both for Lymphocytes and Jurkat, allowing a possible cell subclass identification. For lymphocytes such a kind of heterogeneity is associated to the two subpopulations of B and T lymphocytes that could be then identified by our deformability analysis. Our results are in well agreement with ones found with the same approach for breast cells, distinguished as healthy or pathological depending on the motion regime [15].

IV. Conclusion

The presented microfluidic approach is able to provide a deformability characterization of CTCs and healthy lymphocytes by using in-flow viscoelastic compression forces in a completely contactless manner. The absence of a physical contact avoids possible activation or cell function changes due to the interaction between a probe of mechanical properties with cells. Moreover, with the aim of promoting new rapid diagnostic approaches, our chip can be of significant interest for cell separation applications, developing an additional microfluidic stage with properly conceived channel sections to sort CTCs and healthy cells depending on their own distinct deformation induced cell trajectories or motion dynamics.

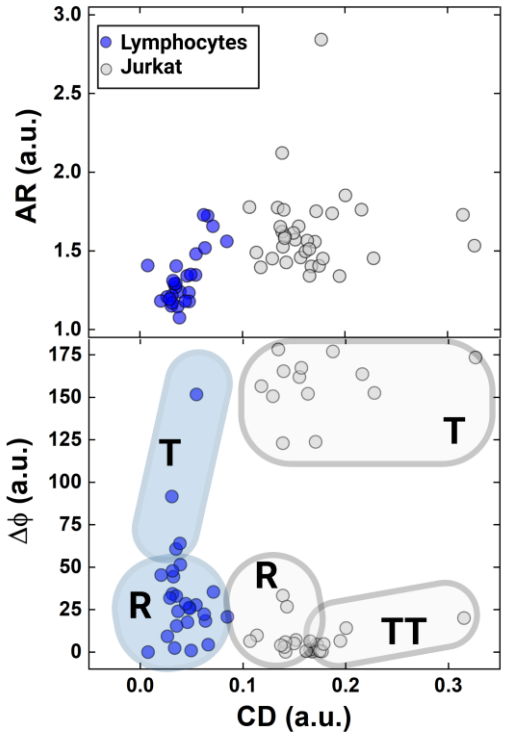

Fig. 2 Deformability measurements of healthy lymphocytes and Jurkat. AR and Δφ variation are shown with respect to CD values. We grouped the data depending on the detected motion dynamics with respect to the obtained range of CD (n_{Lymph}=27 and n_{Jurkat}=34).

***Abstract*—The native extracellular matrix is a dynamic environment, but it is not clear how cells react to time changing signals. To investigate this, we exploited light responsive azobenzene based platforms, able to display spatiotemporal changes of topographic signals. Mesenchymal stem cells were cultivated on either rectangular or circular adhesive islets in order to promote either a high or low contractile phenotype. Submicron scale topography was switched on at selected time points to interfere with adhesion and cytoskeleton assembly. Cells responded to the dynamic changes by altering their mechanical properties, lamins expression and YAP nuclear import. Changes at receptor or cytoskeleton level are observed a relatively small timeframes, whereas Lamins and YAP nuclear accumulation required longer times. Our data could be useful to develop culturing systems able to challenge stem cells with specific programmes of mechanical/topographical signals thus understanding how cells integrate those in time.**

***Keywords*—dynamic substrates, adhesive patterns, topographic patterns, mechanotransduction**

I. INTRODUCTION

THE extracellular matrix (ECM) continuously changes its biochemical/biophysical features displaying different signals to cells in a spatio-temporal dependent manner [1]. Temporal variations of the ECM, including changes in the microarchitecture, play a crucial role in regulating different biological processes in vivo as gene transcription and morphogenesis and also the progression of pathologies [2], [3]. Recently, stimulus-responsive materials have been used as 'dynamic' substrates that replicate some spatio-temporal changes of the ECM, thus enabling understanding cell response to microenvironmental changes [4], [5]. Particular attention has been focused on light-sensitive materials, exploiting the peculiarity of light to be precisely localized over a substrate, programmed in time and space, and remotely addressable at an appropriate wavelength without compromising cell viability. Among the various light-sensitive materials, those containing azobenzene molecules have shown the ability to effectively display topographical features dynamically by providing remarkable surface mass transport under appropriate illumination conditions. Our objective was to investigate cellular response in terms of cell mechanics, nucleus deformation, YAP and lamins density in cells on surfaces on which nanotopography was varied dynamically.

II. EXPERIMENTAL SECTION

Dynamic Sample Preparation: Spin coating technique was used to produce thin films of poly-(Disperse Red 1 methacrylate) (pDR1m) on 10 mm diameter cover glasses. pDR1m was dissolved in chloroform at a 3% w/v concentration. 15 µl of solution was spun over the cover glass at 5000 rpm. Coatings of ~300 nm of thickness were achieved.
Micropatterning protocol: pDR1m substrates were activated by exposure to deep UV light for 15 min. Then the samples were incubated for 1 h with 0.1 mg ml^{-1} poly-L-lysine-g-poly(ethyleneglycol) at room temperature (40 µL for each sample). After washing with distilled water, the treated surface was illuminated with deep UV light through a photomask. The mask contained circles (C) and rectangles (R) having the same surface area (1300 μm^2). 2.5µL of millipore H_2O were added on the quartz mask and the PEGylated side of the sample was gently dropped onto the mask. Using the deep UV Printer, the mask was illuminated for 8 min. The activated side was than incubated 1h at room temperature with 50 µL of fibronectin (final concentration of 50 µg ml^{-1}) and was rinsed with PBS afterwards.
Cell culture: hTERT are cultured in Mesenchymal Stem Cell Basal Medium (ATCC PCS-500-030) with, Mesenchymal Stem Cell Growth Kit (ATCC PCS-500-040). 25000 cells were seeded per sample. Cells were cultured at 37 °C in a humidified atmosphere of 95% air and 5% CO_2.
Nanopatterning protocol: hTERT cells were cultured on pDR1m coated glass slides previously micropatterned (C, R) for 24 h. Afterwards, real-time linear nanopattern inscription on cell-populated samples was performed by using a Axio Observer Z1 microscope. The isomerization of the azopolymer and its consequent mass transport were induced with an Argon laser at 488 nm and 1.3 mW of intensity with a 10x objective lens. Nanopatterns were embossed on the pDR1m substrates by illuminating with the laser light for 60 s in specifically drawn regions-of-interest controlled by software with a high spatial resolution (nm order). The final nanopattern consisted of 7 rectangular relieves (ridges) in the case of the rectangular cell and 17 rectangular relieves in the case of the circular cell. In both cases the relives were oriented parallel to the scan direction. In the reminder we will refer to “flat” substrates as the substrates displaying circular or rectangular adhesive micropatterns without having embossed a topographic pattern. Conversely “patterned” substrates refers to substates displaying circular or rectangular adhesive micropatterns over which a topographic pattern was inscribed.
Cell Mechanics: Mechanical characterization of cells was performed with a JPK NanoWizard II AFM. With SiN cantilevers with a square pyramid tip (k=0.06 N/m). All indentations were performed over the central region of the cell in an area where the nucleus was visible. Typically, 64 force curves were measured over a cell area of 10 x 10 µm. Mechanical properties of cells, in terms of Young’s modulus (*E*) values were estimated by fitting the force-indentation curve with Hertzian model for linearly elastic materials. *E* of

the hTERT cells on each sample was quantified by calculating the median of the eight values with the greatest distance from the substrate (approximately corresponding to the nucleus).
YAP and Lamins immunostaining: Cells were fixed at different time-points: flat and 1 h, 4 h, 24 h, 48 h after pattern inscription. Cell fixation was performed by incubating cells in a 4% paraformaldehyde solution for 15 minutes. Then, cells were permeabilized with 0.1% Triton X-100 in PBS for 15 min. Samples were blocked in 3% bovine serum albumin in PBS for 1 h to avoid non-specific binding. Anti-YAP primary antibodies in BSA were added to the samples and incubated overnight at 4 °C. Subsequently, lamins were labelled by incubating samples with an anti-LMNA for 1 h at room temperature. Samples were then incubated at room temperature with secondary antibodies for 1 h at room temperature.

III. RESULTS AND DISCUSSION

A. *Embossing of topographic patterns*

hTERT cells were seeded on pDR1m flat substrates, which was previously micropatterned using a photomask to produce circular (C) and rectangular (R) adhesive islands with the same area (1300 μm^2). 24 hours after seeding, we embossed a linear topographic pattern on the initial flat surface using a 488 nm laser mounted in a confocal microscope. Patterns were embossed beneath cells adhering on the islets directly through the irradiation for 60 s with the laser (Fig. 1). Using topography analysis performed with AFM we verified the width of each ridge (0.70 ± 0.09 µm) the pitch between two ridges (1.40 ± 0.04 µm) and the height of the ridges (0.20 ± 0.02 µm).

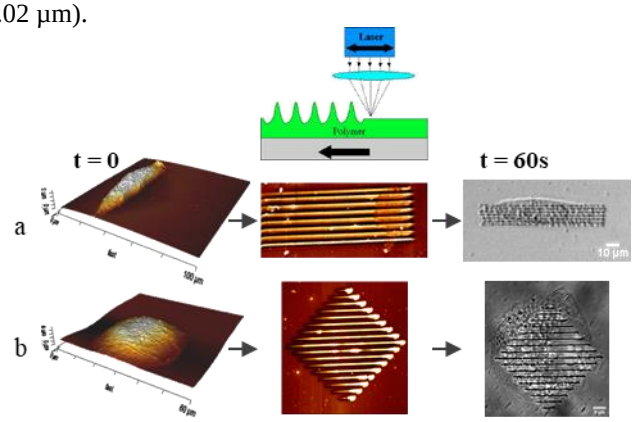

Fig. 1: Representation of the topographic pattern fabrication technique onto the micropatterned substrate. Rectangular pattern (a) and circular pattern (b). 3D reconstruction of the micropatterned cells on flat substrate (left), AFM images of the topographic reliefs (middle), brightfield images of hTERT cells cultivated onto the adhesive micropattern superimposed to the topography (right).

B. *Cell Mechanics on Dynamic Topogrphies*

Changes in the adhesive properties, here in terms of the surface topography, is expected to impact cytoskeleton structure, cell mechanics and nucleus shape. To characterize these changes, we first measured Young's moduli of cells on R in proximity to the nuclear region. Despite the change of surface topography, i.e. the transition from a flat to a grooved surface (Fig. 2a), the values of the cell modulus did not change over time, if compared with the modulus measured immediately before the pattern inscription, t = 0- (Fig. 2b). Also, the elastic moduli of cells cultivated on flat control surfaces (i.e., on which the topographic pattern was not embossed) fluctuated around a constant value (Fig. 2b). In particular, the variance of the measured moduli of the nuclear region of cells on control samples was higher with respect to the variance to the modulus measured on cells on patterned substrates. Therefore, although the superposition of a pattern does not significantly alter the stiffness of the nuclear region, the presence of a submicron scale topographic pattern exerts a stabilizing effect on the cytoskeletal structures, presumably by confining and aligning focal adhesions (FAs). Cell's modulus, at least of the nuclear region, is mostly affected by the macroscopic, rectangular shape, rather than by the presence of an underlying nanotopography.

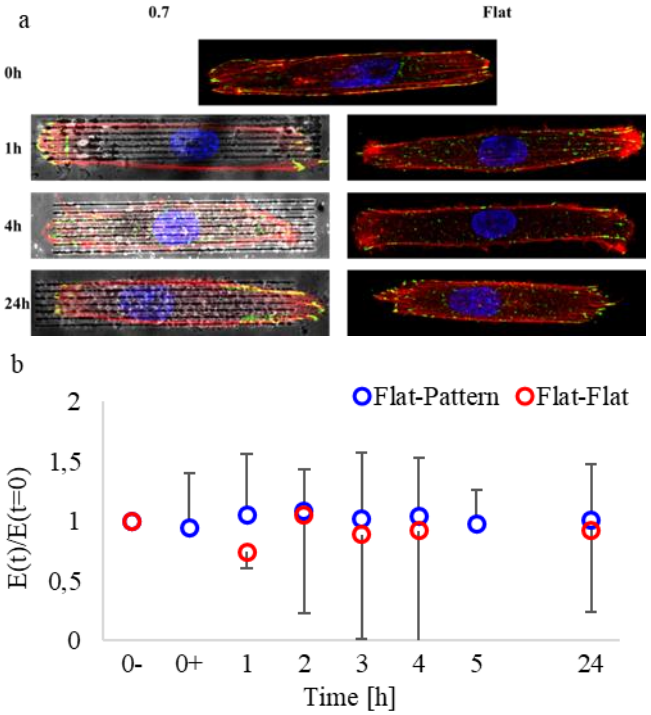

Fig. 2: (a) Confocal images of fixed rectangular hTERT on flat rectangular micropattern and 1, 4 and 24 hours after the linear pattern inscription (left). Cells on flat substrates on the right. Cell cytoskeleton is stained with Phalloidin (red), FAs are immunostained for vinculin (green), and nuclei are stained with DAPI (blue). (b) Plots of the Young's moduli measured up to 24 h after the nanopattern inscription (blue marks) and on flat substrates (red marks).

In contrast, cells confined in circular shapes, in the absence of topography, were characterised by randomly oriented actin fibres (Fig. 3 a). Their Young's moduli evaluated in the nuclear region was constant over time (Fig. 3 b red marks). As soon as the linear nanopattern was applied at t = 0+, there was first a rapid decrease in stiffness followed by a gradual increase up to a roughly constant value (Fig. 3 b blue marks). We associate this behaviour with the redistribution of FAs and the reassembly of the cytoskeleton. In fact, the presence of the topographic pattern induced a greater orientation of the basal fibres even in the case of cells with isotropic shapes compared to flat surfaces. For this reason, the stress fibres re-orientation following the surfacing of the topography, caused the values of the elastic moduli to increase in time. However, the plateaux value was lower than that corresponding to the flat case. This

is probably because when shape confinement affects the FA confinement, the mechanical stability of cells is disrupted by the presence of the topographic nanograting that reduces the space available for FA formation and growth.

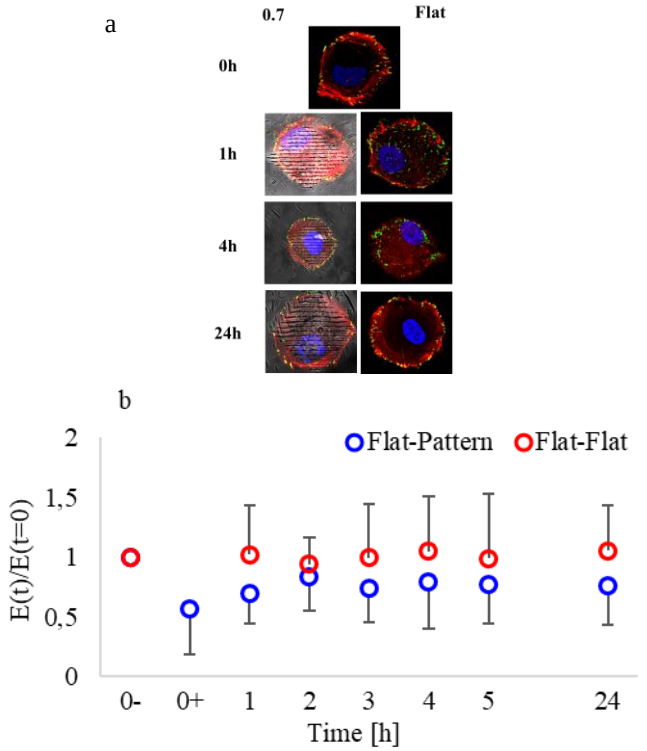

Fig. 3: (a) Confocal images of fixed hTERT on a flat circular micropattern and 1, 4 and 24 hours after the linear pattern inscription (left). Cells on flat substrates on the right. Cell cytoskeleton is stained with Phalloidin (red), FAs are immunostained for vinculin (green), and nuclei are stained with DAPI (blue). (b) Plots of the Young's moduli measured up to 24 h after the nanopattern inscription (blue marks) and on flat substrates (red marks).

C. Lamin and YAP expression and localization

The nucleus is a deformable organelle that adapts to external mechanical stimuli, not only by changing its morphology but also by rearranging its nucleoskeleton and inner composition. A-type lamins and YAP (Yes-associated protein) attracted interest as their mechanosensitive nuclear localization correlates with cell differentiation and other cellular functions [6]. The nuclear lamina performs different essential functions in the mechanotransduction pathway modulating the nuclear stiffness, governing the chromatin remodeling, and transmitting cytoskeletal forces to the nucleus [7]. YAP is a transcription factor widely studied owing to its sensitivity to mechanical (i.e., the ECM rigidity) and topographical signals (i.e., the micro- or nano-pattern) [8]. YAP shuttles between the cytoplasm and nucleus where it associates with diverse promoter-specific transcription factors. Being the expression and localization of Lamins and YAP two important readout of the actual mechanical state of the nucleus and the cell, we stained cell cultures (on flat or on grated surfaces), at different time points for Lamin and YAP. Regarding the nuclei of rectangular cells, we observed that after pattern inscription a slight decrease in Lamins intensity was observed up to 4 hours. Afterwards, Lamins intensity significantly increased and attained a high level of fluorescence intensity up to 48 hours. Conversely, cells on the control, flat substrates, expressed constant levels of Lamins, with some fluctuations at late time-points (Fig. 4). However, Lamins intensity on flat substrates was significantly lower, with respect to the nanopatterned samples at 24 h and 48 h time points.

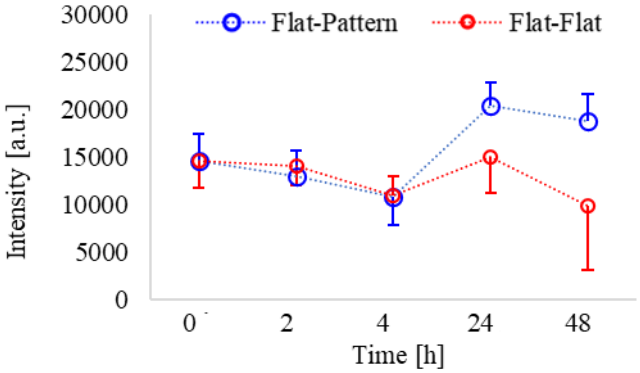

Fig. 4: Plots of the lamins A/C intensity variation over time in nuclei of cells on rectangular micropatterns cultured either on flat surfaces (red indicators) or in contact with nanotopographic pattern (blue indicators).

Concerning the nuclear import of YAP in our experimental setup, we wanted to observe whether the nuclear transport of YAP was sensitive to dynamic changes of the adhesive conditions. We found a higher fluorescence density of YAP in the nuclear region with respect to the cytoplasmic fluorescence density on flat substrates (t=0) (Fig. 5). After pattern inscription, we observed a gradual decrease in YAP fluorescence density in both cellular compartments (2h post patterning). However, at longer time intervals (above 24h), YAP was intensely localized in the nucleus, whereas it remained at low values of fluorescence density in the cytoplasm. Cells on the control substrates behaved in a similar manner at short times, with a gradual reduction of YAP fluorescence in either the cytoplasm or the nucleus (data not shown). Also, fluorescence tended to remain at low levels even at later time points.

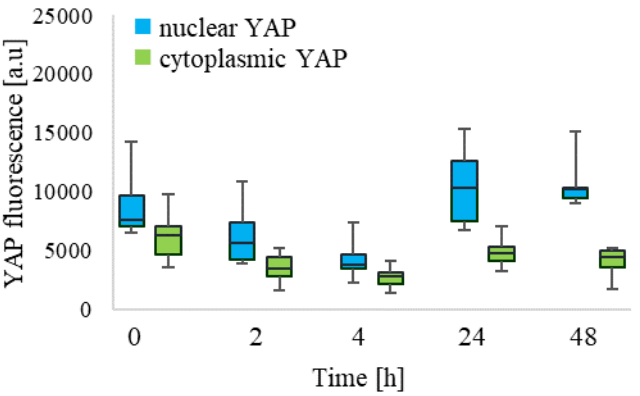

Fig. 5: Box and whiskers of the time evolution of fluorescence intensity of YAP. Cell cultivated on rectangular micropatterns for 48 h after the surfacing of the topographic nanopattern (72 h of culture in total).

Then, we analysed Lamins intensity on the isotropic circular micropattern, which produces a less contractile phenotype as opposed to the rectangular micropattern. Also in this case, we observed an increase in Lamins intensity after the nanopattern superposition, but at a later point (48h) (Fig. 6). Cells on control surfaces (absence of topographic relieves) expressed

constant values of Lamins in the time under consideration (24-72 h post seeding) (Fig. 6).

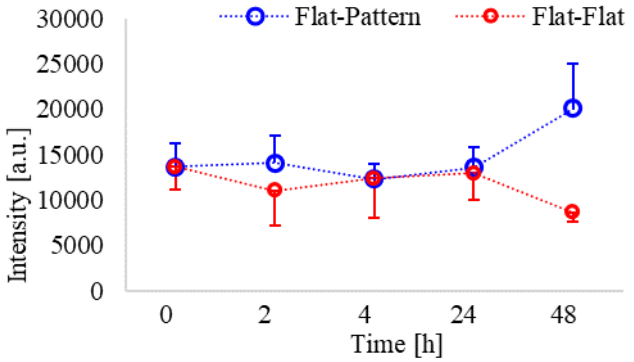

Fig. 6: Plots of the lamins A/C intensity variation over time in nuclei of cells on circular micropatterns cultured either on flat surfaces (red indicators) or in contact with nanotopographic pattern (blue indicators).

Finally, we analysed YAP fluorescence density and its localization in the cells on circular micropatterns. Similarly, to what observed in the case of rectangular micropatterns, we found higher levels of nuclear YAP with respect to cytoplasmic YAP (Fig. 7). The superposition of a topographic pattern did not affect the distribution significantly, for short time intervals (up to 4 h). However, at longer time intervals we observed a marked increase in nuclear YAP. In comparison, cells on control substrates (without nanopattern) exhibited relatively constant values of fluorescence density all over the time frame of the analysis (data not shown). Hence, despite the lower contractile phenotype of cells on a circular adhesive area, the superposition of a topography over the adhesive signal does affect Lamin expression and YAP transport at longer times.

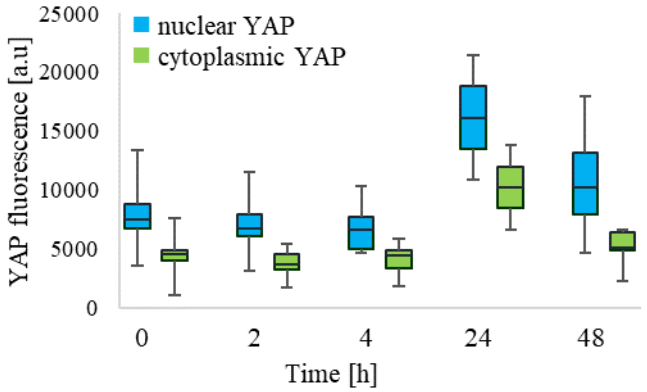

Fig. 7: Box and whiskers of the time evolution of fluorescence intensity of YAP. Cell cultivated on circular micropatterns for 48 h after the surfacing of the topographic nanopattern (72 h of culture in total)

Several works in the literature, including those carried out by Swift et al. [9] and Gonzalez-Cruz et al. [10], found a positive correlation between the expression of Laminin proteins and cell moduli. Here we observed that changes in lamins localization occur at longer time points after the superposition of topographic signal and prior to this no change in cell elasticity was evident. It is likely that cell modulus is affected by lamin localization and cytoskeleton assembly, both affected by the topographic signal. Similarly, a greater influx of YAP is observed 24 h after the inscription of the topographic pattern, suggesting that cells respond to changes to the adhesive microenvironment at long time intervals.

IV. CONCLUSION

Here we have shown how cells sense mechanical signals from their microenvironment and transfer these up to the nucleus affecting its mechanics and composition. In particular, we observed how cell geometric constraints and topographical patterns of submicron scale affect over time the cell mechanical properties and subsequently induce cytoskeleton-mediated alterations in the nuclear properties. Moreover, the changes in the physical properties of the nucleus have been observed to correlate with alterations in nuclear architecture and transcriptional factors expression and localization.

We showed that cell geometry controls these nuclear properties by regulating the local tensile stresses. In more details, we observed how the physical properties of the microenvironment, in particular nano topography, impact the properties of the cytoskeleton and nucleus by regulating the dynamic reciprocities between the tension-dependent formation of FAs, the polymerisation of actin filaments, the stiffening of the nuclear envelope lamina network and the nucleocytoplasmic displacement of transcription factors. These data might be of interest in the biomedical field, for the development of culturing platforms to develop chronoprogrammes to guide stem cells towards differentiation programmes in an efficient manner.

***Abstract*—Extrusion-based bioprinting is currently one of the most used techniques to fabricate constructs for Tissue Engineering applications. When using bioinks (*i.e.*, inks containing cells), the embedded cells may be damaged during extrusion mainly due to high shear stresses and/or the high exposure times to those stresses, posing a severe risk for the correct functionality of the final bioprinted product. The entity of this damage is strictly connected to the printing set-up (*e.g.*, needle shape and internal diameter) and parameters chosen (*e.g.*, printing speed, flowrate, layer height), which should be carefully tuned considering the trade-off with the printability requirements. In this context, we propose a novel mathematical model to predict cell damage during extrusion which integrates with an already existing one for printability assessment. The combined model can help predict *a priori* the outcome of a print, both in terms of cell viability and printability, and to fine-tune the printing parameters according to both constraints. The model equations were implemented in a web-page application (available at https://www.prin-vision.it/resources/), which can be used by the bioprinting community to optimize the printing process and thus speed-up the printing parameters selection process.**

***Keywords*—Extrusion-based bioprinting, mathematical modelling, printability, cell damage.**

I. Introduction

Bioprinting has recently seen a surge of interest as a promising technology to fabricate constructs for Tissue Engineering applications [1]. Among the many available technologies, extrusion-based bioprinting (EBB) is currently the most used, thanks to its simple set-up and the ability to process a wide variety of materials in clinically sized constructs [2]. In the typical EBB set-up, an extruder tool-head is attached to a micro-positioner to deposit an ink (usually stored in a syringe) layer-by-layer on a printing plate. The ink may be made of one or more biomaterials (*i.e.*, a biomaterial ink) or one or more supporting biomaterials mixed with cells (*i.e.*, a bioink) [3].

During extrusion, the ink flows through a syringe needle under the application of a force. When extruding a bioink, cells are subjected to mechanical forces (*e.g.*, pneumatic pressure, extensional and shear stresses), which may damage them if these forces exceed certain thresholds or are applied beyond a certain period. This is a major concern as the number of viable cells is strictly correlated to the final functionality of the bioprinted construct [4]. Shear stress is thought to be the primary mechanism that influence cell damage during extrusion [5]-[7]. Several studies have proposed mathematical modelling as a key tool to predict *a priori* the entity of this damage. For example, Li *et al.* used a probability density function to model cell damage due to shear stress as a function of both the stress magnitude and exposure time. The parameters for this function were determined experimentally and were dependent on the tested cell type [8]. Interestingly, the needle geometry has a significant effect on cell damage. Billiet *et al.* developed a Finite Element model to investigate the shear stress distribution in conical vs. cylindrical needles. The authors found that conical needles induced less cell damage at lower extrusion pressures [9], but this advantage was not present at higher extrusion flowrates [10]. In the latter case, cell damage is correlated more with extensional stresses (*i.e.*, stresses generated due to the abrupt area contraction between the syringe main body and the needle) then shear ones, as recently studied by Ning *et al.* [11]. The authors developed a mixed model that considers the effect of both shear and extensional stresses. By extruding alginate-based bioinks with different pressures and needle diameters, the authors found that cell damage predicted only by shear stresses was not consistent with experimental data above a certain extrusion pressure whereas the addition of the extensional component yields a better fit in this region [11].

Even though the previous examples highlight the importance of mathematical modelling in bioink extrusion, to the best of our knowledge no model is described in literature that combines cell damage with printability evaluation (*i.e.*, a combination of several aspects of the EBB process, including material, scaffold geometry and printing apparatus, that determines *a priori* if the printing process will be successful or not [12]). Such a model would help an *a priori* assessment of the printing process considering both the shape fidelity of the final construct and the cell fate, thus minimizing the trial-and-error tuning of the parameters and the related material and time waste.

In this context, building on a printability prediction tool that we recently published [12], here we propose a 'plug-in' cell damage model that can help optimize the printing parameters considering also shear stress-related cell damage during extrusion. The 'plug-in' model equations were integrated with the printability ones and implemented in a web-page application (accessible at https://www.prin-vision.it/resources/) that can be readily used by the bioprinting researchers to optimize the printing process.

II. Model Rationale

A. Overview of the model

The general pipeline of the model, consisting of the printability and cell damage models, is described in Fig. 1. As can be seen from the figure, the model requires as input information related to: i) cells' properties, including the cell type and related shear stress-exposure time data, from relevant literature or from experiments, ii) the EBB set-up, including for example the needle geometry (internal diameter and length), iii) the material to be used (including its rheological

and mechanical properties), and iv) the printing settings, which may include constraints on the printing parameters like printing speed, flowrate, and layer height, as well as the overall scaffold dimension. The main model output includes a list of optimized printing parameters based on both the cell viability and printability constraints.

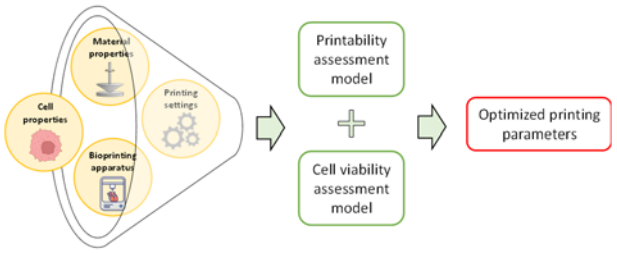

Fig. 1: Overview of the composite model to optimize the EBB process, considering constraints related to both the printability and cell viability.

B. *Printability assessment model*

The EBB printability assessment model for biomaterial inks has already been described elsewhere [12]. Briefly, the model can provide: i) the printability of a given biomaterial ink using a specific bioprinting apparatus, scaffold geometry, and printing parameters, and ii) if the biomaterial ink is found to be printable, provide a set of optimized printing parameters to maximize the shape fidelity. The model was developed by taking into consideration multiple aspects of EBB (referred to as 'stages' for brevity), as can be seen in Fig. 2: i) Stage 1, where the extrudability, *i.e.*, the easiness of extrusion of the given material from the syringe needle, is evaluated, ii) Stage 2, in which the line deposition process when printing the first layer is studied, and iii) Stage 3, where the wood-pile scaffold stabilization after printing is evaluated to assess the final shape fidelity.

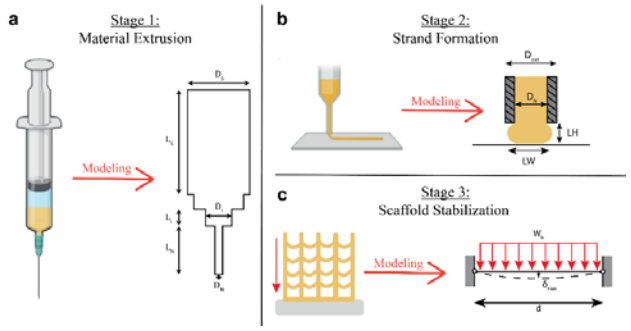

Fig. 2: Summary of the three stages of the printability assessment model. a) Stage 1 refers to the evaluation of the extrudability of the ink from the syringe; b) Stage 2 studies the line formation during extrusion of the first layer; c) Stage 3 evaluates the three-dimensional scaffold stabilization over time and its shape fidelity when compared to the digital design (image adapted with permission from [16]).

The analytical model was implemented in a web-based application (available at https://www.prin-vision.it/resources/) to help determine *a priori* the ink printability and optimize the printing parameters. Briefly, the web application is composed of two pages: a form page, in which the user can input the EBB set-up properties, scaffold overall size, and material properties. At the end of the form, the user can select different optimization constraints, including the layer height, printed line width dimensions, and flowrate to be used. After submitting the form, the results for each separate stage are presented in a new page alongside a brief description and possible ways to improve the printability.

C. *Cell damage assessment model*

A summary of the main symbols used in the cell damage assessment model is reported in Table I. The following paragraphs will detail the hypothesis underlying the model and its governing equations.

Table I: Summary of the parameters considered for the cell viability assessment model, alongside their unit of measure.

Group name	*Parameter*	*Description*	*Unit of measure*
EBB set-up	R	Needle internal radius	[m]
	L	Needle length	[m]
Material properties	K	Flow consistency index	[Pa*s^n]
	n	Flow behavior index	-
	τ_y	Critical yield stress	[Pa]

1) *Model hypothesis*

Fig. 3 shows the case of a bioink being extruded from a syringe needle. To simplify the problem, the bioink will be considered as an incompressible fluid (*i.e.*, with a constant density) under a steady, fully developed, and isothermal flow. Furthermore, we will suppose that cells are homogeneously distributed, and their presence does not alter the rheological properties when compared to an equivalent biomaterial ink, which is valid for cell densities lower than 100x10^6 cells/ml [13].

Regarding the constitutive equations, the bioink will be modelled as Herschel-Bulkley fluid, which is a common case for inks used in EBB [16] (Eq. 1):

$$\tau = \tau_y + K\dot{\gamma}^n \quad (1)$$

Here, K represents the consistency factor (in [Pa*s^n]) and n the consistency index (a-dimensional, and lower than 1 for shear-thinning materials). The Herschel-Bulkley model describes both shear-thinning (*i.e.*, apparent viscosity decreases with an increase of shear rate) and yield stress (*i.e.*, the stress at which the material starts to flow under an applied external force) behaviours, which determine the printability in EBB.

Finally, from a geometry point of view, the cell damage model will focus on the needle region (Stage 1 in the printability assessment model of Fig. 2) as it is the region where the cells are subjected to a high shear stress when compared to the syringe main body. The modelled needle geometry is a cylinder with a length L and an internal radius R, both measured in [m].

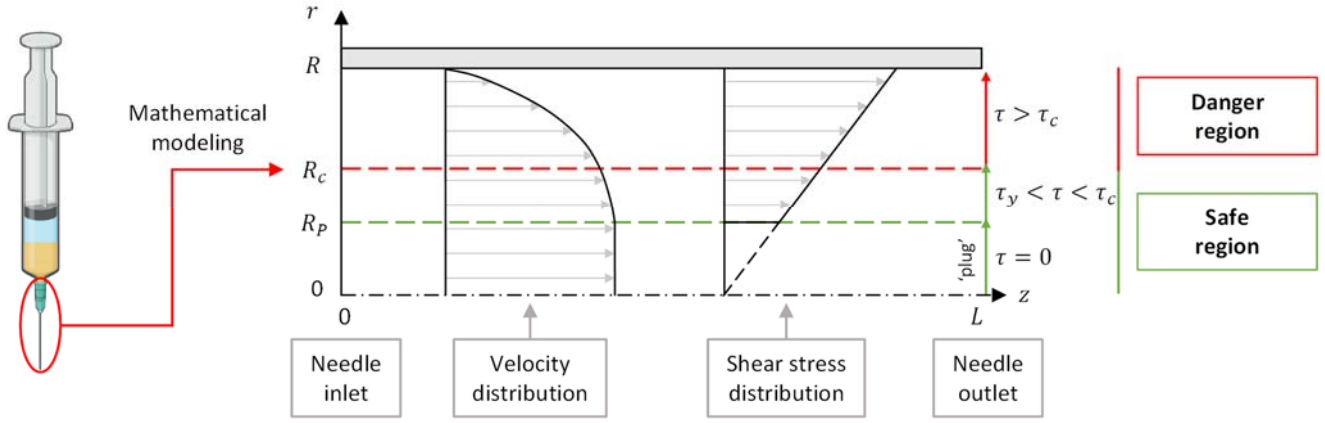

Fig. 3: Summary of the mathematical model set-up to evaluate the cell damage in a bioink during extrusion. The velocity (on the left) and shear stress distributions (on the right) inside the needle region for an Herschel-Bulkley bioink during flow are reported. In the figure, τ_y (in [Pa]) is the yield stress of the material, τ_c (in [Pa]) the stress above which cells embedded in the bioink may be damaged, R_P (in [m]) is the radius of the 'plug' region, R_C (in [m]) refers to the critical radius at which $\tau \geq \tau_C$.

1) Computing the percentage of damaged cells during EBB

The fluid velocity and shear stress distributions are reported in Fig. 3 [15]. As can be seen from the figure, we can divide the problem in two main regions: a 'danger' region, where cell damage may be present due to high shear stresses, and a 'safe' region, where the shear stress is lower and thus all the embedded cells may survive the extrusion process.

Due to the material showing a yield stress, the 'safe' region will include a central 'plug' area of radius R_P (in [m]). R_P represents the radial coordinate at which $\tau(r = R_P) = \tau_y$, while for $r < R_P$ the material behaviour will be solid-like. As a result, no shear stresses will be present inside this area and embedded cells will not be damaged.

Outside the 'plug' area, τ depends linearly on r as in Eq. 2:

$$\tau(r) = \frac{\tau_w}{R} \cdot r \tag{2}$$

where τ_w is the wall shear stress (in [Pa]). In this area, embedded cells may be damaged only if τ exceeds a critical value τ_c (which depend on the cell type). From Eq. 2, we can express the radial coordinate R_c at which $\tau > \tau_C$ as in Eq. 3:

$$R_c = \frac{\tau_w}{\tau_c} \cdot R \tag{3}$$

Thus, for $R_P < r < R_c$, cells will experience shear stresses which are not enough to permanently damage them. On the other hand, the radial coordinates $R_c < r < R$ identify the 'danger' region. Cells in this region will experience a mean shear stress $\bar{\tau}_{damaged}$ which can be found as the mean value between τ_w and τ_c (Eq. 4):

$$\bar{\tau}_{damaged} = \frac{\tau_w - \tau_c}{2} \tag{4}$$

Even though $\bar{\tau}_{damaged}$ may be high enough to damage cells, the mean exposure time $\bar{t}_{damaged}$ (*i.e.*, the time cells remain on average in this high-stress region during extrusion (in [s]) should also be computed. To do so, we consider that the velocity profile $v(r)$ (in [m/s]) outside the 'plug' area for a Herschel-Bulkley fluid is given by Eq. 5 [16]:

$$v(r) = \frac{n}{n+1} \cdot \left(\frac{R^n \tau_w}{K}\right)^{\frac{1}{n}} \cdot \left[\left(1 - \frac{Rp}{R}\right)^{\frac{n+1}{n}} - \left(\frac{r}{R} - \frac{Rp}{R}\right)^{\frac{n+1}{n}}\right] \tag{5}$$

where the 'plug' radius can be expressed from Eq. 2 knowing τ_w as $R_P = \frac{\tau_y}{\tau_w} \cdot R$. The mean speed $\bar{v}_{damaged}$ of the bioink contained inside the 'damaged' region can be found by integrating the velocity profile over r as follows (Eq. 6):

$$\bar{v}_{damaged} = \frac{1}{R - R_C} \int_{R_C}^{R} v(r)\, dr \tag{6}$$

By plugging Eq. 5 in Eq. 6 and solving the integral, we can finally compute $\bar{t}_{damaged}$ as in Eq. 7:

$$\bar{t}_{damaged} = \frac{L}{\bar{v}_{damaged}} \tag{7}$$

The combination of Eq. 4 and Eq. 7 can be used to measure the cell damage ϕ (*i.e.*, the percentage of cells that are not viable after applying a shear stress) by comparing the values with data for example found in literature for specific cell types, as reported in Table II.

Table II: Summary of data available in literature for shear stress-induced damage

Cell type	*Shear stress range [Pa]*	*Exposure time range [s]*	*ϕ range [%]*	*Ref*
Schwann cells	100-1000	10-120	2-31	[12]
Myoblasts	100-1000	10-120	2-26	[12]
Fibroblasts	100-1000	10-120	12-89	[8]

However, ϕ is usually computed by applying a prescribed shear stress using a rheometer and then measuring cell viability afterwards. In such a configuration, the whole bioink is sheared, and, as a result, to translate the ϕ values to the extrusion model, this percentage should be referred to only the 'damaged' region. We can thus find the overall percentage of damaged cells by first computing the volume ratio *VR* (expressed as a percentage) of the 'damaged' region compared to the overall needle as in Eq. 8:

$$VR = \frac{V_{damaged}}{V_{tot}} = \left(1 - \frac{R_c}{R}\right)^2 \tag{8}$$

and then multiplying by ϕ to find the overall cell damage *CD* (Eq. 9):

$$CD = \phi \cdot VR \tag{9}$$

D. 'Plug-in' integration with the printability model

The previously described cell damage assessment model was integrated with the Stage 1 of the printability assessment, described in Fig. 2. In particular, in Stage 1 the wall shear stress is computed for a given ink, syringe geometry, and

extrusion flowrate. For an Herschely-Bulkley fluid τ_w is found by inverting Eq. 5 and solving using iterative methods (bisection root finding method) knowing the flowrate during printing (input to the model) [13].

The computed value for τ_w can then be used to evaluate $\bar{\tau}_{damaged}$ in Eq. 4, as well as the integral $\bar{v}_{damaged}$ (Eq. 6). Finally, the mean cell residency time in the 'damaged' region $\bar{t}_{damaged}$ can be computed from Eq. 7 knowing the needle length (input to the model). The values found using Eq. 4 and Eq. 7 can be than compared to values found in literature (as reported in Table II) or through experimental data (*e.g.*, by measuring cell viability after a prescribed shear stress-exposure time combination at a rheometer) to find the estimated *CD* percent value (Eq. 9).

The two models, connected as above, were then integrated inside the already existing web application. In particular, after writing the required inputs in the form (including the cell type selection among the types listed in Table II), the user can check if they want the cell damage to be computed in the optimization section. If the checkbox is selected, in the Stage 1 results section the predicted cell damage will be computed using data for the cell type specified by the user. Besides the value, suggestions on how to reduce the damage will also be provided to the user, including increasing the needle diameter to decrease τ, or lowering the printing speed. In this way, the user can infer if the optimized set of printing parameters considering only the (bio-)ink printability is compatible with the cell viability requirement and, if not, modify the parameters accordingly.

III. Conclusion

In this work, we presented a novel analytical model to predict cell damage in extrusion bioprinting using a complex constitutive equation for the bioink (*i.e.*, Herschel-Bulkley model), which describes both shear-thinning and yielding behaviour commonly found in EBB inks. The cell damage model was integrated with an already developed printability assessment one, and the related equations were added to a web-page which is freely available at https://www.prin-vision.it/resources/. The improved application will represent a valid tool for the bioprinting researcher to predict *a priori* the printability and cell viability when printing a bioink, but also optimize the printing parameters considering both the shape fidelity of the final construct and the post-extrusion viability of the embedded cells.

Future works will be carried out to experimentally validate the cell damage model by assessing the cell viability post-extrusion using a combination of different printing parameters (including needle geometry and internal diameter, flowrate). Furthermore, at its current stage the model uses shear stress/exposure time data coming directly from the literature. These data are available only for a few selected cell types, so in the future experiments will be carried out to expand this library. Finally, as pointed out in relevant literature, extensional stresses play an important role in determining cell viability during extrusion. Taking into consideration results from the experimental validation, the model will be modified to include cell damage related to these stress components, but also damage in other steps of the printing process (*e.g.*, when depositing lines on the printing bed for the first layer), to obtain a more comprehensive and realistic damage evaluation.

***Abstract*— 3D bioprinting not only has paved the way for advances in life sciences and healthcare but it is also emerging as a key driver behind an ongoing paradigm shift in the production process of various industrial domains, ranging from food to fashion. The potential of such technology is underexplored and this work assesses 3D bioprinting as a valuable approach for developing novel and more effective solutions for leather defect correction during the animal-leather tanning process, with the aim at increasing the outlet market for tanneries.**

***Keywords*—bioprinting, leather defect correction, bioink, robotic biofabrication platform.**

I. Introduction

OVER the past decades, 3D bioprinting has gained a foothold as a high-impact technology in various fields, with major applications in life sciences, healthcare, food technology and cruelty-free fashion, and has led to huge advances in tissue engineering, regenerative medicine, organ printing, high-throughput screening, and drug printing [1], [2]. The potential of 3D bioprinting is enormous; therefore, evaluating and researching potential applications in other fields is essential. The tanning process transforms raw or semi-finished skins and hides, a by-product of the food industry, into a valuable product suitable for various market sectors, from fashion to furniture and automotive [3]. The presence of defects on the grain side deeply affects the product's quality and, thus, its market price. Currently, available defect correction methods are applied in the final stages of the tanning process, when the destination of the leather has already been established [3], which reduces the outlet market for tanneries. Therefore, the possibility to correct defects before the tanning and/or retanning processes would allow tanneries to place themselves in the raw or semi-processed leather segment, a much larger market segment. In this context, 3D bioprinting could be a valuable enabling technology. Gelatin methacryloyl (GelMA) is a widely-used, versatile photo-crosslinkable polymer with tunable properties [4] that has already proven to be an effective solution for a broad range of applications, including wound healing and skin regeneration [5]. This work describes the development of a novel approach for the early correction of leather defects by exploiting the 3D bioprinting technology and GelMA-based bioinks.

II. Materials and Methods

A. Materials

The bioink used in this study was composed of GelMA, as the photo-crosslinkable polymer, and lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) (Sigma-Aldrich, USA), as photoinitiator, embedding bovine fibroblasts, as living component. LAP was chosen over other commonly used photoinitiators (*e.g.*, Irgacure 2959) as it guarantees improved cell viability [6]. GelMA was synthesized according to the procedure described in [7]. Bovine fibroblasts were provided by the Department of Biology of the University of Pisa.

B. Photopolymerisation tests

Photopolymerisation tests were carried out to optimise the light-curing time of the GelMA/LAP solution. Literature evidence assessed the ability of solutions with 5% w/v GelMA concentration and 0.25% w/v LAP concentration to promote cell viability [8]; therefore, such solutions were initially used for this study. After the preparation of a GelMA (5% w/v) and LAP (0.25% w/v) solution, 300 µl aliquots were manually extruded into a 24-well plate and then exposed to 405 nm light using a 3W torch. Such volume (300 µl) ensures complete coverage of the well's bottom. The number and positioning of the filled wells were planned to minimise the amount of energy striking neighbour-filled wells during exposure. The torch was placed at a fixed distance of 17 mm, corresponding to the depth of a standard 24-well plate, since the torch's diameter is larger than the well's diameter. 5, 10, 15, 20, 25 and 30 s exposure times were evaluated.

C. Biological tests on manually extruded bioink

Following the optimisation of the photopolymerisation parameters, biological tests were carried out on the bioink after its manual extrusion into the wells of a 24-well plate and exposure to the 405 nm light. These tests aimed at assessing the viability and metabolic activity of bovine fibroblasts when embedded in 5% w/v GelMA and 0.25% w/v LAP hydrogels. Specifically, after dissociation with Trypsin/EDTA 0.25% (Thermo Fisher Scientific, USA) and cell count, a bovine fibroblasts suspension ($1.25 \cdot 10^6$ cells/ml) was combined in a 1:1 ratio with the GelMA/LAP solution, previously warmed to 37°C and sterilised through a 0.2 µm filter. 300 µl aliquots of the bioink were pipetted into the wells of a 24-well plate and light-cured through exposure to 405 nm light for 10 and 25 s. The plated wells were then filled with culture medium and left in the cell incubator for 24 h. After incubation, the cells were fixed with 4% formaldehyde for 12 min at room temperature. Immunofluorescence analysis was then performed to assess cell presence (DAPI dye), cytoskeletal morphology (alpha-tubulin, TUBA), and the potential presence of apoptotic dead cells (activated caspase 3, cCASP3).

D. *Surface activation of skin samples*

The treatment of the leather's surface with an activating solution was evaluated as a potential approach to increase the bioink's adhesion to the defect's surface on different leather samples. Particularly, one possible strategy involves N-ethyl-N'-(3-dimethylaminopropyl)carbodiimide (EDC) (Sigma-Aldrich, USA) and N-hydroxysuccinimide (NHS) (Sigma-Aldrich, USA) solution, commonly used to promote cell adhesion on glass surfaces. The activation procedure was applied to four 50 x 50 mm specimens of bovine leather samples from different tanning phases (Table I). Pickled and wet-blue-tanned leather samples were chosen since the collection of leather samples following the pickel and wet blue tanning steps is much easier compared to other phases in the tanning process, and this will facilitate the industrial translation of the optimized bioprinting protocol.

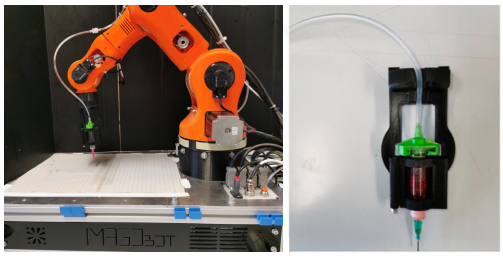

TABLE I: LEATHER SAMPLES USED IN SURFACE ACTIVATION TESTS

Specimen Name	*Description*
NT_pickled	Specimen of pickled leather not to be treated with the activating solution
T_pickled	Specimen of pickled leather to be treated with the activating solution
NT_wetblue	Specimen of wet-blue-tanned leather not to be treated with the activating solution
T_wetblue	Specimen of wet-blue-tanned leather to be treated with the activating solution

Some defects were carved on the specimens using a scalpel. A pH 6.4 buffered aqueous solution of NHS 0.002 M and EDC 0.005 M was then prepared. A quantity of EDC/NHS with the same weight as the T_pickled specimen was mixed with sodium chloride (NaCl) to obtain a final solution with 10% w/v NaCl concentration (quantities and concentrations were established in previous tests); the T_pickled specimen was then immersed in this solution for at least 60 min (NaCl prevents the acid swelling typical of pickled leather when in contact with aqueous solutions). The T_wetblue specimen was immersed in EDC/NHS solution for at least 60 min (NaCl is not necessary as wet-blue-tanned leather does not undergo acid swelling in aqueous solutions). After the 60 min immersion, which is essential for the activation of the leather and defects' surfaces, a 5% w/v GelMA and 0.25% w/v LAP solution preheated to 37°C was manually extruded on the defects of the specimens (NT_pickled, T_pickled, NT_wetblue, T_wetblue) and exposed to 405 nm light for 25 s. The T_wetblue and T_pickled specimens were then left for 60 min under ambient conditions to allow bond formation between the extruded material and the activated surface. The T_wetblue and NT_wetblue specimens were immersed in deionised water (dH_2O) and incubated in an oven at 37°C overnight, while T_pickled and NT_pickled specimens were immersed in dH_2O and NaCl solutions (an amount of dH_2O equal to the weight of the T_pickled and NT_pickled specimens was mixed with NaCl to obtain a 10% w/v NaCl concentration) and were incubated in an oven at 37°C overnight.

E. *Bioprinting tests*

The bioink was printed on 330 x 330 mm samples of pickled and wet-blue-tanned bovine leather. Leather samples of such dimensions are essential to allow the completion of the tanning process in a laboratory test drum after the defect correction phase. Therefore, a 5-axes robotic arm [9] (Figure 1A) equipped with a pneumatic syringe-pump extruder (controlled by the SMC ITV001 2BLQ pressure regulator) as an end-effector (Figure 1B) was used. Indeed, this bioprinting system ensured an adequate workspace (350 x 350 x 350 mm) to print on such wide leather samples.

A B

Fig. 1: 3D bioprinting system set-up. A) Robotic arm. B) Pneumatic extruder.

Optimisation experiments were carried out to define the optimal combination of printing parameters to allow smooth printing of the bioink and adequate defect correction on the leather samples. Specifically, a scalpel was used to obtain three 50 x 50 mm pickled leather specimens and three 50 x 50 mm wet-blue-tanned leather specimens and to manually create defects on their surface (Figure 2). Different GelMA/LAP solutions (Table II, III) were prepared and kept liquid at 37°C. The 5 ml pneumatic extruder's syringe was loaded with the evaluated GelMA/LAP solution and then mounted on the robotic arm's end effector. Finally, the ink was printed on the specimens' defects and then exposed to the 405 nm light for 25 s. LAP concentration was always equal to 0.25% w/v and conic nozzles were used to reduce the shear stress that would be exerted on the cells. In the experiments, different printing parameters were evaluated, such as GelMA concentration values within the ink, extrusion pressure, the time between the loading of the material into the syringe and printing, nozzle gauge values, and printhead's speed values in the XY plane.

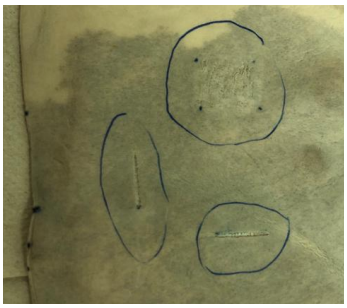

Fig. 2: Image of manually created defects on the pickled leather's surface.

III. RESULTS

A. *Photopolymerisation tests*

The photopolymerisation of the solution occurred for each of the evaluated exposure times. To validate this result, wells containing light-cured GelMA/LAP hydrogels were filled with dH_2O and the plate was subsequently incubated in an oven at

37°C overnight. The following day, the presence of the solidified material in all wells used for the test confirmed the success of the photopolymerisation process.

B. Biological tests on manually extruded bioink

Since the stiffness of the light-cured ink increases with exposure time [10], biological tests were carried out on hydrogels obtained with 10 s and 25 s exposure times, which represent the central values of the [5;15] s and [20;30] s exposure ranges. The results of the immunofluorescence analysis (Figure 3) show that the cells maintained physiological viability with no apoptosis following treatment and started gaining a rather elongated shape, similar to the typical fibroblasts' morphology, after a 24 h incubation. Therefore, the biological tests proved that the GelMA/LAP ink does not affect the viability of bovine fibroblasts. Given the positive outcomes, an exposure time of 25 s was chosen and used as a reference for any subsequent experiment.

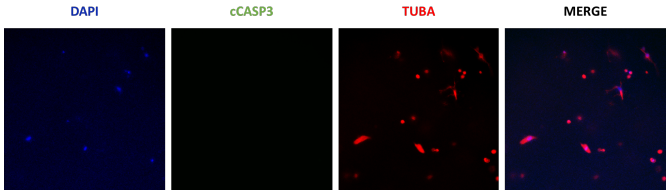

Fig. 3: Immunofluorescence on bovine fibroblasts after 24 h incubation of the GelMA/LAP/bovine fibroblasts hydrogels (25 s exposure to 405 nm light).

C. Surface activation tests of skin samples

The hydrogel on the NT_wetblue sample's defects underwent partial detachment and melting during the 37°C overnight incubation (Figure 4B), while the hydrogel on the NT_pickled sample's defects gained a silver colour (Figure 4A). This didn't happen to the T_pickled and T_wetblue specimens (Figures 4C and 4D). Consequently, the activation tests confirmed the adhesion of the GelMA/LAP hydrogel on leather surfaces previously treated with EDC/NHS solution.

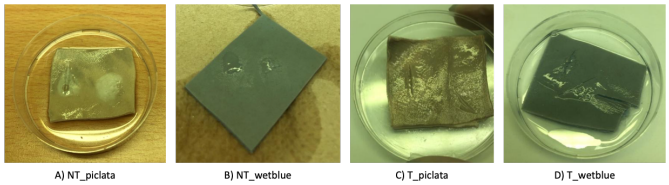

Fig. 4: Light-cured biomaterial ink conditions on the four different specimens after overnight incubation at 37°C.

D. Optimisation tests of the ink's 3D printing parameters

The optimisation experiments were performed over several days and at different times of the day. Since the bioink's rheology doesn't significantly differ from the ink's rheology for cell densities usually used for bioprinting [11], each optimisation experiment involved the loading of the pneumatic extruder's syringe with a cell-free GelMA/LAP solution, previously kept at 37°C. The principal combinations of the different parameters evaluated in this set of optimisation experiments are highlighted in Table II. Since no temperature control of the ink in the pneumatic extruder on the robotic arm was possible, the strong influence of the room temperature on the GelMA/LAP solution's viscosity emerged. Solutions with 5% w/v GelMA required too much time to reach sufficient viscosity levels to allow the printing of the material, whereas solutions with 10% w/v GelMA quickly reached excessive viscosity levels [12] (Table II).

TABLE II: FIRST SET OF OPTIMIZATION EXPERIMENTS

% [a] w/v	*T [b] [min]*	*v [c] [mm/min]*	*P [d] [bar]*	*Nozzle*	*Outcome*
10	4	180	0.7	Conic white 27 G	Failed: ink leakage with no pressure.
	9	60	0.6	Conic white 27 G	Failed: too viscous ink. Ink leakage with no pressure.
	15	180	1	Conic white 27 G	Failed: too liquid ink coming out in drops.
	26	60	1	Conic white 27 G	Failed: too viscous ink. Extrusion is not possible. Nozzle occlusion.
	40	60	1	Conic red 25 G	Failed: too viscous ink. Extrusion is not possible.
5	12	60	0.7	Conic white 27 G	Failed: too liquid ink coming out in drops.
	42	100	0.76	Conic white 27 G	Failed: too liquid ink coming out in drops.

[a] GelMA concentration. [b] Time between syringe loading and printing. [c] Printhead's speed. [d] Pressure regulator's outlet pressure.

Consequently, in a second set of optimization experiments (Table III), the ink-loaded syringe was kept at 4°C before printing in order to reduce the ink's temperature. This allowed to more accurately tune the ink's viscosity and to enable its pneumatic printing.

TABLE III: SECOND SET OF OPTIMIZATION EXPERIMENTS

% [a] w/v	*T_1 [b] [min]*	*v [c] [mm/min]*	*P [d] [bar]*	*Nozzle*	*Result*
7.5	4	180	0.4	Conic white 27 G	Failed: too liquid ink
	2	180	0.4	Conic blue 22 G	Failed: too viscous ink
5	4.5	180	0.4	Conic blue 22 G	Non optimal
	4.5	240	0.36	Conic blue 22 G	Non optimal
	4.5	180	0.4	Conic red 25 G	Good but non reproducible
	6	180	0.4	Conic white 27 G	Good and reproducible

[a] GelMA concentration. [b] Period of time during which the loaded syringe is kept at 4°C. [c] Printhead's speed. [d] Pressure regulator's outlet pressure.

Therefore, the printing parameters that were identified as optimal for this application are the following: a 5% w/v GelMA concentration, loaded syringe kept 6 min at 4°C, a

conic white 27 G nozzle, a 180 mm/min printhead's speed, and a 0.4 bar pressure regulator's outlet pressure.

E. Bioink 3D printing experiments with optimised parameters

Following the leather surface activation and bioink preparation protocols described in sections II C and II D, respectively, and using the experimental setup described in section II E and the optimised printing parameters defined in section III D, GelMA(5% w/v)/LAP(0.25% w/v)/bovine fibroblast bioink printing experiments were performed on 330 x 330 mm samples of pickled and wet-blue-tanned bovine leather. As described before, in order to facilitate the shape retention of the printed pattern, the bioink was pre-cooled at 4°C; moreover, the syringe loaded with the bioink and the nozzle were transferred to the robotic platform within ice, to facilitate the material's subsequent extrusion.

The optimised printing parameters outlined in section III D allowed a successful bioprinting of the bioink on leather defects, and the results of the printing process are shown in Figure 5.

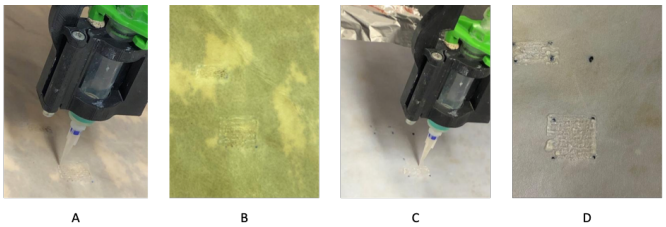

Fig. 5: Bioink printing on leather defects. A) Printing on pickled leather. B) Result of printing on pickled leather. C) Printing on wet-blue-tanned leather. D) Result of printing on wet-blue-tanned leather.

The bioprinted bioink was light-cured with a 25 s exposure to 405 nm light and the samples were then left for 60 min under ambient conditions to allow bond formation between the extruded material and the activated surface. The samples were stored at 4°C.

Five days after printing, dH_2O was poured over the corrected defects on the wet-blue-tanned leather sample. This rehydration procedure confirmed the presence of the hydrogel on the leather sample even five days after the experiment (Figure 6).

Fig. 6: Printed material's condition after rehydration.

IV. Conclusion

The experimental tests demonstrated the effectiveness of the proposed bioprinting approach outlined in section III D for the bioprinting of the GelMA(5% w/v)/LAP(0.25% w/v)/bovine fibroblast bioink on leather defects. Furthermore, the know-how acquired during the optimisation experiments guided the appropriate tuning of the printing parameters during the bioprinting process itself in order to achieve the desired result. Future experiments will investigate the collagen-producing ability of bovine fibroblasts inside the bioink, as it could be essential in the defect-repairing process.

These promising results open up numerous future perspectives, among which the development of a temperature-controlled bioprinting environment (*i.e.*, a heated printhead or a temperature-controlled printing chamber) and the integration of a defect-detection tool (*i.e.*, a vision system) compatible with the robotic arm are of utmost priority for the permanent integration of the technology into the industrial tanning process. Globally, this work sets the foundations for a significant and stable employment of this 3D bioprinting technology in the tanning industry, highlighting the potentialities of evaluating alternative applications and application fields for 3D bioprinting.

Abstract

Breast cancer is one of the most common tumors worldwide featured by heterogeneity. The expression of hormone receptors marks different breast cancer subtypes. Each type is pharmacologically treated by using molecules targeting hormone receptors, but this frequently drives chemoresistance. For this reason, the possibility to replicate this hostile human pathology *in vitro* represents an urgent need to understand the biological basis behind heterogeneity and chemoresistance and explore the efficiency of pharmacological treatments.

***Keywords*: engineered tumor, tumor microenvironment; tumoral micro-tissues.**

A. INTRODUCTION

Cancer development is a complex and dynamic process regulated by interactions between cancer cells and their microenvironment composed of activated stromal cells and soluble and insoluble components of the extracellular matrix (ECM). The dynamic reciprocity existing between cancer cells and their microenvironment is involved in cancer differentiation, proliferation, invasion, metastasis, and drug response. Understanding the molecular mechanisms underlying the cross-talking between cancer cells and their surrounding tissue (*i.e.,* tumor stroma) and how this interplay affects the disease progression, is fundamental to designing and validating a novel, more robust, and reliable therapeutic approaches. As an important regulator of tumor progression, tumoral ECM has been identified as a very promising target of anticancer treatment, revolutionizing the traditional therapeutic paradigm that sees neoplastic cells as the preferential objective to fight cancer[1]. To design and validate such target therapy, advanced 3D preclinical models are necessary to correctly mimic the complex, dynamic, and heterogenous tumor stroma. The possibility to couple 3D bioengineered tumor models with a microfluidic device, open the way to a new class of tumor-on-chip model able to replicate the pathological microenvironment, offering a reliable platform for developing novel anti-cancer approaches[2]. Here we showed the development of a breast cancer micro-tissue model able to present intra- and extra-tumor morphological heterogeneity in a dynamic and responsive endogenous ECM. The 3D tissue consists of MCF7(Adenocarcinoma cells), endothelial cells, and stromal fibroblasts. In this highly physiologically relevant environment, tumor cells show different cluster morphologies in the stroma recapitulating tumor spatiotemporal heterogeneity. We cultured the breast cancer micro-tissue on a customized microfluidic device, to replicate a physiological fluid dynamic environment and to online collect high-throughput data of live cell and ECM dynamics upon time-varying microenvironmental conditions.

B. MATERIAL AD METHODS

Cell Culture

Human mammary fibroblasts (HMFs) were extracted from healthy breast biopsies and cultured in enriched MEM: MEM with 20% of FBS, 2% of Non-Essential Aminoacids, 1% of L-Glutamine and 1% of penicillin/streptomycin, until passage 4/7. HUVECs (GIBCO C0035C) were cultured in enriched M200: M200 (GIBCO Invitrogen) supplemented with LSGS Kit until passage 3. Human breast adenocarcinoma cells (MCF7) were kindly donated by Daidone's group (IRCCS, Istituto Nazionale dei Tumori, Milano, Italy) and cultured in enriched RPMI: RPMI-1640 medium supplemented with 10% FBS, 1% L-glutamine, 1% penicillin/streptomycin. MCF7 cells weretransfected with pLVX-ZsGreen1-N1 (λex 493nm, λem 505 nm) viral vector purchased from Clontech, USA

MicroTissue Fabrication

As described in the reference[3], 3,5 10^6 P5/8 HMF were seeded on 64mg of engineered porous gelatin microspheres in spinner flask bioreactors After 7-9 days of suspension culture, de-novo synthesized ECM occupied inner porosity and covered

microbeads surface. At this time, 10^6 HUVECs were seeded on the HMF-ECM-microsphere system. After other 9 days of culture, 7 10^6 MCF7 were added to obtain the final Tumor micro-tissues (T-μT). By following the same approach we fabricated:

- MCF10-μT (by adding nonmalignant epithelial cells);
- Control-μT (tissue without endothelial and composed of fibroblasts and HUVECs).

Immunofluorescence on tissue samples

Sample were fixed in 4% Paraformaldehyde for 30 minutes at Room Temperature (RT) and washed in PBS1X. They were permeabilized using 0,1% Triton in PBS1X for 5 min at RT, washed in PBS1X and blocked in 3%BSA, 3%FBS, 0,01%Triton in PBS1X for 1 hour at RT. The tissues were stained with Rhodamine Ulex Europaeus Agglutinin I at a final concentration of 20 μg/ml in blocking solution to mark the endothelium. The nuclei were stained with 40,6-diamidino-2-phenylindole (DAPI) diluted 1:10.000 in PBS1X for 20 min at RT. Samples were investigated by Confocal Leica TCS SP5 II. Images were analyzed using Image J.

Quantitative Capillary-like structures (CLS) analysis

Whole samples were investigated by Confocal Leica TCS SP5 II performing z-stacks in different random points of different μTPs. Each stack was composed of 16 sequential images with a z-slice-space of 1,98 μm. Samples were observed using λex = 543 nm/ λem=550/560 nm to detect Rhodamine (UEA 1) and λex=700 nm (two photons)/ λem = 400/450 nm to detect DAPI. The stacks were acquired with a resolution of 12 bit, 512x512 pixels, by using a 25X water immersion objective (HCX IRAPO L 25.0X0.95 Water, n.a. 0.95). Image analysis was performed by Image J.

Imaging of newly formed collagen

Cell-assembled collagen was detected by Second Harmonic Generation (SHG). SHG is generated by collagen type I, without staining, when the sample is exited under two-photon light at λex = 820 nm and acquiring the signal at λem = 420 nm. Image analysis was performed by Image J.

Image analysis of hyaluronic acid quantity

Hyaluronic acid was detected by immunofluorescence on tissue sections after enzymatic with CaCl2 and Trypsin. Image analysis was performed by Image J.

Device fabrication and tissue dynamic culture

The microfluidic device was designed using computer-aided design software. The CAD file was converted into a computer-aided machine (CAM) file using DESKAM software and used to obtain a poly(methylmethacrylate) (PMMA) stamp by a micro milling machine. The microfluidic device was fabricated by replica molding technique by curing Polydimethylsiloxane (PDMS) on the PMMA master. The chip was composed of two chambers in series for microtissues and two channels, adjacent to the chambers and separated by pillars. The chip was connected to a syringe pump by tubes and connectors and operated at Q=1μl/min.

C. Results And Discussion

The T-μTs are composed of tumor epithelial cells, stromal cells, and endothelial cells embedded in their native environment. T-μTs present intra- and extra-tumor morphological heterogeneity in a dynamic and responsive endogenous ECM. In this highly physiologically relevant environment, tumor cells showed different cluster morphologies in the stroma recapitulating tumor spatiotemporal heterogeneity. In Fig. 1A and 1B, TME of the breast cancer micro-tissue is shown: cell-synthesized collagen network in grey, malignant cells clusters in green, and the vascular network in red. The initial porous gelatin microsphere had the unique role to induce fibroblasts in synthesizing new ECM components, as described in our previous works[4–7]. Graphics in Fig.1C, D, and E show the extension of capillary-like structure (CLS in Fig. 1C) as well as the amount of neo-formed collagen (Fig. 1D) and neo-formed hyaluronic acid (Fig. 1E) after 10 days of heterotypic culture. Figure 1 demonstrates that our model replicates some important features found in human TME. The presence of MCF7 induces an increase in CLS fraction according to the abnormal vascularization of tumoral tissues and also induces hyperproduction of collagen and hyaluronic acid. When cultured in a microfluidic device (Figure 2) the dynamic flow promotes the synthesis and assembly of endogenous ECM among multiple T-μTs as detected using Second harmonic generation imaging at multiphoton microscopy. In this condition, the T-μTs were able to sustain long-lasting culture (up to 27 days), maintaining high viability and a well-structured collagen network (Figure 3). The effect of specific drugs and their combination on collagen architecture, and cell

viability, will be assessed to establish the best therapy on the chip.

D. Conclusion

Here we have presented a tumor-on-chip model to replicate a functional tumor microenvironment. We were able to detect the variation of the collagen network, vascular network organization, and cell invasion mechanisms over tumor progression. The possibility to culture the 3D bioengineered tumor models in a microfluidic device, open the way a new class of tumor-on-chip model able to replicate the pathological microenvironment, offering a reliable platform for developing novel anti-cancer approaches.

***Abstract*— Duchenne Muscular Dystrophy (DMD) is an X-linked neuromuscular disease which is, to date, incurable. The main cause of death, in the advanced stages of the disease, is due to the manifestation of dilated cardiomyopathy. However, the pathogenesis is still unclear since the existing cellular and animal models are not able to fully reproduce the human disease phenotype. In this study, cardiac organoids from patient-derived pluripotent stem cells (DMD-CO) and isogenic-corrected controls (DMD-Iso-CO) were generated to investigate if DMD-related cardiomyopathy and disease progression occur in the organoids upon long-term culture. RNA sequencing analysis were carried out supporting a distinct transcriptomic profile in DMD-CO. These were associated with functional enrichment in hypertrophy/dilated cardiomyopathy, adipogenesis and fibrosis pathways. Moreover, five miRNAs were identified to be crucial in this dysregulated gene network. In conclusion, a patient-derived cardiac organoid model was obtained. Specifically, it displayed DMD-related cardiomyopathy and disease progression phenotypes in long-term culture. Currently, we are focusing on developing a more complex, realistic, and reliable *in vitro* 3D human cardiac-model to study DMD-related cardiomyopathies, exploiting 3D bioprinting technology.**

***Keywords*—Duchenne Muscular Dystrophy, Cardiac Organoids, RNA sequencing, 3D models.**

I. Introduction

Muscular dystrophies (DM) are an heterogeneous complex of genetically determined diseases characterized by a chronic and progressive degeneration of skeletal and cardiac muscles. [1], [2]. One of the most widespread and common forms of the aforementioned group of pathologies is Duchenne Muscular Dystrophy (DMD), a neuromuscular disorder caused by mutations affecting the dystrophin gene (DYS), located on the short arm of the X chromosome, which results in the total expression absence of the homonymous protein (DYS) [3], [4]. The lack of the dystrophin protein expression, which essential function is to stabilize the fibers during contractions, results in symptoms manifestation including muscle weakness and atrophy, respiratory and cardiac insufficiency significantly aiding the probability of death before the age of 30 [5], [6].

The main cause of death, in the advanced stages of the dystrophic cardiac pathology, is to be attributed to the manifestation of Duchenne dilated cardiomyopathy (DDC); DDC can occur as a result of an initial cardiomyocyte degeneration – due to the activation of an inflammatory response - resulting in replacement of heart muscle with adipose and connective tissue, thus causing reduction in heart wall thickness [7], [8]. To date, no great research attention has been directed to DDC despite is being the main cause of death in patients with DMD. Indeed, the main reason is partly due to limited accessibility to human cardiac tissues, and the intrinsic limitation of two-dimensional (2D) cardiomyocyte cultures since it is not yet able to reproduce, *in vitro*, a biological model as similar as possible to the pathophysiological one *in vivo* [9].Thus, this project aimed to develop a three-dimensional (3D) in *vitro* model that allowed to reproduce, and therefore to study, the progression of DDC. The creation of 3D patient-derived cardiac organoids (COs) from induced pluripotent stem cells (hiPSCs), – generated by Sendai virus technology - enabled to fill this scientific gap. All experiments were carried out using in parallel isogenic control iPSCs, generated by CRISPR/Cas genomic modification system, originally discovered from the microorganism *Streptococcus pyogenes* [10], [11].

II. Material and Methods

Induce Pluripotent Stem Cell Culture

Experiment were performed using Duchenne Muscular Dystrophy iPSC (DMD-hiPSC) obtained from DMD fibroblast patients carrying a point mutation in exon 35 (c.4 996C>T; p.Arg1,666X) of the Dystrophin gene that leads to a premature stop codon [10]. Human DMD isogenic control (DMD-Iso iPSC) was obtained using CRISPR/Cas9 gene editing from the *S. pyogenes* system (5'-NGG PAM) as previously described [10], [12]. Both human iPSC lines were cultured feeder-free on Geltrex LDEV-Free hESC- and maintained in Essential 8 Flex Basal Medium supplemented with Essential 8 Flex Supplement and 0.1% penicillin–streptomycin, at 37 °C under normoxic conditions (21% O2 and 5% CO2). HiPSC colonies were routinely passaged non-enzymatically with 0.5 mM EDTA in Phosphate-Buffered Saline (PBS).

Human iPSC cardiac differentiation in monolayer culture

DMD-hiPSC and isogenic-corrected control were differentiated into functional cardiomyocytes (CMs) according to a monolayer-based cardiac differentiation protocol, as previously described by Burridge et al.,[13].

Cardiac organoids generation

DMD-hiPSC and isogenic-corrected control were detached as mentioned above and re-suspended in specific hiPSC medium,

were plated in agarose inserts and incubated at 37 °C under hypoxic conditions (5% O2 and 5% CO2) to promote embryoid bodies (EBs) formation. Cardiac differentiation of the EBs into cardiac organoids (COs) was initiated as previously described by Burridge et al.,[13]. Afterwards, the COs were transferred from the agarose moulds to an ultra-low attachment 6-well plate and dynamic culture was carried out using an orbital shaker. Contracting COs start to appear from day 8 of the differentiation protocol. The samples were collected at different time points for further analysis.

RNA isolation, RNA sequencing and bioinformatic analysis

For RNA sequencing assays, total RNA was isolated and treated according to manufacturer protocol (Purelink® RNA mini kit and Turbo DNA free kit). As quality control, the concentration of extracted RNA (>10 µg) was measured with Nanodrop and quality was checked with Bioanalyzer.

The Lexogen QuantSeq 3' mRNA-Seq library prep kit was used according to the manufacturer protocol, then the libraries were measured with Qubit and put on the Fragment analyser, hence the libraries were pooled equimolar. Thereafter, final pool (2 nM) was made for single-read sequencing on the HiSeq4000. Splice aware alignment was performed running HiSat2 against the human reference genome hg38 using the default parameters. Reads mapping to multiple loci in the reference genome were discarded. Resulting BAM alignment files were handled with Samtools v1.5 [14]. Reads quantification per gene was performed using HT-seq Count v2.7.14. Count-based differential expression analysis was carried out with R-based Bioconductor package DESeq2 (Love et al., 2014). Reported p-values were adjusted for multiple testing with the Benjamini-Hochberg procedure. Gene Ontology (GO) and Biological Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analyses were identified using g:Profiler [15]. The significant terms and pathways were selected with the threshold of adjusted p-value < 0.05.

Protein-protein interaction (PPI) network generation

The PPI network of differentially upregulated genes in DMD-CO was generated by using a list of gene symbols and their log2fold changes into the NetworkAnalyst platform (http://www.networkanalyst.ca/) using the IMEx interactome database. Afterwards, the gene-miRNA interactions for the selected KEGG pathways were made based on the miRTarBase (v8.0) database, and the network was reduced using the Steiner Forest Network (SFN) algorithm. The degree of each node was calculated based on its number of connections to other nodes. In the network, the colour represents the expression and the area of an individual node specify the degree. The identified top five miRNAs were mapped out in the KEGG pathways for showing their interactions with the genes of a specific pathway.

Statistical analysis

All data were statistically analysed using GraphPad Prism. Differences between groups were analysed for statistical significance using ANOVA test. Significance of the differences was shown as follows: *p <0.05, **p < 0.01, ***p < 0.001, and ****p<0.0001.

III. Results

Cardiomyocyte monolayer differentiation protocol was adapted to generate cardiac organoids (COs) by direct differentiation of embryoid bodies (EB). Self-aggregation of the DMD-hiPSCs and DMD-Iso-hiPSCs into EBs was stimulated by using the agarose microwell culture insert. The resulting DMD-CO and DMD-Iso-CO, after 5 days of differentiation protocol, were transferred to plates on orbital shaker for dynamic culture thus promoting self-organized cellular structures and contractile cardiomyocyte clusters. Immunofluorescence assays for studying Sarcomeric Actin proteins α(αACTN) and NKX2.5 expression were performed to evaluate the expression of the key genes of cardiac differentiation and the contractile proteins activation. Indeed, a transient expression of the gene marker NKX2.5 in both *DMD-CO and DMD-Iso-CO* and a progressive decrease of α-sarcoglycan (SCGA) protein expression in CO-DMDs, compared to isogenic controls was observed. Subsequently, the progressive worsening of the DMD-CO phenotype was demonstrated by carrying out histological analyses: indeed, fibrotic and adipocytic areas - pathological manifestations like those associated with cardiomyopathies - were observed. To confirm what previously observed, RNA sequencing analyses were performed. RNA transcriptomic data were displayed in Figure 1. Based on the enhanced volcano plot, out of 22371 gene variables, 1518 and 554 genes were differentially upregulated in DMD-CO and DMD-Iso-CO, respectively (Cut-off: $\log_2$ fold change = 1.5; $-\text{Log}_{10}$ p = 10^{-14}). Among the most differentially upregulated genes in DMD-CO, the expression of MGP, MYL1, COL1A2, HAPLN1 and OGN were the five most significant upregulated genes in DMD-CO (Fig.1). Hence, in order to identify the molecular pathways and biological information related to the aforementioned genes, a Gene Ontology analysis was performed on the set of isolated genes based on gProfiler analysis.

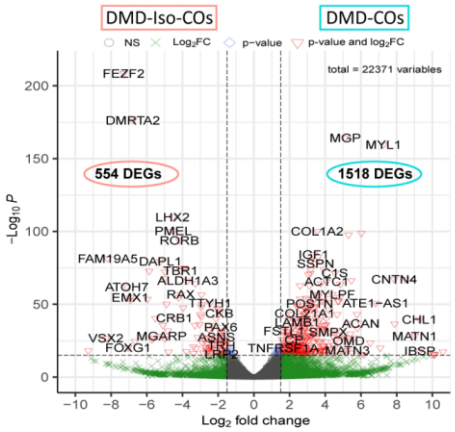

Fig. 1, *adapted from Fig.6B in* [8]: Enhanced volcano plot showing the differentially expressed genes (DEGs) in DMD-COs versus DMD-Iso-COs. Cut-off $\log_2$ fold change = 1.5; Cut-off $-\text{Log}_{10}$ p = 10^{16}.

Gene ontologies which were significantly enriched for molecular function in extracellular matrix regulation (*i.e.*, collagen and glycosaminoglycan; GO:MF), cardiac tissue structure formation (*i.e.*, external encapsulating structure such as sarcolemma; GO:CC), and cardiovascular development (GO: BP) were identified in DMD-CO (Fig. 2).

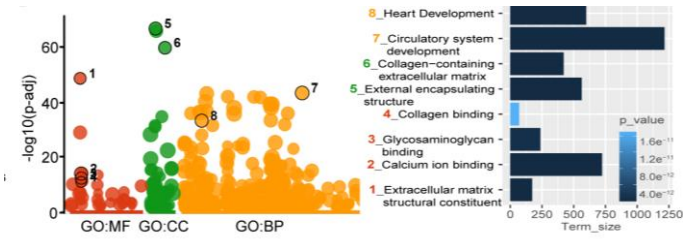

Fig. 2, *adapted from Fig.6D in* [8]: Functional enrichment analysis of the differentially upregulated genes in DMD-COs versus DMD-Iso-COs using gProfiler2 for Gene Ontology.

In addition, the gProfiler analysis also identified three top miRNA regulators for the differentially upregulated genes in DMD-CO, *i.e.*, hsa-mir-335-5p, hsa-mir-29a-3p and hsa-mir-29b-3p. Moreover, KEGG pathways associated with protein digestion and absorption, dilated and hypertrophic cardiomyopathy, ECM-receptor interaction, and cGMP-PKG signalling pathway were significantly enriched in DMD-CO. These findings were corroborated by the analysis on human phenotype ontology. Overall, the RNA sequencing data corroborated the histological observations (data not shown) on cardiomyocyte deterioration, adipogenesis and fibrosis at the transcriptomic level. Subsequently, a Protein-protein interaction (PPI) network analysis of differentially upregulated genes in DMD-CO was performed to identify the most significant genes in the complex network of gene interconnections. The identification of genes with the major regulatory potential of the entire network was carried out by node (gene) grade analysis, thus referring to the number of interlinked genes. Integration of miRNA-gene hybridization data from the mirTarBase v8.0 database identified two more miRNAs, hsa-mir-124-3p and hsa-mir-26b-5p, associated with HNF4A genes (rank = 257), UBC (degree = 108), UBD (degree = 66), APP (degree = 38), and EGR1 (degree = 31) (Fig.3).

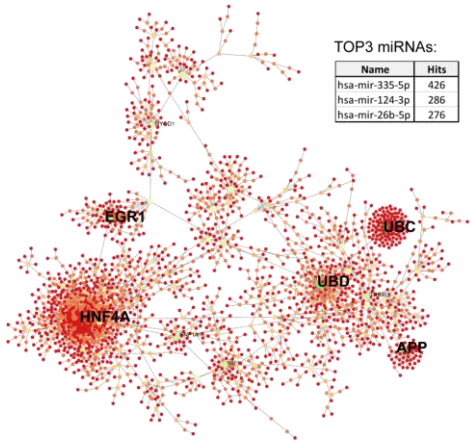

Fig. 3, *adapted from Fig.7A in* [8]: Protein-protein interaction network analysis based on differentially upregulated genes in DMD-COs using Network Analyst platform in DMD-COs showing the top five hub genes (HNF4A, UBC, UBD, APP and EGR1) based on the degree level.

To identify the association between the ontology result and the miRNAs identified were mapped among the gene-miRNA regulatory networks obtained for each KEGG pathway characterizing the DMD-CO condition, previously obtained through the analysis of the Biological Process ontology (BP): hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy (ARVC), PPAR pathway for adipogenesis, PI3K-Akt pathway for cardiac fibrosis. The results showed that the hypertrophy and dilated cardiomyopathy networks shared the same gene set (50 nodes, 49 edges), miRNA interactions (Fig.4A), and similarity of 16 genes with the ARVC network (Fig.4B). Except for hsa-mir-124-3p, the other four major miRNAs mapped into these three networks, respectively.

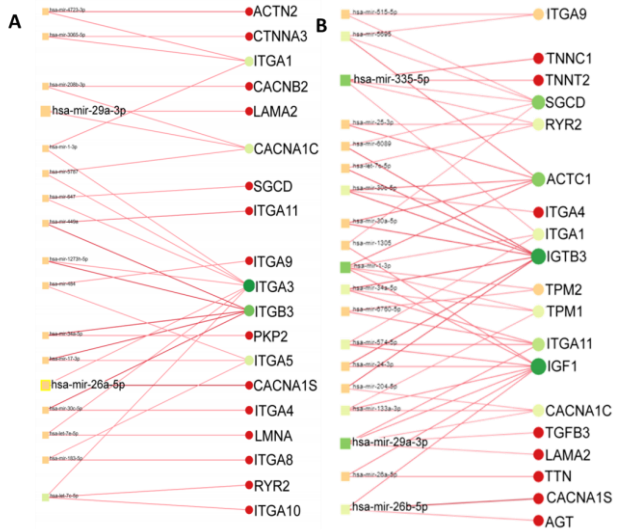

Fig. 4, *adapted from Fig. 7B and 7C in* [8]: The gene-miRNA networks for arrhythmogenic right ventricular cardiomyopathy (A), hypertrophy/dilated cardiomyopathy (B).

In addition, the PPAR signalling gene-miRNA network consisted of 33 nodes and 43 edges (Fig.5A) and has-mir-29b-3p, hsa-mir-26b-5p and hsa-mir-355-5p were the main miRNA regulators in the PI3K-Akt signalling (147 nodes, 146 edges), which interact with one of the two hub genes CCND2 (Fig. 5B).

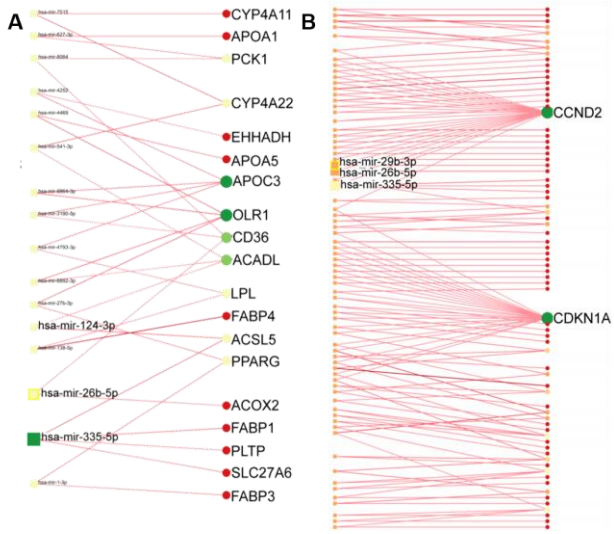

Fig. 5, *adapted from Fig. 7D and 7E. in* [8]: The gene-miRNA networks for PPARgamma (A) and PI3K-Akt (B) signaling pathways.

IV. Discussion

There is currently no cure for DMD patients, thus they are treated symptomatically via palliative therapies used in conjunction with cardio-respiratory supporting devices in case of cardio-pulmonary complications – a main lethal cause in DMD patients. DMD related cardiomyopathy often occurs as hypertrophic or dilated heart due to cardiomyocyte damage followed by fibrosis and adipose tissue formation. For these reasons, it should be necessary to develop a new therapeutic strategy to prevent the occurrence of these pathological events; therefore, it is crucial acquiring a thorough knowledge of the mechanism through which disease develops. However, to date due to limited accessibility to patient biopsy and the intrinsic limitation of 2D cardiomyocyte cultures, have precluded this scientific endeavour. Hence, in this study *in vitro* 3D human cardiac-mimics of DMD-relevance to bridge this scientific gap were developed. In this study, DMD-CO that functionally and transcriptionally modelled the cardiac evolution in DMD patients were generated. Particularly this model showed a lack in proliferative capacity, cell death and a progressive deterioration of cardiomyocytes in early culture stage (10, 14, 28 days) followed by adipose tissue and fibrous-like tissue formation at later culture stage. These results were corroborated through RNA sequencing analysis demonstrating that the DMD-CO generated on long term culture (93 days) were a 3D cellular models to gain insight into the disease mechanism of DMD-associated hypertrophic/dilated cardiomyopathy, as well as adipogenesis and fibrosis. Hence, we focused on mapping out the functionally enriched pathways based on the differentially upregulated genes in DMD-CO as compared to DMD-Iso-CO, as well as their main miRNA regulators. Among the top five hub genes identified in the protein-protein interaction network, only HNF4A ($log_2FC = 1.89$, $p<2.92e^{-5}$, UBD ($log_2FC = 2.69$, $p<7.37e^{-5}$) and EGR1 ($log_2FC = 1.47$, $p<5.31e^{-12}$) were significantly and differentially upregulated in DMD-CO. Afterwards, assays for identifying regulating miRNAs for genes overexpressed in pathological COs were performed, producing three potential sequences: hsa-mir-335-5p, hsa-mir-29a-3p, hsa-mir-29b-3p, hsa-mir-124-3p and hsa-mir-26b-5p. According to literature, the 5 identified miRNAs may be associated with different conditions: the miRNA hsa-mir-335-5p is responsible for controlling the regulation of cardiac differentiation since, potentially mediated by the activation of WNT and TGFβ pathways [16], is able to upregulate the commitment of cardiac progenitors; hsa-mir29a-3p and hsa-mir-29b3p are overexpressed in patients with congenital heart disease; hsa-mir-26a/b-5p is highly expressed in patients with cardiac hypertrophy [17] and is responsible for activating the cell death process caused by myocardial infarction [18]; finally, hsa-mir-124-3p promotes the activation and proliferation of cardiac fibroblasts [16] and its inhibition protects against acute myocardial infarction, by inhibiting the apoptosis process of cardiomyocytes [19]. Therefore, the use of the RNA sequencing technique and of the *in-silico* analysis allowed the identification of five miRNAs significantly expressed in the pathological COs that could be associated with the development of dilated cardiomyopathy and with the pathways of adipogenesis and fibrosis – confirming what was observed with the morphological tests.

***Abstract*—The extracellular matrix plays a pivotal role during nervous system development, offering adhesion points for neuronal growth and differentiation, as well as for nervous tissue formation. For that reason, neuronal functional and morphological *in vitro* studies have been performed functionalizing culture supports by extracellular matrix components or synthetic biopolymers. In this study, chitosan was validated as an alternative adhesion. Primary neurons and neurons differentiated from human induced pluripotent stem cells were plated onto chitosan and standard adhesion factors modified supports. The development of individual cells was followed at daily intervals until both axons and dendrites had been established; electrophysiological behavior was studied to validate the ability of chitosan to sustain long-term maturation.**

***Keywords* — Chitosan, Cell adhesion factors, Neuronal development, Electrophysiological characterization.**

I. Introduction

The main extracellular matrix components involved in the developing nervous system are the glycoproteins laminin and fibronectin, which are expressed at stages critical for neuronal differentiation and are functional in neurite outgrowth in vitro [1]. Usually, neuronal culture supports, such as plastic or glass surfaces for traditional 2D neuronal cultures, can be bioactivated either with molecules able to interact with the negatively charged cell membrane [2], or with receptors on the cell membrane [3], [4] to guide neuronal adhesion and growth. Poly-ornithine, laminin and poly-lysine are the most popular adhesion molecules. These macromolecules containing amino groups, have been frequently used as coating materials for *in vitro* neuronal substrates, as electrostatic interaction between the positive charges of the NR_3^+ groups on a culture substrate and the negatively charged neuronal membranes has been suggested as an indispensable factor for stable neuronal adhesion and proper development, [5]-[7].

In the last year, 3D tissue model gained a great popularity. As for 2D culture supports, biomaterials used for 3D cultures need surface functional groups to promote neuronal adhesion and development. Researchers have focused on functionalizing biomaterials surfaces with adhesion molecules [8].

Among the different tested biopolymers for nervous tissue engineering, chitosan has been investigated both in 2D and 3D neuronal cultures. Chitosan is a copolymer of glucosamine and N-acetyl-glucosamine, obtained by the deacetylation of chitin, which is the main component of crustacean and insect exoskeletons [9]. Chitosan is well known for its biocompatibility, biodegradability, muco-adhesiveness as well as its antibacterial activity. Moreover, in chemical structural terms, chitosan shows similarities to the extracellular glycoprotein carbohydrates. In this respect, recently studies showed the ability of chitosan to sustain the development of 3D functional neuronal networks, both for primary rat neurons and neurons differentiated from h-iPSCs without any pre-functionalization [10]-[12]. Based on these results, the starting hypothesis of this work is that chitosan can be used as an adhesion molecule in standard 2D cultures of rat and human neurons, promoting the formation of functional networks comparable with traditional commercial adhesion molecules and. Cell culture upports were bioactivated using chitosan (*Chito*) and poly-ornithine (*PolyO*) or poly-ornithine /laminin (*PolyO/Lam*) as controls. Primary hippocampal and cortical neurons and h-iPSCs differentiated in excitatory cortical neurons (iNeurons) were plated onto the functionalized supports. In order, to validate the ability of chitosan to support neuronal adhesion, networks development and the differentiation capacity, morphological and functional characterization were carried out. This model has been compared with the well-established model introduced by Dotti et al. for the polarization process on hippocampal neurons evaluating plating efficiency, neurite outgrowth at different stages after plating and found that, on poly-ornithine as control substrate, [13]. As relates to iNeurons, plating efficiency and polarization were evaluated and compared to those obtained by using *PolyO/Lam* coated supports, following the protocol by Frega et al. [14].

This work demonstrated that chitosan, besides all its well-known properties, displays bioactivity towards both rat neurons and iNeurons. Moreover, as already demonstrated in literature [10]-[12], *chito* can be easily shaped both in 2D and 3D without any modification of its chemical cues, representing an innovative bridge between different neuronal dimensional *in vitro* models.

II. Material and Methods

A. Culture supports functionalization

Chito solutions were prepared at concentrations of 0.1 and 1% w/v in 0.1M acetic acid. *PolyO* and *Lam* were used at a concentration of 0.15 µg/ml and 5 µg/ml in ${}_{dd}H_2O$ respectively. 0.1% *Chito* solutions were sterilized by

filtration, while 1% *Chito* solution was autoclaved at 120 °C. Culture supports were functionalized by solution casting following the standard protocol [15] and incubated overnight at 37°C. The excess of solutions was removed, supports were then washed twice with sterile $_{dd}H_2O$ and finally normalized in cell culture medium. For iNeurons, after *PolyO* functionalization, *Lam* solution was pipetted on the supports and incubated for 2 hours at 37 °C; later, the supports were washed with sterile $_{dd}H_2O$ and normalized in the proper cell culture medium.

B. *Cell plating*

Cells were plated at low cell density (28-30 cells/mm^2) in the presence of astrocyte conditioned medium, for the evaluation of neurite outgrowth. The synaptic count was carried out onto cultures with a cell density of 260-300 cells/mm^2. The electrophysiological characterization was performed with a cell density of 1200 cells/mm^2. Primary hippocampal and cortical cultures were prepared according to methods developed by Banker and Goslin, [15]. H-iPSCs were generated by lentiviral transduction from fibroblast taken from a healthy donor. Cells were kindly provided by Frega et al. Full protocol regarding generation and maintenance of the rtTa/NgN2 positive cell line have been described in Frega et al. [14]. The experimental protocol was approved by the European Animal Care Legislation (2010/63/EU), by the Italian Ministry of Health in accordance with the D.L. 116/1992 and by the guidelines of the University of Genova. All efforts were made to reduce the number of animals used for the project and to minimize their suffering.

C. *Characterization of coatings*

To determine the amount of free amino groups, ninhydrin (Sigma-Aldrich, NHN) assay [16] was carried out. *Chito*, *PolyO* and *PolyO/lam* films adsorbed were obtained following the same procedure exposed in "Culture supports functionalization" section. The amount of free amino groups was proportional to the optical absorbance of the solution at 570 nm.

D. *Morphometry evaluation*

Morphometry study was carried out to characterize neuronal development and polarization. The main neuronal development parameters were extracted: number of neurites per cell, total neurite length per cell, length of major neurites per cell, total length of all minor neurites per cell and polarity index.

E. *Morphological characterization*

To evaluate neuronal network development, microtubule-associated protein (MAP-2), glial fibrillary acidic protein (GFAP) and Dapi were used to show dendritic arborization, glial cells and nuclei, respectively. Moreover, neuronal cultures were co-immunostained for the excitatory pre-synaptic maker vesicular glutamate transporter and the excitatory post-synaptic density marker to carry out the synaptic count.

F. *Electrophysiological characterization*

Standard MEA-60 (MultiChannel System) were used to record the electrophysiological activity of neuronal network. Electrophysiological activity was recorded at different developmental stages.

III. RESULTS

A. *Characterization of coatings*

As it is reported in literature, free amino groups of polyaminoacid electrostatically interacts with the negative charges of the cell membrane, promoting cell adhesion. In this respect, NHN assay was carried out to evaluate the amount of free amino groups of all used adhesion factors [16]. The amount of free amino groups for 0.1 % and 1 % Chito was respectively three and six times higher compared to the one for *PolyO*, Fig.1.

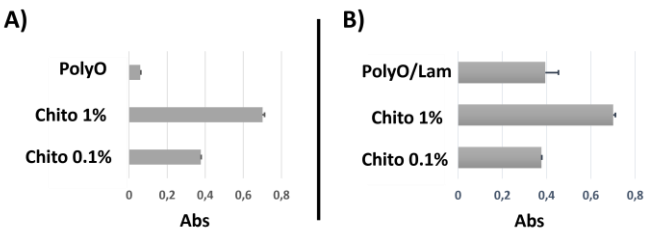

Fig. 1: Amount of free amino groups of Chito, *PolyO* and *PolyO/Lam*

B. *Morphometric evaluation*

The morphological differentiation (two distinct types of processes, namely, axons and dendrites) of rat and human neurons was investigated onto all coatings at 24h intervals between 0 and 72h *in vitro*. Fig.2 and Fig. 3 show the main parameters characterizing neuronal early-stages development: number of neurites, average length, average length of minor and major neurites. For both rat neurons and iNeurons, the number of neurites per cell increased during the whole culture period. In terms of the average neurites length, no significant differences between the coatings were observed for both neuronal populations. The mainly difference observed in rat neuronal development onto two different substrates, is that *Chito* showed a temporary decrease of total neurite length, favouring the growth of major neurites over the growth of the minor ones, and therefore promoting neuronal polarity at later stages of neuritogenesis Fig.2.

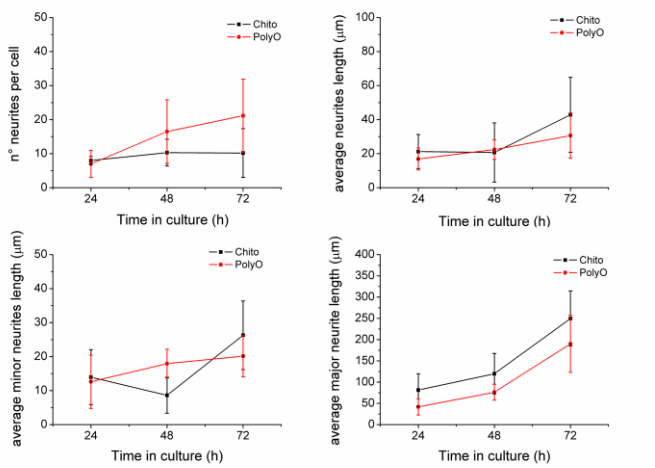

Fig. 2: Coatings influence on number of neurites, neurites lengths, minor neurite lengths, major neurites lengths of Rat neurons over time.

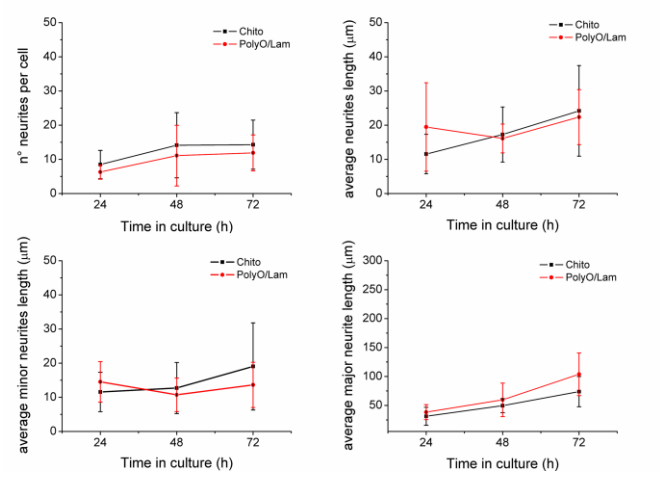
As relates to iNeurons, *Chito* favoured the growth of the minor neurites over the growth of the major one Fig. 3. These results suggest that iNeurons axonal growth is slower than the primary neuron one. This has been attributed to different maturation of primary rat neurons and iNeurons.



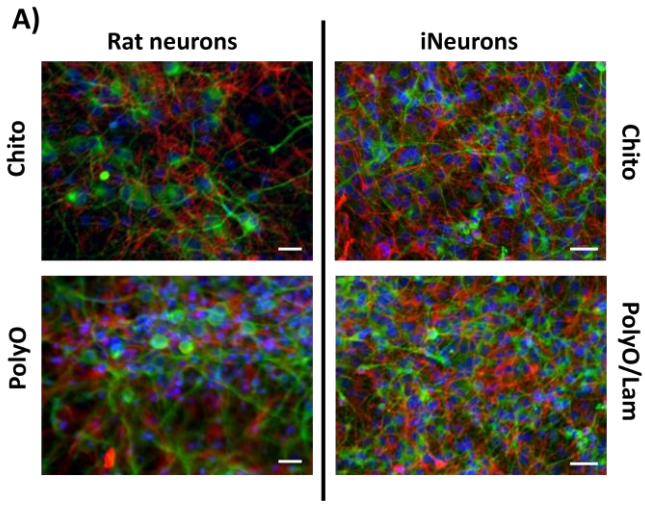


Fig. 3: Coatings influence on number of neurites, neurites lengths, minor neurite lengths, major neurites lengths of iNeurons over time.

C. *Morphological characterization*

The immunocytochemistry characterization allowed us to obtained information on the morphology of 2D neuronal networks after 21 days of culture and distinct features of the neurons and glial cells, Fig. 4A. For both rat neurons and iNeurons, the two cells' populations (neurons in green and glia in red) present a morphology similar onto all coatings showing a homogeneous distribution and the formation of a dense network.

A related to synaptogenesis, the expression of synaptic puncta increased with time in all experiments, for both neuronal populations onto all coatings, pointing out a progressive and adequate cell maturation, Fig. 4B. For both cell types, during the first week of culture, synapse development was almost absent. For rat neurons, after 14 days a robust synaptogenesis was observed on *Chito* as well as on *PolyO* coatings. For iNeurons, synaptogenesis wasn't observed, Fig.4B, since not all marker signals matched, confirming that iNeurons maturation is slower than the one of primary rat neurons.

21	0.98 ± 0.03 µm	1 ± 0.04 µm

Fig. 4: A) Immunochemistry staining images of Rat neurons and iNeurons onto *Chito*, *PolyO* and *Poly/Lam* at DIV21, labelled for MAP2 (green), GFAP (red) and DAPI (blue). Scale bar: 20 µm. **B)** Quantification of synaptic puncta in rat neurons at DIV 7 and 14 and in iNeurons at DIV 7, 14 and 21.

D. *Electrophysiological characterization*

The spontaneous activity of rat neuronal networks and iNeuronal networks developed onto all coatings was recorded. The electrophysiological analysis showed that both cultures on all coatings increased their activity towards mature network dynamics, indicating a stable interface between the coatings and adherent cells.

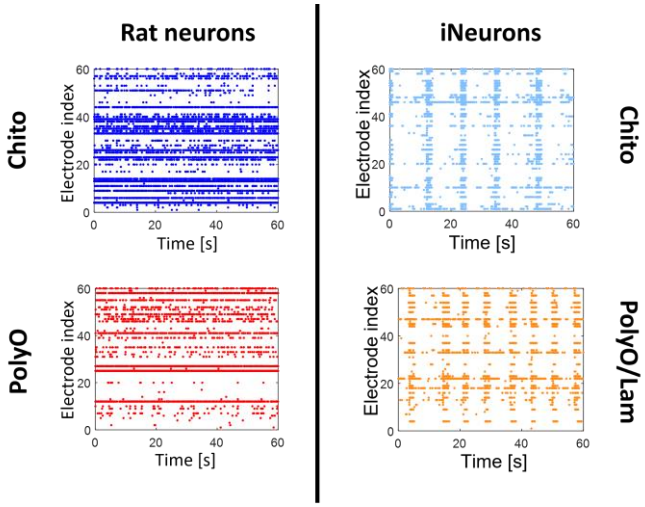

Fig. 5: Raster plots showing 60 s of spontaneous activity of 2D rat neuronal networks at DIV26 and 2D iNeuronal networks at DIV42.

IV. Conclusion

The results of this study show that *Chito* can be used as an alternative adhesion molecule to support neuronal culture, showing strong neuronal adhesion properties, and promoting neuritic growth in way comparable with the traditional adhesion molecules. In terms of functional development, *Chito* sustained a maturation of neuronal networks in long-term cultures. The validation was carried out for both rat neurons and human derived neurons. The advantage to have a material that can be used both in 2D and 3D cultures without any further bioactivation, represents a great advantage since 2D cultures are always considered the gold standard in neuroengineering, neurophysiological and neurodegenerative experimental studies, favouring thus the comparison of the results obtained for the two different configurations.

***Abstract*—Four Dimensions (4D) printing is a fabrication approach which adds the fourth dimension "time" at the three spatial dimensions of Three-Dimensional (3D) printing. A 4D printed object can change its shape and function after receiving an appropriate stimulus. 4D printing finds application in tissue engineering and biofabrication. Indeed, the change in shape of a 4D printed object can mimic physiological movements, and promote cell growth and differentiation. In this work, we developed an analytical model to predict, in space, the movement of a scaffold that, from a planar geometry, turns into a tubular one. This specific shape change, referred to as "folding", has been chosen because it can mimic several anatomical structures, such as trachea, blood vessels and, in particular, the neural tube, which will be here modelled through human pluripotent stem cells.**

***Keywords*—4D printing, bioprinting, modelling, neural stem cells.**

I. Introduction

4D printing is a fabrication technique that increases capabilities and application of additive manufacturing (AM) adding time dependent shape changing. In general, a 4D printed structure is defined as a 3D printed structure that changes shape, function and properties because of a predefined external stimulus [1]. Active materials are at the base of 4D printing. They can change their properties in a predefined way after the application of an external stimulus (*e.g.*, variation of moisture, pH, temperature and electromagnetic field). Thus, by combining different materials in a specific spatial distribution it is possible to achieve the desired change of the structure's shape [2]. The control in the spatial arrangement of different materials is achieved with AM, that allows to deposit different materials in a specific pattern with limited constraints [3]. Biomedical related fields of application of 4D printing include: tissue engineering, drug delivery and medical devices. For example, Zareck *et al.* developed a personalized luminal stent using shape memory polymers. More in detail, the device was printed by stereolithography and was capable of increasing its diameter by unfolding once it reaches the site of interest (ideally the patient trachea). Therefore, the final shape of the device is equal to the anatomical site of interest [4]. Another example of 4D printed biomedical application is given by shape memory hydrogels, which have been used to control the target delivery and controlled release of a certain drug after receiving an appropriate stimulus [5]. In the tissue engineering field, 4D printing has been used to produce scaffolds that can influence cell differentiation and growth by shape changing. An example is the study of Hendrikson *et al.* in which they produced a scaffold based on memory shape polyurethane by extrusion based bioprinting, seeded it with human mesenchymal stem cells and demonstrated that scaffold stretching and contraction improved cell activity and adhesion [6]. All these applications are only possible with an appropriate modelling of the shape changing phenomenon. A model is needed to predict the final geometry once the initial shape, material properties and intensity of stimulus are known, due to the several variables that are entangled in the 4D printing process [7]. In this study, an analytical model is developed to predict the shape changing of planar bilayer structures that turn in tubular ones (*i.e.*, self-folding) after immersion in a water solution. More in detail, these structures are homogeneous films of gelatin (fabricated by solvent casting, using an applicator) at high concentration with parallel lines at lower concentration, that were 4D printed on top of the casted gelatin film. Dipping these structures in a water-based solution, the two layers absorb water differently, due to the different gelatin and crosslinker concentrations that determinate a difference of expansion coefficient. This leads to the folding of the structure (Fig.1). The selection of a tubular shape is linked to the evidence that several anatomical parts have a hollow-cylinder like geometry, as examples: blood vessels, nerves and trachea. Additionally, this particular movement is present in the neural tube formation during embryogenesis [8]. The developmental process of neurulation involves a series of coordinated morphological events during embryogenesis, which result in the conversion of the flat neural plate (generated from dorsal ectoderm) into the neural tube, the primordium of the entire central nervous system (CNS) (Fig.1). Failure during neurulation results in neural tube defects, main cause of sever neurodevelopmental pathologies in human [9]. Here, the 4D bioprinted self-folding structure was used to model the neural tube formation, to validate its usability in a biological environment.

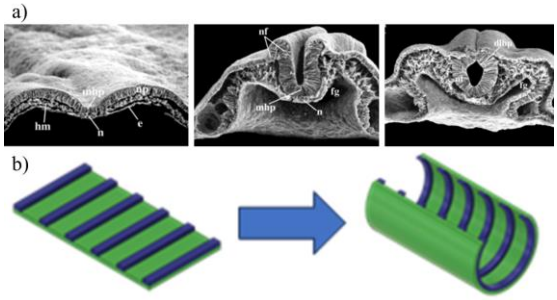

Fig. 1: a) Neurulation process [10] *. b) Folding of produced scaffold*

II. MATERIAL AND METHODS

A. Geometry definition and known models

The geometry to be modelled, can be schematized as a parallelepiped with a series of smaller parallelepipeds on its top (Fig.2).

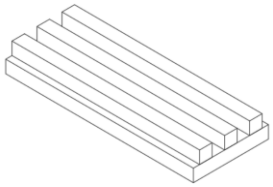

Fig.2: View of modelled geometry

In literature, the most used analysis to predict the bending of a bilayer structure is the Timoshenko's model [11]. In 1925 Timoshenko developed a model that can predict the radius of curvature of a bimetal beam once known the section dimension, mechanical and physical properties of the used materials and the temperature difference. The model is formulated only for beams and in consequence limited to one dimensional (1D) structure. In the next sections, the same steps of Timoshenko's analysis have been applied to the geometry of Fig.1b to obtain the radius of curvature as function of geometric parameters (*e.g.*, moment of inertia of section, thickness of layers, number and dimension of printed lines), material properties (*e.g.*, elastic modulus, expansion coefficient) stimulus intensity (*e.g*., temperature variation).

B. Hypothesis and simplification

Before starting with model derivation a few assumptions need to be done.

- Since shape morphing happens only where there are two different materials in the film, if parallel lines are thin enough, we can assume that the lines will bend like Timoshenko's beams.
- Zones with only one material will expand but do not contribute to structure folding.
- If the beam width is small enough, the bending angle in this direction can be considered negligible.

With these hypotheses we can assume that the printed lines create a preferential direction for shape change and this direction is the same of the printed ones. In other words, the main axes of the hollow-cylindrical shape will be perpendicular to the printed lines. Moreover, for an easier analysis, expansion coefficients incorporate stimulus intensity. Briefly, instead of expansion coefficient multiplied by the stimulus intensity, we consider directly the resulting strain. This is justified by the use of moisture as trigger, because moisture intensity is always the same in water solutions.

C. Model derivation

The following material and geometrical properties are known: Young's modules (E_1 and E_2), expansion coefficients along L direction ($\alpha_1$par, $\alpha_2$par), expansion coefficients along h direction ($\alpha_1$per, $\alpha_2$per), thickness of homogeneous film and printed lines (h_1, h_2), width of lines (D), width of homogeneous film (W) (Fig.3). Hypotheses are verified if D is negligible compared to W and to total length (L). Therefore, without external forces we can consider only internal forces (P) and torques (m) acting along the direction parallel to lines. All geometrical parameters and acting forces are shown in Fig.3.

Since no external forces are present, internal forces and torques are in equilibrium (Eq.1 and Eq.2):

$$P_1' + P_1'' = P_2 = P \quad (1)$$

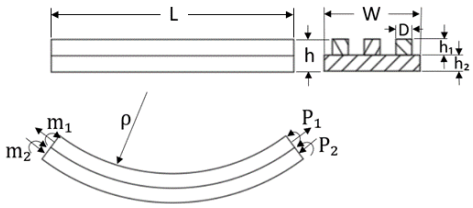

Fig.3: Geometrical parameter and acting force on the structure, before and after shape change.

$$P * \frac{h}{2} = m_1' + m_1'' + m_2 \quad (2)$$

In the Eq.1 and Eq.2 only two lines of material 1 are considered. More in general, since we have N printed lines, total force and momentum in the lines is the sum of forces and momentum in each line (Eq.3 and Eq.4):

$$\sum_1^N P_{1i} = P_2 = P \quad (3)$$

$$P * \frac{h}{2} = \sum_1^N m_{1i} + m_2 \quad (4)$$

If we consider that printed lines have all same size and are equally spaced, then also lines internal forces and torques are all equal ($P_1 i = P_1 \; and \; m_1 i = m_1$), and Eq.3 and Eq.4 become Eq.5 and Eq.6, respectively.

$$N * P_1 = P_2 = P \; (5)$$

$$P * \frac{h}{2} = N m_1 + m_2 \quad (6)$$

Defining ρ as radius of curvature of the structure, torques are obtained from Eq.7, where $I_1 = \frac{D * {h_1}^3}{12} \; and \; I_2 = \frac{W * {h_2}^3}{12}$.

$$m_1 = \frac{E_1 * I_1}{\rho} \qquad m2 = \frac{E_2 * I_2}{\rho} \; (7)$$

Substituting Eq.7 in Eq.6 we obtain Eq.8:

$$P * \frac{h}{2} = \frac{N * E_1 * I_1 + E_2 * I_2}{\rho} \quad (8)$$

The sheared surface between the two materials (parallel direction) the strains of the two materials must be equal (Eq.9):

$$\alpha_1 + \frac{P_1}{E_1 * h_1 * D * N} + \frac{h_1}{2 * \rho} = \alpha_2 - \frac{P_2}{E_2 * h_2 * W} - \frac{h_2}{2 * \rho} \; (9)$$

In Eq. 9 the first terms $\alpha 1$ and $\alpha 2$ are deformations caused by material expansion, second terms are strain calculated according to Hooke model and third terms describe the folding from Navier's Equation.
Substituting Eq.8 in Eq.9 we obtain Eq.10:

$$\frac{1}{\rho} = \frac{(\alpha_2 par - \alpha_1 par)}{\frac{h}{2} + \frac{2 * (N * E_1 * I_1 + E_2 * I_2)}{h} * \left(\frac{1}{E_1 * h_1 * N * D} + \frac{1}{E_2 * h_2 * W} \right)} \; (10)$$

Defining $m = h_1/h_2$, $n = E_1/E_2$ and $\beta = ND/W$, Eq.10 can be written as Eq.11:

$$\frac{1}{\rho} = \frac{6(\alpha_2 par - \alpha_1 par)(m+1)^2}{h\left(3(m+1)^2+(1+\beta mn)(m^2+1/\beta mn)\right)} \quad (11)$$

The radius of curvature results proportional to the total thickness and inversely proportional to the difference in elongation of the two materials. The other parameters m, n and β influence the value of ρ but in a not trivial way.

D. Model validation

To validate this analytical model we produced samples with the same geometry described in section IIA.

These structures were made by a homogeneous film produced by solvent casting using an applicator, thus guaranteeing a homogeneous thickness, composed by a 15% w/v type A gelatin from porcine skin in PBS solution 1X with the addition of 92µl of γ-glycidoxypropyltrimethoxysilane (GPTMS) for each gram of gelatin. On top of the film equidistant parallel lines were printed by extrusion-based bioprinting. Those lines consist of a 5% w/v type A gelatin from porcine skin in PBS solution 1X with 368µl of GPTMS for each gram of gelatin (Fig.4a).

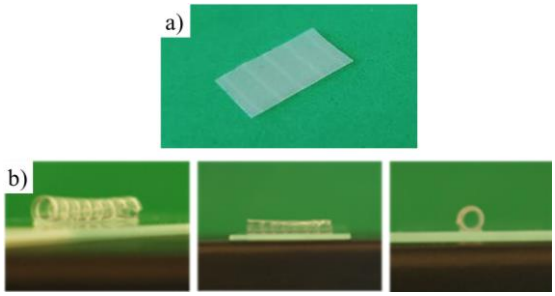

Fig. 4: Scaffold produced of dimension 10x5mm, a) before actuation, b) after folding

The material was chosen for its biocompatibility [12], and the solutions concentrations were chosen to maximise the difference of swelling ratio between the two materials (data not shown). Since the two layers are made by the same bulk materials a chemical bound occur between the two layers. This phenomenon eliminates the risk of delamination of the structure. Both materials have been physically and mechanically characterized to determinate elastic modulus (under wet and dry conditions) and expansion coefficients ($\alpha = \frac{final\ length - initial\ length}{initial\ length}$). The results of these characterization are shown in Table I.

TABLE I: MECHANICAL AND PHYSICAL PROPRIETIES

Material	E wet (MPa)	E dry (MPa)	αpar (%)	αper (%)
Gelatin 15%	3.81 ± 0.43	3170 ± 280	8.54±1.35	164.70±8.67
Gelatin 5%	63.13 ± 26.72	1820 ± 550	3.14± 1.89	38.67±16.52

Values are written as mean ± standard deviation, 4 samples are used to estimate E and 10 samples are used to estimate α

Validation of the model is based on comparing the model predicted radius of curvature (mean and standard deviation STD of the model derived from estimated variability of physical/mechanical properties) of the structure and the effective radius of curvature measured on the real samples, as function of one or more parameters. The thickness of the homogeneous film is the parameter that, from Timoshenko's model, gives larger variation of the radius of curvature. For this reason, the radius of curvature was measured for different h2 values and compared to the predicted ones.

Fabricated samples are 10x5mm on plane and have a total thickness varying from 50µm to 160µm. Layers thickness was measured with a micrometer (h_1, h_2 and h), while lengths on the plane was measured from hi-res figures using the software ImageJ (D and W). Results of measurement are shown in Table II. To trigger the shape changing of the structures the samples were dipped in PBS 1X and after 3 hours (time needed to reach the plateau of expansion, determined during the measure of the expansion coefficient, data not shown) the radius of curvature was measured from pictures using ImageJ.

TABLE II: GEOMETRICAL PARAMETERS

h2 (µm)	h1 (µm)	D (mm)	W (mm)
50-160±5	33.1 ± 14.1	1.0±0.1	10.2±0.4

Values are written as mean ± standard deviation, 30 samples are used to obtain h1, D and W measures

E. Biological application

Scaffolds used to validate the model have been also used to explore the effects of 4D bioprinting in cell differentiation and growth. More in detail, *in vitro* modelling of neural tube formation was explored. A customized holder was put on the scaffold while it was still flat in water-based solution to kept the scaffold flat. The operator just needed to remove the holder to actuate the folding movement. Holder was needed to give time to cell to attach on the scaffold, otherwise shape changing would start too early and the cells would not follow the scaffold movement.

Human induced pluripotent stem cells (hiPSCs) were seeded on 4D bioprinted scaffolds and on 2D static films. After 24 hours, 4D scaffolds were actuated and 3 days later, when the cells reached > 90% confluence, neural induction protocol [13] started. After 12 days of neural induction, cells were driven to differentiation for 4 days, by adding neural differentiation supplemented with the neurotrophin BDNF. Neural differentiation was evaluated through immunofluorescence assay. Confocal imaging of immunoassayed 4D scaffold revealed homogeneous positivity for Nestin [14] (intermediate filament protein of neural progenitors) and SOX2 [15] (transcription factor expressed in neural progenitors), thus confirming successful neural identity.

III. RESULTS

A. Predicted and measured radius comparison

Radius of curvature values are plotted as function of the total thickness as shown in Fig.5.

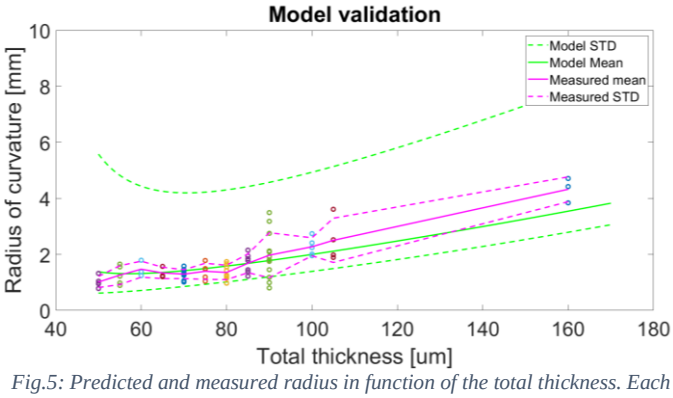

Fig.5: Predicted and measured radius in function of the total thickness. Each dot is a sample.

Mean values of the model (continuous green line) are calculated using mean value of measured material and geometrical parameters (*i.e.*, Young's modulus, expansion coefficients, film thickness, lines thickness and width) STD values of the model (dotted green lines) are calculated using upper and lower values of material and geometrical parameters. For each thickness and radius measure a dot is plotted, obtaining mean (continuous magenta line) and STD (dotted magenta lines). Predicted and experimental values fall in the same region, when the total thickness of the 4D printed structure is between 55 and 105µm.

B. Biological application

Cells attached to the scaffold within 24h after seeding (Fig.6a, top panels). After holder removal, cells still adhere to scaffold surface and within 48h colonize the whole scaffold surface (Fig.6a, bottom panels). Morphological changes occurring during neural induction phase suggest neural commitment (Fig.6b).

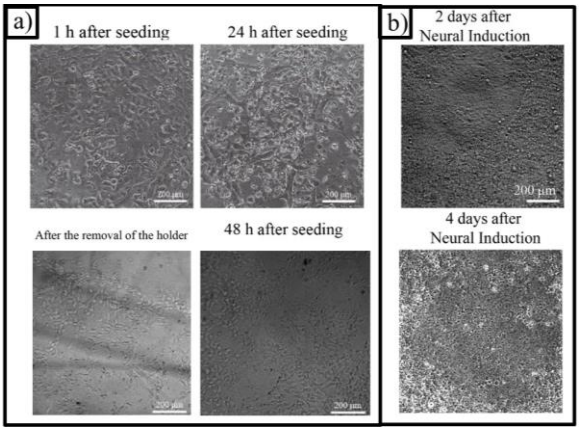

Fig. 6: a) Cells attachment after seeding b) Cells are homogeneously distributed on scaffold surface during neural induction showing morphological change due to neural commitment

After 12 days of neural induction, cells extensively express Nestin and SOX2 neural progenitor typical markers (Fig.7a) and organize into neural rosettes (Fig.7a, bottom panel). Moreover, after 4 days of differentiation, cells seem to be oriented along the thickness of the scaffold, showing a similar organization of neural progenitors in the native neural tube (Fig.7b).

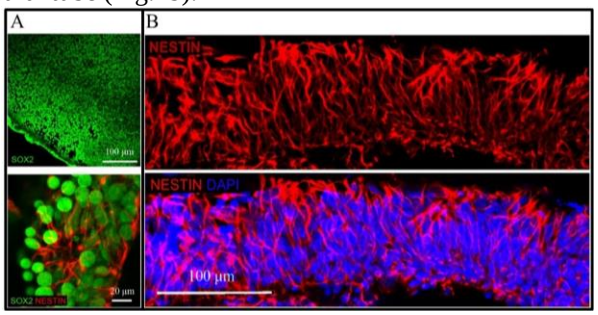

Fig.7: Representative confocal analysis showing A) neuroepithelial-like structure expressing Nestin and SOX2 (DIV12) B) maintenance of the apical-basal orientation of neural precursor at DIV16

IV. Conclusion

The developed model can be used to design self-folding scaffolds that can have multiple purposes in tissue engineering. The model allows to completely control bending orientation and predict the curvature radius of the scaffolds, and to achieve self-folding scaffolds with customizable length, diameter and degree of curvature as a result. Looking at the mathematical model itself, it needs to be improved by adding the time dependent behaviour. In this way, we can achieve a model capable to predict the change in shape through space and time.

The 4D printed scaffold was then used to develop a neural tube in vitro model. Indeed, the self-folding movement of the scaffold recapitulate the formation of neural tube in vitro. The scaffold resulted to be highly biocompatible. Moreover, shape change seems to sustain neural differentiation as showed by immunofluorescence assay with diagnostic markers. Neural tube experiment showed the differentiation from pluripotent cells (hiPSCs) to patterned neural progenitor cells, as highlighted by the expression of Nestin and SOX2. An exhaustive gene characterization in longer period of differentiation is ongoing, to evaluate if 4D printed scaffolds can support neural progenitor differentiation into mature neurons.

***Abstract*—In this work, we stimulated M0-like and M1-like macrophages (obtained from the THP-1 cell line) with low-intensity pulsed ultrasound (LIPUS) and pulsed electromagnetic fields (PEMF) to induce beneficial anti-inflammatory effects in terms of gene expression and cytokine release. The results show a significant reduction of some pro-inflammatory markers (IL-8, TNF-α after LIPUS stimulation and IL-1β, IL-8, TNF-α after PEMF stimulation) and a significant increase of anti-inflammatory markers (IL-10 after LIPUS and IL-10, CD206 after PEMF). These results show the potential of LIPUS and PEMF for possible future clinical translation, in clinical settings in which decreasing inflammation has a crucial role to enable therapy efficacy.**

***Keywords*—Biophysical stimulation, LIPUS, PEMF, macrophages.**

I. INTRODUCTION

Inflammation is a key factor in several diseases [1]. Pharmacological treatments to lower inflammation levels are often poorly effective and can cause side effects, dangerous for the organism [2]. Very promising results have been recently obtained by applying biophysical stimulation technologies, such as low-intensity pulsed ultrasound (LIPUS) [3], [4] and pulsed electromagnetic fields (PEMF) [5], [6]. Both these tools show interesting features such as safety, non-invasiveness and low cost. The Food and Drug Administration clinically approved LIPUS for fracture healing [7] and started analyzing several PEMF devices [8].

The efficacy of LIPUS and PEMF in regulating the inflammatory response has also been explored in the last years, with promising results [5], [9], [10]. However, the underlying mechanisms at the biological level have not been fully understood yet. Moreover, the set-ups used in the state of the art did not guarantee precise control of the dose, a factor that hampers finding a proper and reliable dose/effect correlation [11], [12].

When inflammation is active, macrophages produce a large variety of pro-inflammatory cytokines, such as IL-1β, IL-8 and TNF-α [13]. In this work, we investigated possible anti-inflammatory bioeffects induced by LIPUS and PEMF regimes in terms of possible decrement of pro-inflammatory cytokines and increment of pro-inflammatory cytokines, using two custom-made in vitro stimulation systems, which guaranteed high control of the dose released to the cells.

II. MATERIALS AND METHODS

A. THP-1 cell culture

THP-1 cells (ATCC) were seeded at a density of 10^6 cells/mL on a polystyrene thin film (Goodfellow) stretched and mounted within a CellCrown™ insert (Scaffdex). Cells were kept in growth medium (GM) composed of RPMI (Gibco), supplemented with 10% fetal bovine serum (FBS, Sigma-Aldrich), 100 IU/mL penicillin, 100 µg/mL streptomycin (Sigma-Aldrich) and 0.05 mM of 2-mercaptoethanol (Gibco). Cells were differentiated into an M0 phenotype by adding 100 ng/mL Phorbol 12-myristate 13-acetate (PMA, Sigma-Aldrich) to GM, for 24 hours. To further differentiate M0 into M1 or into M2 phenotypes, PMA was removed and 1 µg/mL Lipopolysaccharide (LPS, Sigma-Aldrich) for 24 hours or 50 ng/mL IL-4 (Sigma-Aldrich) for 24 hours was added to GM, respectively.

B. Study design

Five groups were defined, for both the LIPUS and PEMF experimental sessions: (i) group named "M0", in which macrophages were not treated neither with LPS nor with IL-4 and just cultured in GM for 3 days; (ii) group named "M1", in which macrophages were treated with LPS, then cultured in GM for 3 days; (iii) group named "M2", in which macrophages were treated with IL-4, then cultured in GM for 3 days; (iv) group named "M0+LIPUS" in which M0 macrophages were cultured in GM for 3 days and stimulated with LIPUS; (v) group named "M0+PEMF" in which M0 macrophages were cultured in GM for 3 days and stimulated with PEMF; (vi) group named "M1+LIPUS" in which M1 macrophages were cultured in GM for 3 days and stimulated with LIPUS; (vii) group named "M1+PEMF" in which M1 macrophages were cultured in GM for 3 days and stimulated with PEMF.

C. LIPUS and PEMF set-ups and stimulation protocols

In this work, a highly-controlled LIPUS setup was used [14]. The system guarantees high precision in delivering the ultrasound dose to the cells, in terms of applied parameters, i.e., frequency (F), intensity (I), Duty Cycle (DC), sonication time (T), and pulse repetition frequency (PRF). The LIPUS system is composed of a 5 MHz piezoceramic transducer (Precision Acoustic) and a wave generator (Image Guided Therapy). The PEMF system was provided by BAC Technology s.r.l (Florence, Italy) and consisted of a wave modulator, connected to a generator, able to generate a signal and a polycarbonate retaining system in which cells are placed during the stimulation. The parameters that could be varied were F, DC, T, and PRF. PEMF output I was fixed for the system generator and equal to 0.3 mT. The LIPUS and PEMF setups are depicted in Fig. *1*.

In light of safety considerations and previous studies, for the LIPUS stimulation protocol the parameters applied were: F = 5 MHz, I = 500 mW/cm^2, DC = 20 %, PRF = 1 kHz, and T = 5 min/day for 3 days. For the PEMF stimulation protocol, the parameters applied were F = 13.5 MHz, I = 0.3 mT, DC = 10%, PRF = 20 Hz, and T = 3 h/day for 3 days.

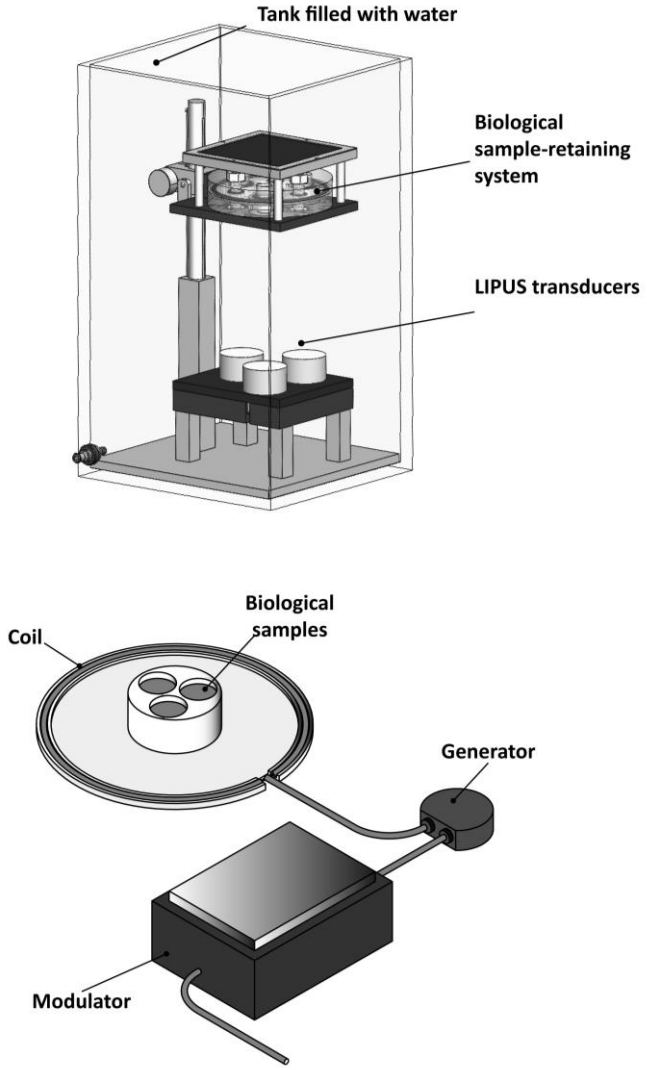

Fig. 1: LIPUS and PEMF set-ups.

D. Real-Time Quantitative Reverse Transcription Polymerase Chain Reaction (qRT-PCR) analysis

Twenty-four hours after the last stimulation, the total RNA was extracted with TRIzol® (Invitrogen) and purified with ReliaPrep™ RNA Miniprep System (Promega). Reverse transcription was performed using PrimeScript™ RT Master Mix (Takara Bio) and Real-Time qRT-PCR using PowerUp™ SYBR™ Green Master Mix (Thermo Fisher) in a Rotor-Gene Q (Qiagen). Relative gene expression of TNF-α, IL-1β, IL-6, IL-8, CD206 and IL-10 were normalized to 18SrRNA, analyzed with the ΔΔC(T) method [15] and expressed as Fold Change with respect to "M0" group for both the experiments.

E. Enzyme-Linked Immunosorbent Assay (ELISA)

Twenty-four hours after the last stimulation, the supernatant was collected and the concentration of TNF-α, IL-1β, IL-6, IL-8 and IL-10 was determined using Human ELISA kits (Invitrogen). The outcome was read in terms of absorbance at 450 nm with a Victor Nivo Multilabel plate reader (PerkinElmer).

III. RESULTS.

A. LIPUS stimulation

The results are represented in Fig. *2* (cytokine release) and Fig. *3* (gene expression). The gene expression of IL-8 decreased in the "M1+LIPUS" group, compared to the "M1" one. For IL-8, the same behavior was observed also at cytokine release level. An increase in IL-10 cytokine release was observed in the "M0+LIPUS" and "M1+LIPUS" groups, with respect to non-stimulated control.

B. PEMF stimulation

The results are shown in Fig. *2* (cytokine release) and Fig. *3* (gene expression). Both the gene expression and cytokine level of IL-1β and IL-8 decrease in the "M1+PEMF" group, compared to the "M1" group. Only for IL-8, a decrease was observed also comparing the "M0+PEMF" with the "M0" group. Moreover, a decrement of TNF-α was observed between the "M1+PEMF" group with respect to the "M1" group, both at gene and cytokine levels. An increase in IL-10 gene expression was observed in the "M0+PEMF" group, with respect to the "M0" group, whereas an increase in the CD206 marker was observed in the "M0+PEMF" group, compared to the "M0" group.

IV. DISCUSSION AND CONCLUSION

When inflammation occurs, ion channels are deeply involved in the activation of intracellular signal cascades and the corresponding production of cytokines. Mechanosensitive and calcium ion channels have been shown to be activated by ultrasound [16] and electromagnetic fields [17], respectively. This may be the reason for the beneficial results obtained, by applying LIPUS and PEMF stimulation protocols. The results of this work could constitute the ground for future studies, in which the underlying mechanisms of such a cell response could be investigated. Furthermore, LIPUS and PEMF treatments, thanks to their inherent safety, can be easily translated in vivo for the treatment of many diseases in which inflammation plays a key role.

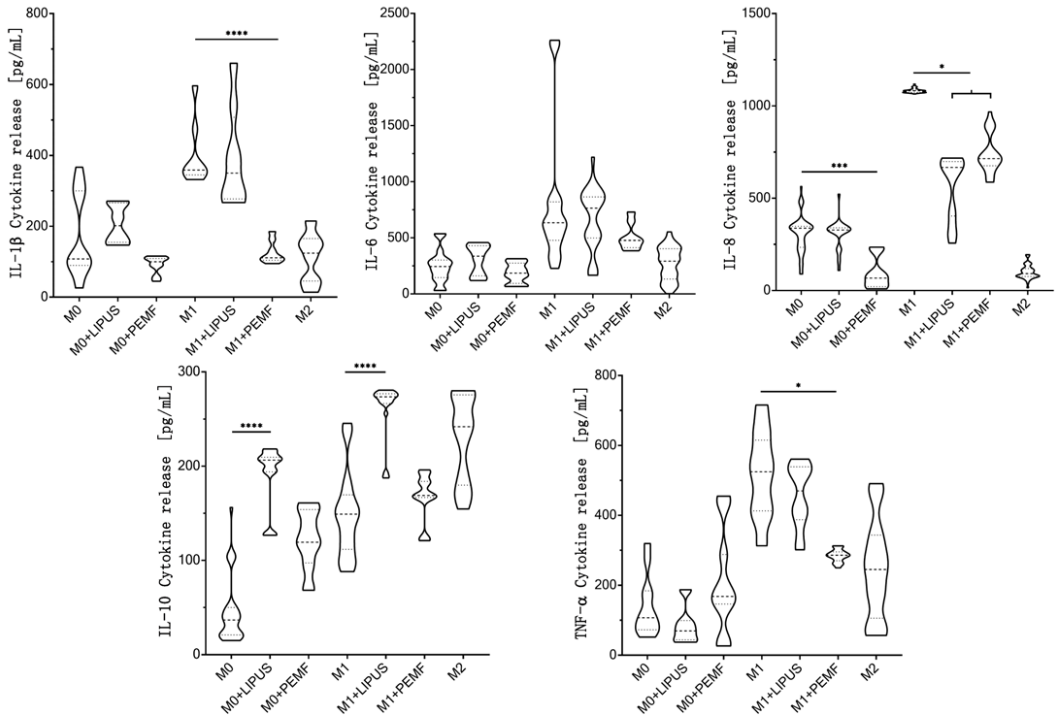

Fig. 2: Cytokine release of pro-inflammatory markers (IL-1β, IL-6, IL-8, TNF-α) and anti-inflammatory marker (IL-10), after LIPUS or PEMF stimulation. Only statistical differences between the "M0" groups and between the "M1" groups are reported. Kruskal-Wallis was applied, followed by Dunn's post-hoc test (GraphPad Prism 8); * = $p < 0.05$; ** = $p < 0.01$; *** = $p < 0.001$; **** = $p < 0.0001$. (N = 3)

***Abstract*—Mechanobiology aims at disclosing the functions and mechanisms by which mechanical, and architectural signals of the tissue microenvironment, control cell behaviors and cell states. Alteration in cellular mechanoperception and responsiveness is now recognized at the roots of cancer, and this is particularly well-appreciated in the context of lung adenocarcinoma. Here, adopting cutting-edge techniques from materials science, the different mechanical properties of microenvironment were precisely tuned within 2D polyacrylamide platforms over a range of pathophysiological stiffness (0.2–20 kPa). A first biophysical characterization of the effects of these platforms on normal (BEAS-2B) and tumoral lung epithelial cells (NCI-H23 and NCI-H1573) was performed. It emerged that cell ability to respond to substrate stiffness by regulating their adhesion and mechanical properties was progressively reduced with increasing cell tumorigenic potentials from BEAS-2B to NCI-H23 and metastatic NCI-H1573. Surprisingly, cell migration was less affected by both substrate stiffnesses and cell tumorigenicity, when analyzed in terms of cell speed. However, cell directionality, a parameter that describes cell ability to migrate in a persistent way without changing direction and then, to reach distant sites, was significantly increased in metastatic lung cells. This preliminary work lays the foundation for exploiting the behavior of lung adenocarcinoma cells in relationship to their mechanical microenvironment and unveil its potentiality as a diagnostic and/or prognostic and /or therapeutic.**

***Keywords*—Mechanobiology, Lung Adenocarcinoma, ECM stiffness, Cell Mechanics.**

I. Introduction

In the context of cancer mechanobiology, a large body of knowledge is continuously growing providing comprehension of the mechanical role of the local microenvironment as a cooperator of tumor cells in tumor onset and progression [1,2]. It is now widely appreciated that, during tumor growth, morpho-physical features of both cells and their neighborhood extracellular matrix (ECM) are altered, and these alterations result into a departure from the homeostatic cell-ECM mechanical equilibrium towards a new status characterized by an increased stiffness of the cell microenvironment. The tissues affected by malignant tumors are, in fact, characterized by ECM accumulation, that leads to a severe fibrotic response, known as desmoplasia, and consequent tumor stiffening [3]. Furthermore, the stiffening process occurring at the ECM level promotes the invasive nature of different tumor cells through the activation of specific molecular pathways and the mechanical transformation of tumor cells [4]. The lung adenocarcinoma, which is the most common histologic subtype of lung cancer in men and women [5], recapitulates the typical physical and mechanical properties of solid tumors: tumor cells undergo a softening process although residing in a stiffer matrix [6]. In fact, an altered ECM cross-linking has been found within lung cancer, where high laminin-5 expression and Lysyl oxidase-mediated collagen crosslinking correlated with lung cancer invasiveness [7]. All these aspects enlighten the pivotal role of the mechanical microenvironment in mediating tumor cell transformation and call for a systematic analysis to disclose the collaborative and synergistic interaction between cells and ECM in lung adenocarcinoma.

This can be performed by evaluating what happens in terms of biophysical and mechanical cell transformation, when lung cells with different oncogenic and tumorigenic potentials interact with highly controlled mechanical microenvironments. For this purpose, tissue engineering offers very advanced technological strategies to develop in vitro microenvironments with precisely incorporated topographical, biochemical, and mechanical cues. Specifically, hydrogels are considered crucial biomaterials in the field of tissue engineering since their mechanical properties (or stiffness) can be accurately tuned to replicate a variety of different human tissues, both in physiological and pathological conditions [8]. Here, epithelial cells of normal human lung (BEAS-2B cell line), and two mutant cell lines, the first one derived from a primary lung adenocarcinoma (NCI-H23) and the second one from a soft tissue metastasis of a stage 4 lung adenocarcinoma (NCI-H1573) were plated in sparse culture condition on soft (~0.2 kPa) and stiff (~24 kPa) polyacrylamide substrates which corresponds to the stiffnesses of normal and tumor tissues, respectively [9], and characterized in terms of adhesion, migration capability and mechanical properties.

II. Materials and methods

A. Preparation of substrates for cell culture

Polyacrylamide substrates were prepared as previously described [10] by using two solutions of acrylamide and methylene-bis-acrylamide (2.5% acrylamide/0.15% methylene-bis-acrylamide and 10% acrylamide/0.1% methylene-bis-acrylamide corresponding to 0.2 and 24 kPa,

respectively). Briefly, glass-bottom culture dishes (WillCo Wells, HBST-3522) were treated with 3-aminopropyltriethoxysilane (Sigma-Aldrich, St. Louis, MO, USA) for 10 min and the activated with 0.5% glutaraldehyde for 10 min. Polymerization of acrylamide/methylene-bis-acrylamide solutions was initiated by adding 1/100 total volume of 10% ammonium persulfate and 1/1000 total volume N,N,N′,N′-tetramethylethylenediamide (TEMED, Sigma-Aldrich, T7024, St. Louis, MO, USA). Twenty-five microliters of acrylamide/methylene-bis-acrylamide solutions were pipetted on the functionalized dishes and covered with a 20-mm coverslip. After 20 min, the coverslip was removed and PBS was added to the dish. To allow for cell adhesion, substrates were functionalized with ECM proteins. Briefly, the polyacrylamide was activated by covering the substrates with 0.5 mg/ml sulfo-SANPAH (Sigma,22589) in double-distilled water and exposing to 365 nm UV light for 6 minutes. The process was repeated once with a fresh aliquot of sulfo-SANPAH before substrate washing with 1× phosphate buffer saline (PBS, Microgem L0615) to remove unreacted reagent. Then, the hydrogels were coated with 30 µg/ml collagen solution from bovine skin (Sigma, C4243), 10 µg/ml fibronectin (Sigma, F0895) and 10 µg/ml bovine serum albumin (BSA, Sigma, A3059) and incubated at 37 °C for 3 hours before cell culturing.

B. Cell culture

BEAS-2B were cultured in BEBM Bronchial Epithelial Cell Growth Basal Medium (Lonza, CC-3171) complemented with the related growth factors and supplements (Lonza, CC-4175). NCI-H23 and NCI-H1573 were cultured in HiGlutaXL (TM) RPMI-1640 (Microgem, AL028G) supplemented with 10% fetal bovine serum (FBS, Sigma F7524), 1000 U/L penicillin and 100 mg/l streptomycin (Sigma, P4333). They were cultured at 37 °C in 5% CO2 in a humidified incubator.

C. Cell adhesion analysis

Cells were fixed and immunostained to evaluate the spreading area at 24 h from seeding. They were washed in PBS, fixed in 4% paraformaldehyde (Sigma Aldrich, 158127) for 15 min, and then rinsed three times with PBS and permeabilized in 0.1% Triton X-100 (Sigma-Aldrich) for 15 min. Cells were washed twice in PBS and blocked for 1 h and 30 min in 3% BSA. After washing in PBS, cells were incubated with Alexa 488 phalloidin (Invitrogen, A12379) at a dilution of 1:200 in PBS for 1 h and 30 min. Then, to facilitate cell recognition, nuclei were stained with Hoechst 33342 (ThermoFisher, 62249), at a dilution of 1:1000 in PBS for 15 min.

Specimens were imaged using an inverted microscope system (Multiphoton microscope, Leica) equipped with a 20× objective. The images were imported into ImageJ software (NIH, USA) for postprocessing and analysis. Individual cells were manually outlined, and their spreading areas were determined. At least 50 cells were analysed for each condition.

D. Cell mechanical properties

The cell mechanical properties were probed with a commercial atomic force microscope (AFM, Nanowizard II, JPK Instruments, Germany) as previously described [10]. At least 5 square arrays of 8 × 8 indentations, covering (2 × 2) µm^2 areas of cells were performed to quantify cell stiffness (Young's modulus).

E. Cell motility

To explore cell dynamics, migration experiments were performed using time-lapse microscopy (STED Leica inverted microscope with 10× objective and integrated stage incubator). The images were acquired at 10-minute intervals for 24 hours. The trajectories of individual cells were analysed using the software Fiji (NIH, Bethesda, MD, USA). The average cell speed was calculated as the path length divided by time and the cell directionality as the straight-line length between the start point and the endpoint of the migration trajectory, divided by the length of the trajectory. At least 40 cells were analysed for each condition.

F. Statistical analysis

Statistical comparisons were performed with a Student's unpaired test when data exhibit a normal distribution. Otherwise, a nonparametric Kruskal–Wallis test followed by post-hoc Dunn's test was used and the *p*-value is indicated (*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$).

III. Results and Discussion

A. Cell Adhesion

A large body of literature has accumulated showing the relationship between ECM mechanical properties and cell adhesion. To evaluate the ability of all three cell lines to mechano-sense the external microenvironment, their adhesion was analysed in terms of cell spreading area on soft and stiff substrates (Fig. 1).

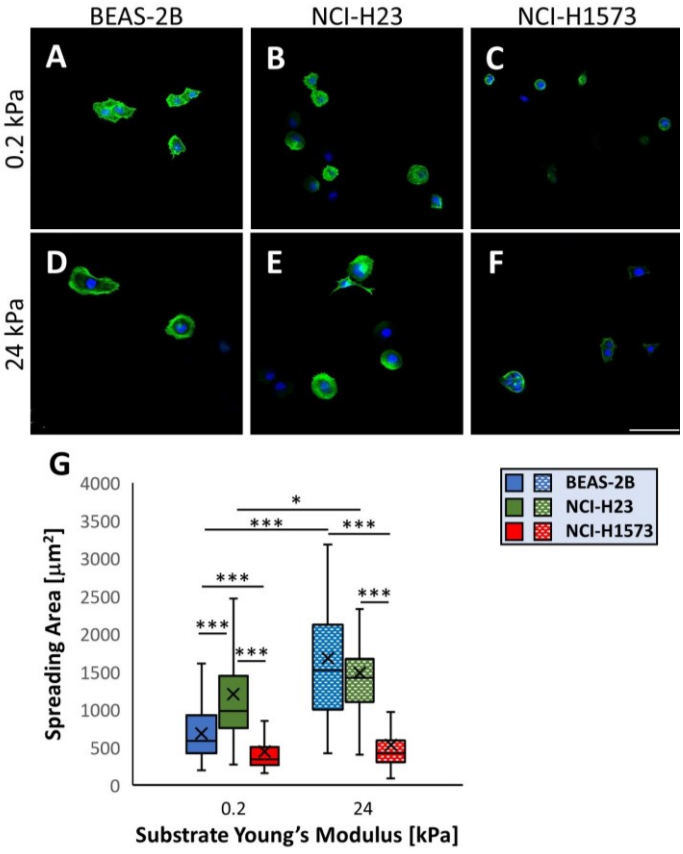

Fig. 1: Representative images of BEAS-2B (A, D), NCI-H23 (B, E) and

NCI-H1573 (C, F) cultured on soft, i.e., 0.2 kPa (A-C), and stiff, i.e., 24 kPa (D-F), are shown. Box plots (mean, median, and interquartile range) of spreading areas (G). Scale bar, 100 µm.

All three cell lines showed a cell spreading area positively correlated with substrates stiffnesses, except the metastatic cell line, i.e., NCI-H1573. Furthermore, NCI-H23 cells exhibited a higher spreading area than that of BEAS-2B on the soft substrate, whereas this behavior was reversed on the stiff one. A similar behavior has been observed in KRAS-mutated breast cancer cells (MDA-MB-231) characterized by greater and mature focal adhesion complexes when cultured in 1 kPa polyacrylamide substrates [10]. The most aggressive cell line (NCI-H1573) exhibited a significantly reduced adhesiveness on both soft and stiff substrates, indicating an impaired mechanosensory machinery.

B. Cell mechanics

A broad spectrum of works has demonstrated that the intimate association between substrate stiffness and cell morphology is mediated by adhesive structures formed in the plasma membrane, which connect the external ECM to the actin cytoskeleton. These structures can mature into larger structures called focal adhesions only when internally supported by the formation of contractile actin cables (stress fibers) which foster the cell spreading in a proportional way to their tensional state [11].

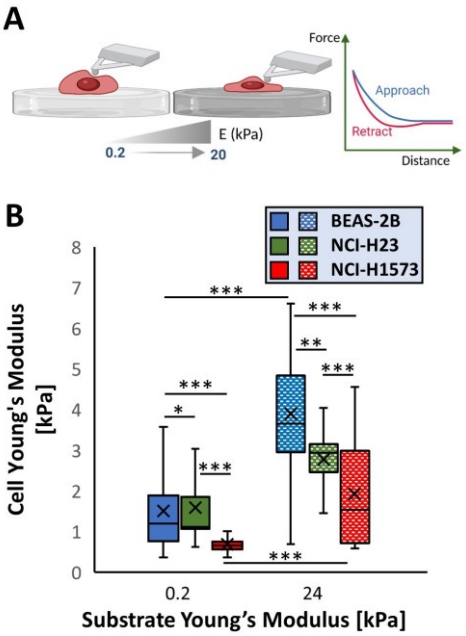

Fig. 2: Measuring the mechanical properties of cells cultured on substrates with different stiffnesses by AFM. Spherical AFM probe (6 µm-diameter) were used to squeeze the cortex filaments by applying 100 nm-indentation depths (A, left). Schematic diagrams of a force curve used to calculate cell mechanical properties (i.e., Young's modulus, A, right). Box plots (mean, median, and interquartile range) of cell Young's modulus (B).

Considering the differences in terms of cell adhesion among the three cell lines (Fig. 1), it is easy to figure that the actin cytoskeleton could be differently structured impacting on their mechanical properties. To validate this hypothesis, the AFM technique was used to investigate in which way changes in the oncogenic potential and substrate stiffness affected the elastic modulus of all cells (Fig. 2A). As expected, the cell Young's modulus positively correlates with the spreading area. Specifically, (1) a positive correlation between polyacrylamide stiffness and cell Young's modulus was found in all three cell lines, and, as reported for many other cell lines [6,10,12-14], (2) cell deformability directly correlates with the progression of a transformed phenotype form benign (BEAS-2B), tumor (NCI-H23) and metastatic cells (NCI-H1573, Fig. 2B).

C. Cell migration

The migration capability of BEAS-2B, NHI-H23, and NCI-H1573 cells in response to substrate stiffness was evaluated by computing two parameters: the average cell speed over a 24-h period and the cell directionality (Fig. 3).

As shown in Fig. 3A, NCI-H23 cells exhibited the lowest speed compared to the other two cell lines which resulted to move at similar average speed. Furthermore, all the three cell lines exhibited a cell speed which reduced with substrate stiffness, even if not in a significant way expect. This result can be explained by considering that substrate stiffness affects cell adhesion and mechanics and, probably, focal adhesion dynamics. Cell migration is, in fact, a process regulated by repeated cycles of adhesion to and de-adhesion from the ECM whose duration directly depends on focal adhesion dimensions: greater focal adhesions, generally associated to greater level of adhesion and stiffer cytoskeleton (as happens on stiff substrates), are characterized by longer life cycles which slow down the cell migration velocity [15].

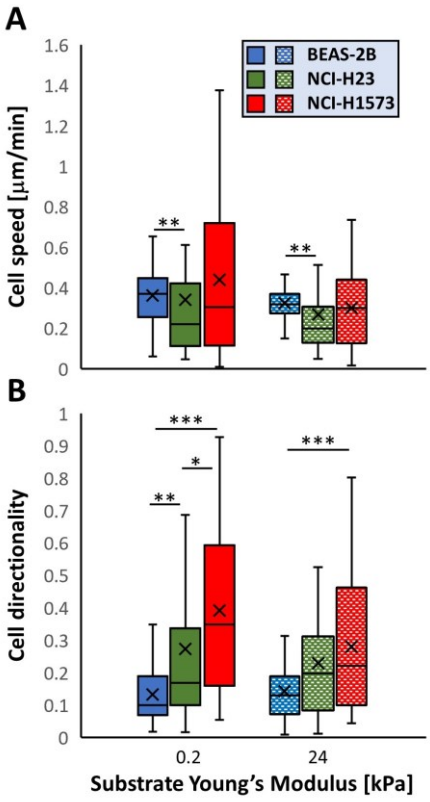

Fig. 3: Box plots (mean, median, and interquartile range) of cell speed (A) and cell directionality (B).

However, it is interesting to notice that the spread of cell speed in the data set of NCI-H1573 (see box plots in Fig. 3) is significantly larger compared to BEAS-2B and NCI-H23, because of a very inhomogeneous behavior with highly dynamic cells and other unable to move. On one side, the high cell dynamics can be explained by the increased level of focal adhesion kinase (FAK, a nonreceptor tyrosine kinase which regulates the disassembly process of focal adhesions) exhibited by some tumor cells [16]; on the other side, when the cell adhesion strength is very low (i.e., cell cytoskeleton is made by disorganized and not well-structured actin filament bundles), the contractile stress of the acto-myosin cytoskeleton is not sufficient to retract the trailing edge and to protrude forward the leading edge (i.e., cell migration is absent). Additional investigations will be performed to ascertain these hypotheses. It is important to underline that all the experiments on NCI-H23 and NCI-H1573, included migration, were performed in low-glucose conditions, even if ATCC recommends the use of high-glucose media. Further experiments will be conducted to evaluate the influence of the glucose concentration on cell functions and migration.

Another relevant parameter which describes the efficiency of cell migration is the directional persistence, here calculated as cell directionality. This parameter is the ratio between the start point-endpoint distance and the total length of cell trajectory. Values close to 0 indicate curved trajectories, whereas when the directionality approaches to 1, the trajectories are straight lines. What emerged from the experimental results was that cell directionality increased significantly with cell tumorigenic potential, whereas no substantial differences were found on soft and stiff substrates. This finding, in agreement with previous study performed on other tumor cells [10,17], indicates the natural propensity of metastatic tumor cells to move directionally.

IV. Conclusion

The stiffened tumor mechanical microenvironment of lung adenocarcinoma results to be involved in very important pathways associated with the cell malignant transformation. Notably, lung adenocarcinoma undergoes to an asymmetric mechanical modification of ECM and cell components: a lysyl oxidase-mediated collagen cross-linking engenders a stiffened ECM, whereas the mechanical properties of lung cancer cells result to be reduced in comparison with those of normal lung cells. It is worth considering that both modifications are correlated with stages of tumor development and seem to constitute conspicuous regulator factors of cancer invasiveness. Here, a first and preliminary analysis of the correlation between tumor ECM and oncogenic cell state has been proposed. Future investigations are needed to evaluate how the biophysical and mechanical properties of lung cells with different oncogenic and tumorigenic potentials and interacting with highly controlled mechanical microenvironments, are correlated with biomolecular pathways and, specifically with the activation of the epithelial-mesenchymal transition and the triggering of Hippo-YAP/TAZ signaling pathway.

***Abstract*—Rheumatoid arthritis (RA) is a chronic, inflammatory autoimmune disease that can cause irreversible joint damage and significant disability. Joint inflammation in RA is closely related to infiltration of immune cells, among which circulating T-cells and synovial resident macrophages play a critical role. Thus, including immune system in in vitro models is of crucial importance to better understand RA pathogenesis. Here, we developed a novel 3D microfluidic platform aimed at evaluating the active role of immune cells involved in RA. In particular, the platform was used to study spontaneous migration of Th1 T-cells towards pro-inflammatory M1 macrophages, thanks to the insertion of specific valves mechanism, allowing the trapping of immune cells inside the device and the stimulation of different cell types separately.**

***Keywords*—rheumatoid arthritis, immune cells, organ-on-chip, microfluidic valves.**

I. Introduction

RHEUMATOID arthritis (RA) is a chronic autoimmune disease involving diarthrodial joints that seriously affects human health [1], whose hallmark is an uncontrolled systemic inflammatory response that first undermines the synovium and progressively leads to articular joint damage, with severe joint swelling and pain [2]. In detail, joint inflammation in RA is closely related to the disruption of signalling networks and to the involvement of multiple immune cell types, among which synovial resident macrophages and circulating T-cells are considered key players [3]. However, the exact mechanism of RA development is still unknown, and it is well established that none of the currently available animal models fully represents human onset and progression [4], [5]. In this scenario, organs-on-chip offers a valuable solution to evaluate *in vitro* the involvement and the interaction of different cell types in RA conditions, and to assess patient-specific differences. To this end, we developed a novel microfluidic platform allowing to study the active role of immune cells involved in RA, initially aiming at validating a known mechanism in RA, characterized by the migration of Th1 T-cells towards pro-inflammatory macrophages [6], [7].

II. Materials and Methods

The proposed microfluidic platform (Fig. 1a) is realized through replica molding procedure and is composed of three PDMS layers: a top layer hosting valves mechanisms, a culture chamber layer, and a bottom unpatterned membrane (Fig. 1b). In detail, the culture chamber layer comprises two separate culture areas, whose communication is controlled through normally closed curtain valves (Fig. 1c). The first compartment, named *3D chamber*, is intended to host cells seeded in a 3D matrix, e.g. synovial resident macrophages, and is made of a central gel channel separated by two rows of post from two lateral medium channels. The second compartment, named *sieving valve chamber*, is composed of a single channel and is designed to precisely locate and culture cells in suspension, e.g. T-cells.

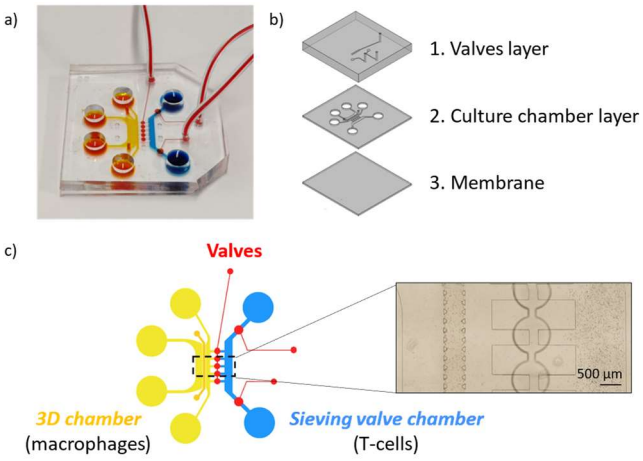

Fig. 1: a) Assembled microfluidic device; b) PDMS layers; c) Layout of the microfluidic device, with brightfield image of the two culture compartments.

The sieving valve chamber encompasses a novel technology, named *sieving valves*, which relies on normally closed curtain valves with underneath microgrooves that at rest allow the perfusion of fluids, but impair cell escaping, while once opened permit cell seeding and retrieval (Fig. 2).

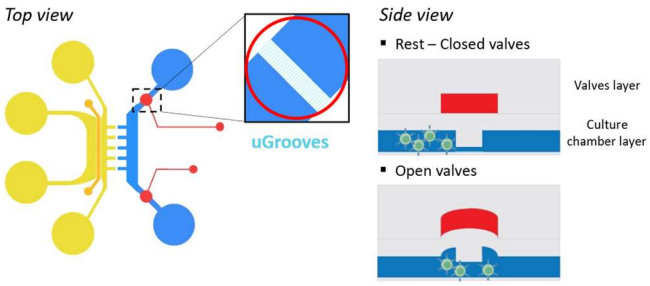

Fig. 2: Schematic of the *sieving valves* and their working mechanism.

After design and fabrication, the microfluidic platform was technically characterized. Firstly, sieving valves working mechanism was evaluated by using spherical polystyrene beads to mimic cell seeding in the *sieving valve chamber* with open sieving valves, as well as to assess proper cell trapping upon valves closure. Fluid perfusion over time through microgrooves with closed sieving valves was evaluated using color dyes. Moreover, this set-up was used to monitor beads behaviour upon central valves opening, in order to verify that

beads were not moving towards the *3D chamber* compartment due to convection given by the opening. Finally, FITC-dextran was used to assess proper communication between the two compartments with open communication valves, as well as the possibility to generate a concentration gradient from the *3D chamber* to the *sieving valve chamber*. In detail, the central channel of the *3D chamber* was filled with fibrin gel, and 4 kDa FITC-dextran was injected in the outermost medium channel. FITC-dextran diffusion towards the *sieving valve chamber* with open communication valves was then assessed through quantification of fluorescence intensity over time along the width of the culture chamber layer (Fig. 3).

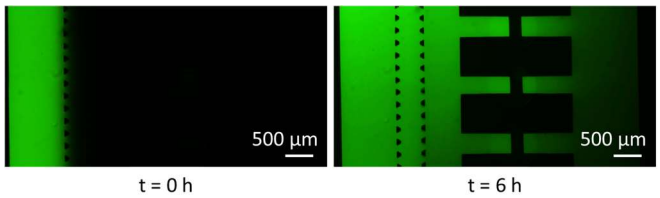

Fig. 3: Fluorescence microscope images showing FITC-dextran diffusion over time.

To carry out the biological experiments, after isolation by magnetic cell separation from human buffy coat, CD14+ monocytes were pre-cultured in flask for 5 days with MCSF (20 ng/ml), in order to let them differentiate into macrophages. Then, they were seeded into the *3D chamber* embedded in a fibrin gel (i.e., 10 mg/ml of fibrinogen and 2.5 U/ml of thrombin) at a final cell density of 12,5 x 10^6 cells/ml, and culture conditions were optimized to induce a pro-inflammatory M1 phenotype. Specifically, culture medium was supplemented with 100 ng/ml IFN-γ and 100 ng/ml TNF-α for three days, and proper macrophage polarization was assessed at day 3 and at day 4 through immunofluorescence analysis of M1 markers (e.g. CD80, CD86) and of CXCL16, i.e. a protein relevant in RA mechanisms [8].

A protocol was then optimized to induce T-cells differentiation towards Th1 phenotype. Naïve CD4+ T-cells isolated from human buffy coat were seeded in the *sieving valve chamber,* taking advantage of the novel technology, and stimulated for three days with 2 µg/ml anti-CD3, 2 ng/ml IL-12 and 5 µg/ml anti-IL-4. T-cells polarization was evaluated through flow cytometry analysis of intracellular cytokines (i.e. IFN-γ), as well as through immunofluorescence staining of transmembrane markers, e.g. CXCR6 [8].

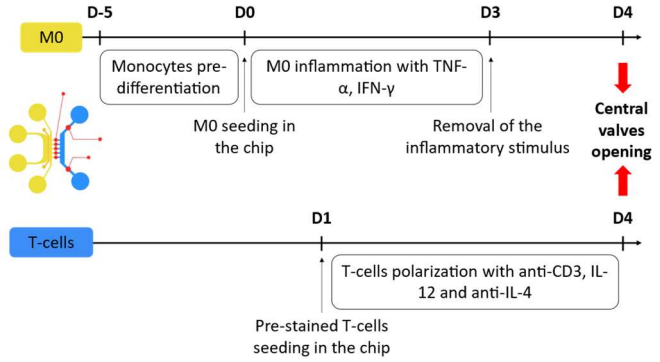

Fig. 4: Schematic of the experimental plan to assess Th1 T-cells migration towards M1 macrophages inside the microfluidic platform.

Finally, an experiment was carried out to study the interaction between pro-inflammatory macrophages and Th1 T-cells. Briefly, human monocytes-derived macrophages (M0) embedded in fibrin gel were seeded at day 0 in the *3D chamber* and stimulated with TNF-α, IFN-γ for 72 hours to induce polarization towards M1. At day 3, the inflammatory stimulus was removed. CD4+ T-cells were stained with CellTracker™ Green CMFDA (Invitrogen), seeded in the *sieving valve chamber* at day 1, and stimulated with anti-CD3, IL-12 and anti-IL-4 until day 4. On day 4, recruitment of Th1 T-cells operated by M1 macrophages upon central valve opening was evaluated. The experimental plan is summarized in Fig. 4.

III. RESULTS

Technical characterization with polystyrene beads proved the necessity to include sieving valves to trap cells in suspension inside the platform. After seeding beads in the *sieving valve chamber* with open sieving valves, a blue dye was inserted in the medium reservoirs. With open sieving valves, i.e. simulating the absence of sieving valves, all the beads were immediately flushed away. On the other hand, with closed sieving valves, beads remained confined in the *sieving valve chamber*, and a slow but sustained perfusion of dye through the microgrooves was detected over time (Fig. 5a). Moreover, specific tests confirmed that beads migration does not occur just upon central valves opening, while slow diffusion of the color dye could be observed.

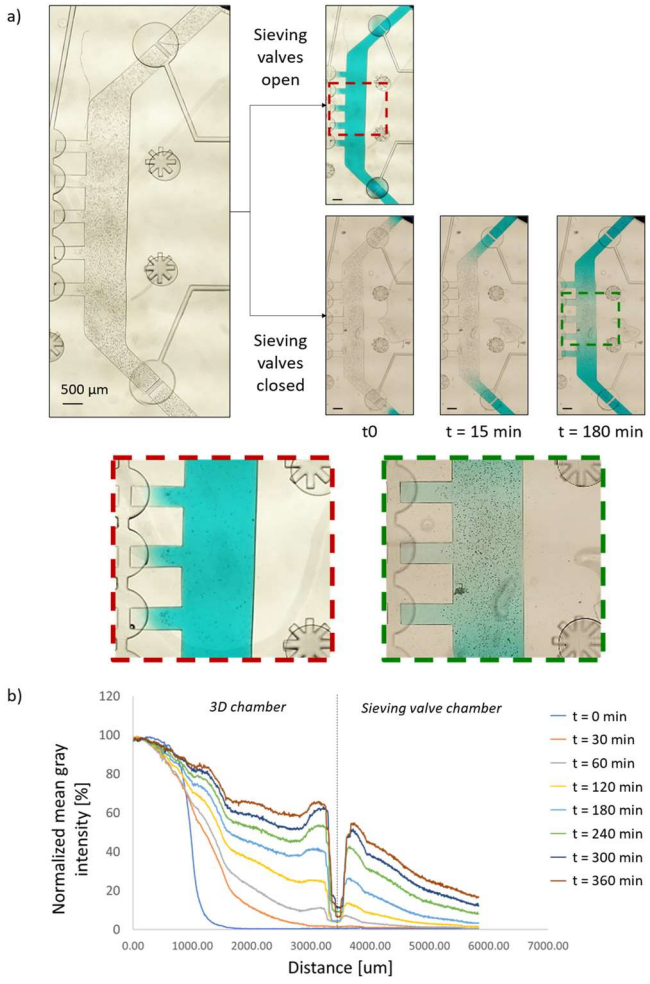

Fig. 5: Technical validation of the platform. a) Characterization of sieving valves working mechanism by using polystyrene beads and color dye. b) Quantification of dextran diffusion from the 3D chamber towards the sieving valve chamber at different time-points.

Results of the FITC-dextran diffusion tests demonstrated that the two culture compartments were in proper communication with open central valves, and that a FITC-dextran gradient was created from *3D chamber* to *sieving valve chamber* and was maintained up to 6 hours (Fig. 5b), confirming that this device can be used to recapitulate a concentration gradient to induce cells migration towards an appropriate chemotactic stimulus.
As proven by immunofluorescence staining (Fig. 6) of M1 marker CD80, macrophages polarized to a pro-inflammatory state after three days of inflammatory stimuli inside the platform. Moreover, an increase in the secretion of CXCL16 was detected. Importantly, these results were maintained also at day 4, i.e. one day after having removed the inflammatory stimulus. This indicates that the pro-inflammatory phenotype is stable, and in a complete experiment it gives the possibility to open the central valves at day 4, having removed from the culture medium cytokines (i.e. TNF-α, IFN-γ) that could mask the effect of proteins directly secreted from the macrophages.

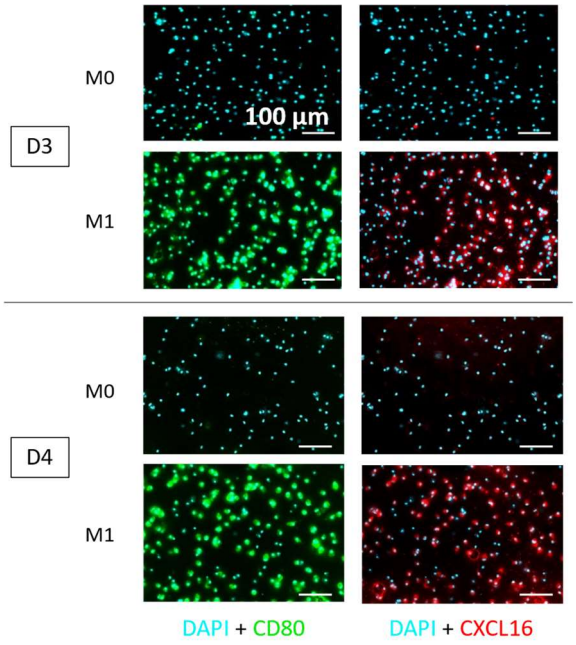

Fig. 6: Immunofluorescence staining of macrophages embedded in fibrin gel in the device, in control (M0) vs. inflammatory conditions (M1).

Consequently, as demonstrated through flow cytometry analysis of intracellular cytokines (i.e. IFN-γ), T-cells stimulation could induce polarization to Th1 phenotype after three days. Moreover, Th1 T-cells overexpressed CXCR6 with respect to controls (Fig. 7).

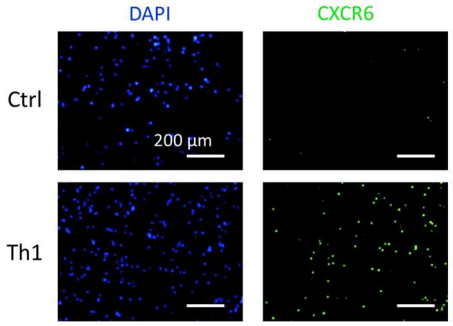

Fig. 7: Immunofluorescence staining of T-cells inside the platform in control (Ctrl) vs. inflammatory conditions (Th1).

Finally, after having validated the possibility to stimulate the two cell types independently thanks to the platform compartmentalization, a comprehensive biological validation was performed, assessing CXCR6-expressing T-cells migration from the *sieving valve chamber* towards the *3D chamber* in presence of M1 macrophages. After stimulation, migration of Th1 T-cells towards pro-inflammatory macrophages (M1) occurred spontaneously (Fig. 8), as compared to controls (M0), indicating the suitability of the platform to study immune cells cross-talk and migration due to chemoattraction.

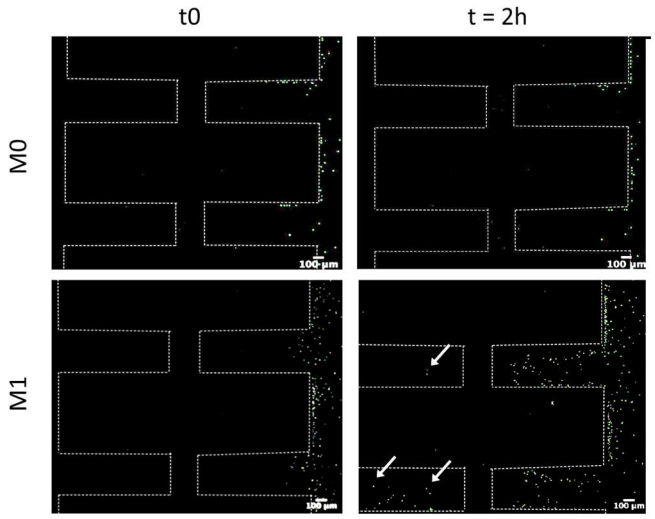

Fig. 8: Migration of pre-stained T-cells from the *sieving valve chambers* towards the *3D chamber*, comparing the effect of M1 macrophages with respect to control (M0 macrophages). White arrows indicate migrating T-cells.

IV. Conclusion

The proposed device offers an innovative solution to trap a limited number of immune cells inside microfluidic chips and to study the cross-talk between different cell types, having the possibility to stimulate them separately. The platform was proved to be a suitable tool to assess Th1 T-cells migration towards pro-inflammatory resident macrophages, replicating a known mechanism in RA. The use of the technology in combination with more complex synovial microscaled constructs is currently under evaluation, and will eventually increase the understanding about unknown mechanisms in RA progression. Moreover, the *sieving valves* technology is highly versatile and can be potentially applied to assess the interaction of immune system in manifold disease and more complex models.

***Abstract*— In recent years *in situ* bioprinting has gained more attention thanks to the possibility of automatically and precisely depositing biomaterials ink/bioinks directly on the patient's site, thus, overcoming the limitations of the current approaches. This study aimed at evaluating the possibility of using a valve-jet technology for *in situ* bioprinting. When combined with other bioprinting technologies, such as extrusion-based bioprinting, multimaterial and multiscale *in situ* bioprinting can be achieved to recapitulate the complex structure and architecture of native tissues.**

***Keywords—In situ* bioprinting, valve-jet technology, multimaterial/multiscale scaffolds.**

I. Introduction

Recently, *in situ* bioprinting has gained more attention since the possibility to print directly inside the patient's body, for instance, by using a robotic system, which resolves the limitations of conventional bioprinting approaches, e.g., scaffold manipulation and sterilization, incomplete tissue-scaffold integration, the need for bioreactors [1].

Different bioprinting techniques have been adapted *for in situ* bioprinting, such as extrusion-based bioprinting (EBB), laser-assisted bioprinting (LAB), and droplet-based bioprinting (DBB). While the first is usually applied for printing high viscous solutions, the others can process low viscous bioinks which, however, limit the fidelity of the fabricated structures [1]. This issue may be overcome by combing diverse bioprinting strategies as reported by Moncal et *al.,* who applied EBB to print a high viscous bone bioink and DBB for printing skin layers with less viscous bioinks [2].

Among the DBB technologies, valve-jet technology is a promising Drop-on-Demand deposition system with the capability of handling solutions with a wide range of viscosities (i.e., 0.05-500 Pa*s [3]) than conventional inkjet printing, as well as larger drop volumes (i.e., more than 1nL vs. 1-100 pL for thermal/piezoelectric inkjet [4]). It is possible to generate a greater force by adjusting the pneumatic pressure, as opposed to conventional inkjet where the driving force is heat or acoustic waves. In fact, an orifice-valve mechanism controls the droplet generation and the break-up through a piezoelectric or solenoid actuator [5]. The valve-jet mechanism is also useful for printing solutions containing drugs and/or biomolecules which may be susceptible to the processing conditions such as temperature and stress elements [4]. Furthermore, some studies demonstrated the feasibility of the valve-jet technology in the bioprinting of cells, such as human pluripotent stem cells (hPSC) and human embryonic stem cells (hESC) without interfering with their biological properties and vitality [6,7].

Taking into consideration the potential of valve-based systems, this study aimed at integrating valve-jet technology in a previously designed robotic platform for *in situ* bioprinting [8]. Compared to the pneumatic extrusion currently used in the robotic platform, this will give the possibility to print more viscous biomaterials, and deposit precise volumes. Firstly, hardware and software upgrades were made by developing ad-hoc electronics for controlling the valve-jet system. Secondly, the valve-based dispensing system was characterized in terms of the printability of solutions with Pluronic® F-127 since the well-known rheological properties [11]. Droplets were quantitatively (*i.e.*, diameter dimension) evaluated by changing the printing parameters (*i.e.*, applied pressure, valve signal period, and distance from the substrate) while keeping the same dispensing needle. Keeping the applied pressure and distance constant, the optimal valve signal period was chosen in order to have a good overlapping between droplets, enabling the formation of a continuous line. Lastly, as a proof-of-concept, *in situ* printing tests were executed on a 3D printed poly-L-lactic acid (PLA) complex substrate.

II. Materials and Methods

A. In situ bioprinting platform

The bioprinting platform consists of a 5 Degrees-of-Freedom (DoF) robotic arm – IMAGObot – featured with different tools for surface scanning and reconstruction, and EBB *in situ* bioprinting, also on moving substrates [8–10]. The platform is controlled through LinuxCNC, a software for Computer Numerical Control (CNC) machines control, while a previously designed MATLAB Graphical User Interface (GUI) is used for the generation and planning of the *in situ* bioprinting path.

B. Hardware and software upgrades

The valve-jet system used in this study is a needle valve (DA 400 EV, DAV tech, Italy) designed to dispense in a controlled, precise, and repeatable way, fluids with medium to high viscosity[11]. The valve is featured nozzles in various shapes and sizes. Since the solenoid valve is mounted directly on board, it allows a high-precision deposition making it ideal to be integrated into automated systems, such as robotic arms. The valve jet was connected to the robotic arm taking advantage of the previously designed semi-automatic tool change. Briefly, this consists of an electromagnet on the end-effector and a metallic disk placed on the tool, whose connection/disconnection is controlled by the user through the LinuxCNC GUI [9] (Fig. 1).

Ad-hoc electronics were designed to control the opening/closing of the solenoid valve through an Arduino UNO microcontroller. A pressure regulator (ITV0011-2BL-Q, SMC Pneumatics) was used to control the material extrusion via flexible tubing.

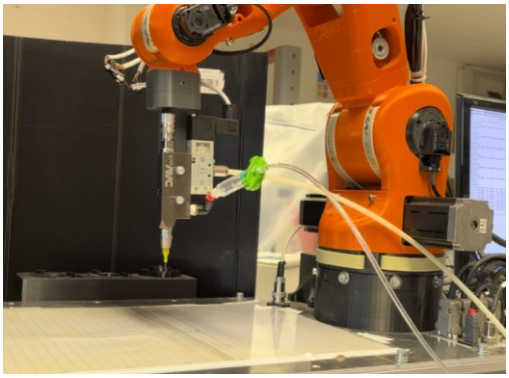

Fig. 1. *In situ* bioprinting robotic platform integrated with the valve-jet deposition system

A user-defined command was created, namely *M103*, to control the valve opening/closing through the G-code file uploaded in LinuxCNC. In detail, the opening and closing are controlled by the M command parameter *P* (*i.e.*, *M103 P1* and *M103 P0* to open and close the valve, respectively). A Python script was written to send, by serial communication, the value assigned to *P* to the Arduino digital pin which controls the valve status.

Two different modalities were created: (i) pausing the movements between droplets deposition; (ii) continuous deposition while moving. In the first case, the opening and closing time is defined by the G-code command *G4 PX*, which stops the program for *X* seconds, keeping the robot in a fixed position. Thus, the droplet is generated by alternating the opening command (*M101 P1*), the pause (*G4 PX*), the closing command *(M101 P0),* and another pause. In the second case, another parameter is added to the opening command *M101 P1*, namely *QX*, which defines the valve signal period in seconds (*i.e.*, *M101 P1 Q1* means that the valve is kept open and close for 0.5s each). The command is sent to Arduino at the beginning of the G-code, enabling droplet formation and deposition while the robot is moving.

The valve signal period, as well as the droplet generation modality, is defined by the user in the MATLAB GUI used for *in situ* printing path planning.

Similarly, the pressure applied to the reservoir is controlled through a specific M command, *M3* which allows the material extrusion to define the desired pressure in *bar*. The command is defined at the beginning of the G-code, or before the valve opening command if changed during the printing process (Fig. 2B). As for the opening valve time, the pressure is set by the user in the MATLAB GUI.

C. *Printing tests*

Preliminary printing tests were performed by using a solution of Pluronic® F-127 (Sigma-Aldrich, Italy) 20% (w/v) with a 0.66mm-inner diameter dispensing needle. Since its well-known rheological properties (*e.g.*, viscosity of 200 mPa*s at 25 °C 20% (w/v) [12,13]), this limits the printing parameters to investigate the reservoir pressure, the valve signal period, and the end-effector distance from the substrate. The generated droplets were quantitively and qualitatively characterized by analyzing their diameter and shape. In detail, arrays of 4 droplets (5mm equally spaced) were deposited on a glass slide along the X axis, keeping the nozzle diameter constant, and changing one of the parameters at a time, *i.e.*, the applied pressure (from 0.5 bar to 1bar), the valve signal period (from 0.02s to 1s) and the distance from the substrate (from 2.5 mm to 10 mm). For each test, the droplet diameter was measured in ImageJ software [14].

Once the optimal pressure and distance were selected, droplets were weighted with a precision balance (1µg), and the droplet volume was estimated given the solution density.

To perform a continuous deposition of droplets (i.e., second printing modality), it is necessary to define the optimal valve signal period in order to guarantee a good overlapping between consecutive droplets. Hence, different arrays of droplets were continuously deposited only varying the valve signal period and keeping the robot's linear speed at 1 mm/s.

Lastly, as a Proof-of-Concept, the valve-jet system was used for the *in situ* printing Pluronic® F-127 of a serpentine pattern onto a substrate 3D printed in PLA, using the optimal printing parameters (i.e., applied pressure, distance, and valve signal period) which ensured the formation of continuous lines.

III. Results and Discussions

The possibility of using the valve-based technology on the *in situ* printing platform was feasible thanks to the upgraded electronics and software. As expected, the diameter of the dispensed droplets increased with the applied pressure (Fig. 2A) and the valve signal period (Fig. 2B)

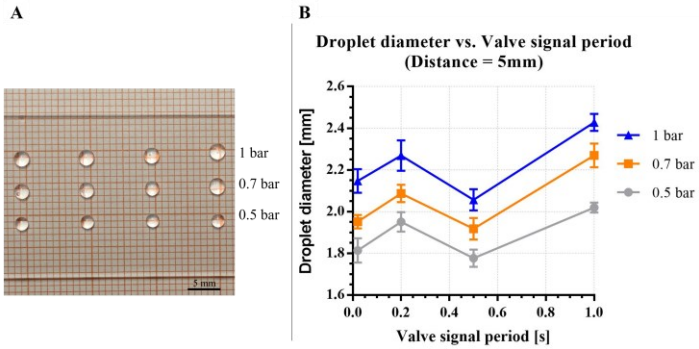

Fig. 2. (A) Array of droplets deposited varying the applied pressure (0.5-1 bar) and keeping the distance and valve signal period respectively at 5mm and 1s; (B) Droplet diameter vs. Valve signal period, varying the pressure from 0.5 bar to 1 bar, and keeping the distance at 5mm.

Since droplets formed and deposited only when varying the pressure between 0.5 and 1 bar, a pressure of 1 bar was selected in order to ensure the formation of the droplets. Considering the distance from the substrate, a 5 mm distance was selected, giving an average droplet diameter of 2.2 mm (Fig. 3).

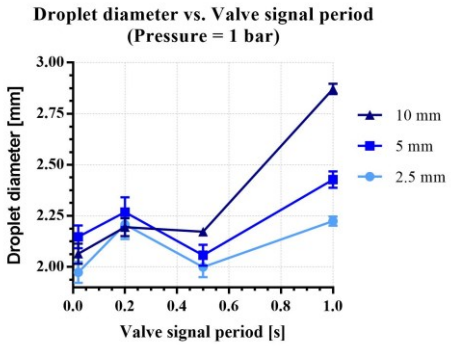

Fig. 3. Droplet diameter vs. Valve signal period, varying the distance from 2.5mm to 10mm, and keeping the pressure at 1 bar.

Keeping the pressure of 1 bar and the distance at 5mm, the droplet volume varied from 0.5 to 1 µL as the opening time (depending on the valve signal period) increased (Fig. 5).

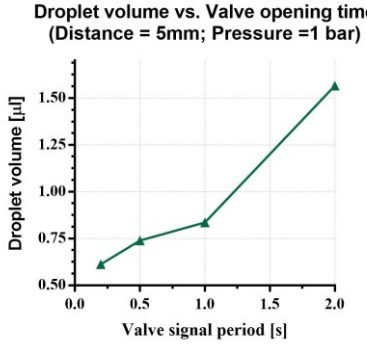

Fig. 4. Droplet volume vs. Valve signal period, keeping the pressure and distance at, respectively, 1 bar and 5mm.

Considering the valve signal period, the optimal that ensured a good overlapping was 1s, as depicted in Figure 6.

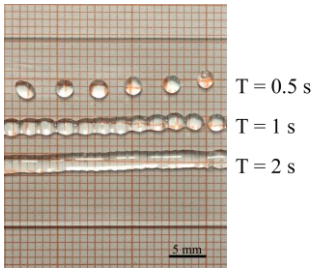

Fig. 5. Droplet deposition varying the valve signal period (0.5-2s) to form a continuous line while moving.

Thus, *in situ* printing tests were performed with Pluronic® F-127 keeping the pressure at 1 bar, a distance of 5mm from the substrate, and a valve signal period of 1 s, and keeping the robot linear speed at 1mm/s. *In situ* printing was successfully performed on a substrate 3D printed in PLA, featuring a complex curved surface. As expected, continuous lines were formed with the optimal parameters selected (Fig. 6).

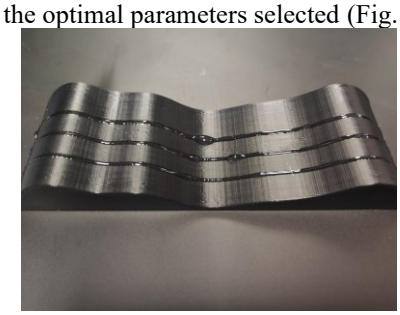

Fig. 6. Proof-of-Concept: *In situ* printing test on a curved surface substrate, with the optimized printing parameters to form a continuous line.

CONCLUSION

The present study demonstrated the possibility to use the valve-jet technology for *in situ* bioprinting applications with a robotic platform. The versatility of the valve-based techniques in handling various viscous solutions combined with the presented robotic platform enables the possibility to deposit droplets in a precise and automatic manner compared to the current pneumatic extruder used in the robotic platform. In addition, valve-jet technology can also be used in drug delivery, specifically, to print drug-loaded solutions, and thus create functional patches or scaffolds not printable with other AM technologies. Furthermore, by exploiting the semi-automatic change-tool system of the robotic platform, the valve-jet and extrusion bioprinting tools can be combined to print hydrogels with different viscosities and creating structures at different scales, which could be useful to recapitulate the complex multimaterial/multiscale structures of native tissues.

***Abstract*—Biological tissue substitutes need to be appropriately stored in order to provide ready-to-use solutions for patients with immediate necessity. In this preliminary study, different native porcine tissues (i.e., pericardium, ureter, descending aorta, and small intestinal submucosa) were subjected to cryopreservation at -80°C with a specific solution based on the use of 10% DMSO with the aim to evaluate the effects on ECM composition by means of histological analysis and biomechanical tests (i.e., tensile and stress-relaxation tests). Morphologically, all tissues appeared microscopically well preserved; from the biomechanical point of view, some tissue-dependent changes were detected.**

***Keywords*—Cryopreserved tissue, tissue engineering, regenerative medicine.**

I. Introduction

THE need for ready-to-use substitutes for surgical purposes is increasingly growing in order to repair or substitute non-functional or diseased organs and tissues. Next to synthetic materials, which have the advantage of suitable and predictable mechanical features and biodegradability, but with limited biocompatibility, biological materials derived from animal tissues are preferred for their biological characteristics that can favour tissue regeneration upon *in vivo* implantation, since they are rich in growth factors. However, one of the limitations in the use of biological tissues is due to the time needed to decellularize them and make them compatible by removing all the animal cells and DNA, while maintaining the integrity of the extracellular matrix (ECM) which has to work as a scaffold for the recipient's cells. Generally, decellularization procedures take some days; moreover, a sterilization step is also needed after decellularization and before seeding the tissue with the patient's cells, thus extending the duration of the procedure. For these reasons, the possibility to cryopreserve the decellularized tissue in order to have a ready-to-use scaffold with unaltered morphological and mechanical features is becoming more and more attractive. In this way, cryopreservation allows the immediate availability of implantable tissues and organs. Until now, several studies on cryopreservation have been reported especially for ovarian tissue [1]–[3] and for other materials [4]–[19], but only limited investigations concern decellularized tissues [20], [21].

In this preliminary study, we decided to focus on native tissues, which include porcine pericardium, small intestinal submucosa (SIS), ureter and descending aorta; future experiments will be performed on decellularized tissues in order to assess and optimize the cryopreservation protocol.

Native tissues were cryopreserved using a solution with 10% Dimethyl Sulfoxide (DMSO) and 10% FBS at -80°C and were compared with fresh ones in terms of mechanical behaviour and histology, in order to evaluate possible effects of cryopreservation on different types of native tissues.

II. Materials and Methods

A. Tissue collection and cryopreservation

Porcine pericardium, ureters, jejunum and descending aorta were obtained from a local slaughterhouse, whose protocols followed EC regulations 1099/2009, were supervised by the Italian government, and approved by Food and Consumer Product Safety Authority. Pericardium was isolated as illustrated by Aguiari et al. [22] and SIS as described by Casarin et al. [23]. In the case of ureter and descending aorta, external fibrous tissue was removed by surgical scissors.

Native tissue samples were split into 2 groups: the fresh group and the cryopreserved group. Once grossly dried, the native tissues underwent the cryopreservation protocol: it consisted in soaking the tissues in a solution composed by 10% FBS (Fetal Bovine Serum, Gibco, cod. 10270106) and 10% DMSO (Dimethyl Sulfoxide, Sigma, cod. 452301) in DMEM high glucose (Life technologies, cod. 41965-039) and immediately stored at -80°C. When needed for subsequent analyses (after 1.5 – 4.5 months), cryopreserved tissues were thawed at 37°C in a water bath and then statically washed at room temperature with saline solution, which was changed several times until samples remained completely transparent.

B. Histological Analysis

Fresh and cryopreserved native tissue samples were frozen in optimum cutting temperature (OCT) compound and then cryosectioned with 6 µm thickness. Hematoxylin and Eosin (BioOptica, cod. 04-061010) were performed following manufacturer's instructions in order to stain nuclei in blue and cytoplasm in pink.

C. Mechanical tests

Mechanical evaluations of fresh and cryopreserved native pericardium, SIS, ureter and descending aorta were assessed along the circumferential and/or longitudinal direction as specified in Table I.

TABLE I: DETAILS OF TESTS PERFORMED ON FRESH AND CRYOPRESERVED TISSUES

Tissue	*Test*	*Type*	*Test direction*	*# samples*
Pericardium	Rupture	Fresh	Circumf	9
		Cryo		13
	Stress relaxation	Fresh	Circumf	4
		Cryo		4
Ureter	Rupture	Fresh	Longitud	18
		Cryo		10
	Stress relaxation	Fresh	Longitud	9
		Cryo		7
SIS	Rupture	Fresh	Circumf	12
		Cryo		6
		Fresh	Longitud	12
		Cryo		6
	Stress relaxation	Fresh	Circumf	9
		Cryo		4
Descending aorta	Rupture	Fresh	Circumf	9
		Cryo		9
		Fresh	Longitud	9
		Cryo		9
	Stress relaxation	Fresh	Circumf	8
		Cryo		6

Cryo = cryopreserved native tissue; Circumf = circumferential direction; Longitud = longitudinal direction.

Conduits (i.e., SIS, descending aorta and ureter) were cut longitudinally, along the parallel direction of the conduit axis, and circumferentially, along the perpendicular direction. For pericardium, the chosen direction was the circumferential one, which corresponds to the circumferential direction of the heart.

Tissues were cut into dog-bone shaped specimens (gauge dimensions of 5mm × 2mm) [24] and their thickness was measured with a digital calliper (Mitutoyo, ID-C112XB). Samples were submitted to uniaxial rupture tests and stress-relaxation tests at room temperature using a custom-made apparatus (IRS, Padova, Italy); during the tests, samples were maintained hydrated with saline solution. Before each type of test, samples were pre-loaded up to 0.1 N and then subjected to a constant mechanical load with 0.2 mm/s elongation rate (L_0=5mm). Rupture tests were performed elongating the sample until failure; from the corresponding stress-strain curve, the Young's modulus (E) was calculated as the slope of the curve in the linear region, while the Ultimate Tensile Strength (UTS) and the Failure Strain (FS) were calculated as maximum resistance and elongation, respectively. Finally, stress-relaxation tests were realized by elongating samples (0.2 mm/s) until 10, 20, 30 40 and 50% of the initial length with 300 s holding time after each elongation. Stress decreasing (%) was evaluated as the difference between the maximum stress and the plateaux of the curve.

Graphs of mechanical tests were obtained with an in-house developed Matlab® script (Mathworks, Natick, MA, USA).

D. Statistical Analysis

All variables were expressed as mean ± standard deviation. Comparisons between native and cryopreserved tissues were conducted with t-test using GraphPad Prism (version 7.0 for MacOs) (GraphPad Software, San Diego, California, USA). Significance was set at $p<0.05$.

III. RESULTS

A. Histological evaluations

Microscopically, fresh and cryopreserved tissues were histologically evaluated using Hematoxylin and Eosin staining (Fig. 1), which demonstrated optimal ECM preservation in all investigated tissues.

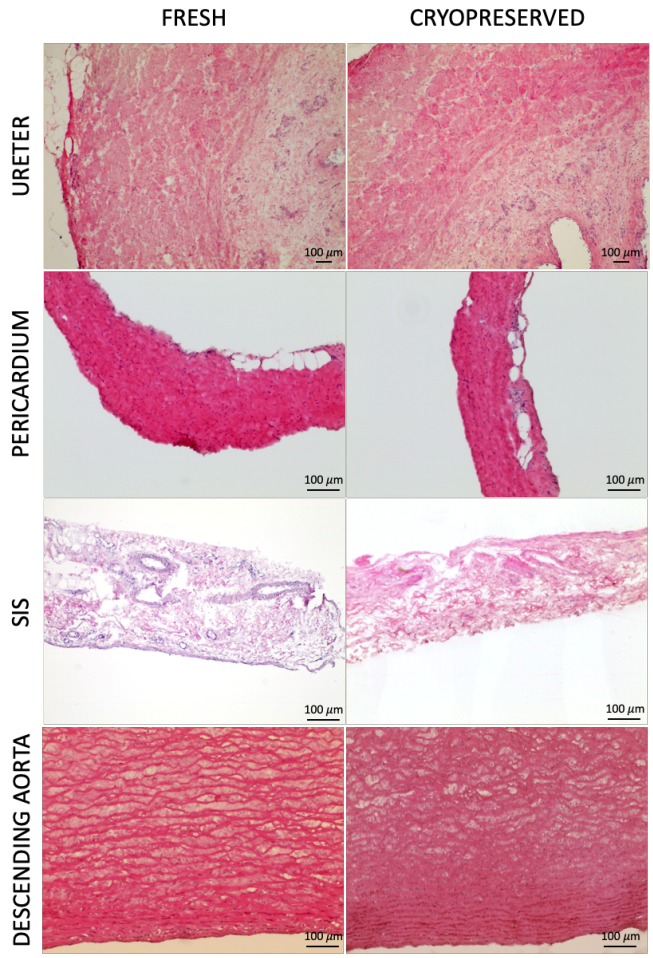

Fig. 1: Histological evaluation with Hematoxylin and Eosin staining of fresh and cryopreserved ureters, pericardia, SIS, and descending aortas.

B. Mechanical evaluations

Rupture tensile tests performed on fresh and cryopreserved pericardium demonstrated the absence of any significant difference between the two groups in thickness, FS, E and UTS, while in the case of ureters, significant differences were found in FS (it increased in cryopreserved tissue) and E (it decreased). Significative differences were observed also in SIS thickness ($p < 0.0001$), which increased in the case of cryopreserved samples, and Young's modulus both in circumferential and longitudinal directions: it decreased in cryopreserved tissues, but no statistical difference was found in FS and UTS values along both directions. Overall, tissue anisotropy was maintained after cryopreservation process. Finally, a significant increase of thickness ($p = 0.0443$) and UTS along the circumferential direction was detected in aorta samples; significant increases of FS along the longitudinal direction and of E along the circumferential one were found.

No significant difference was checked for FS along the circumferential direction and for E along the longitudinal one. The biomechanical parameters from the rupture tests are shown in Fig. 2 and thickness values are reported in Table II.

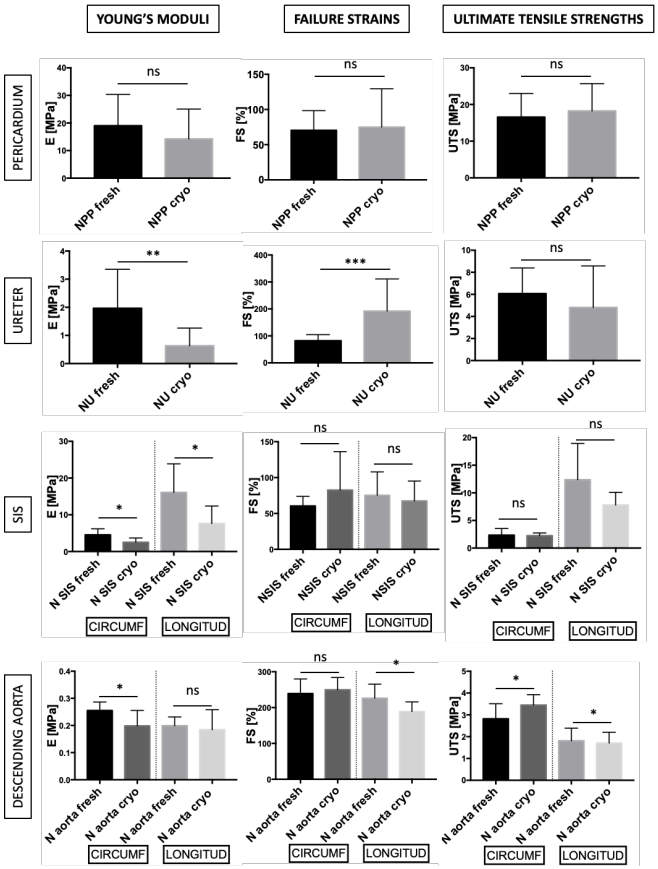

Fig. 2: Biomechanical parameters (E, UTS and FS) from rupture tests of fresh and cryopreserved pericardium (NPP), ureter (NU), small intestinal submucosa (SIS) and descending aorta. SIS and aorta were tested both along circumferential (circumf) and longitudinal (longitud) directions. Data on graphs are expressed as mean ± standard deviation; data were statistically analysed by t-test: ns=non-significant difference, *p<0.05, **p<0.01 and ***p<0.001.

TABLE II: THICKNESS OF FRESH AND CRYOPRESERVED SAMPLES (MEAN ± STANDARD DEVIATION).

Sample	*Thickness [mm]*
NPP fresh	0.14 ± 0.03
NPP cryopreserved	0.15 ± 0.04
Ureter fresh	0.78 ± 0.14
Ureter cryopreserved	0.86 ± 0.26
SIS fresh	0.08 ± 0.03
SIS cryopreserved	0.13 ± 0.02
Descending aorta fresh	1.28 ± 0.17
Descending aorta cryopreserved	1.41 ± 0.19

Results of the stress relaxation tests are reported in Fig. 3. Relaxation decreases over time for all tissues as reported in Table III. However, there is a significant difference between the relaxation reached after 300s by fresh and cryopreserved pericardium (p = 0.0002), and between native and cryopreserved SIS (p = 0.034). There is no significant difference between native and cryopreserved samples from ureter and descending aorta.

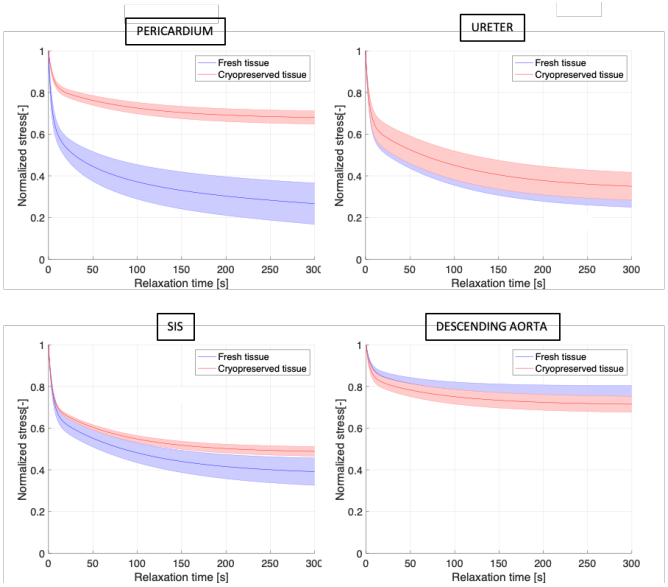

Fig. 3: Stress relaxation normalized curves of porcine pericardium, ureter, SIS and aorta. Each graph compares native tissue (red) with cryopreserved tissue (blue). Curves were normalized and then fitted by 3-term Prony series.

TABLE III: TISSUE RELAXATION (%) VALUES (MEAN ± STANDARD DEVIATION).

Sample	*Relaxation [%]*
NPP fresh	73.34 ± 9.8
NPP cryopreserved	31.97 ± 3.1
Ureter fresh	68.61 ± 6.4
Ureter cryopreserved	64.98 ± 6.6
SIS fresh	60.87 ± 6.5
SIS cryopreserved	51.16 ± 2.28
Descending aorta fresh	25.42 ± 5.8
Descending aorta cryopreserved	28.54 ± 3.8

IV. CONCLUSION

Cryopreservation procedure can provide ready-to-use biological tissues as graft materials for surgical purposes. Specific cryopreservation protocols have to be investigated for each particular tissue, in order to assess possible effects on ECM microarchitecture integrity and mechanical resistance. In this preliminary study, four different tissues were compared: they were studied in terms of ECM integrity and thickness, and from the histological and biomechanical points of view, before and after cryopreservation using 10% DMSO and 10% FBS in DMEM High Glucose solution. Histologically, the optimal maintenance of the ECM structure for all tissues (e.g., porcine pericardium, ureter, SIS and descending aorta) was demonstrated. From the mechanical point of view, uniaxial

rupture tests highlighted good preservation of pericardium behaviour, which did not show any significant difference between fresh and cryopreserved samples. However, stress-relaxation tests allowed checking a significant decrease in relaxation for cryopreserved samples in comparison with fresh ones. For the other tissues, some significant differences were found as to the values of E, UTS and FS during tensile tests to rupture; only in the case of SIS, a significant difference was found during stress-relaxation tests. This result suggests that the cryopreservation protocol can affect the mechanical behaviour of tissues, but the effect depends mainly on tissue composition and thickness.

This preliminary study represents the first effort to evaluate how and how much cryopreservation protocols can alter the characteristics of the treated tissues in terms of histological and mechanical properties. Further studies have to be performed to optimize the cryopreservation procedure with the aim to: i) increase the mechanical resistance of decellularized tissues; ii) quantify the residual presence of DMSO in cryopreserved tissues before proceeding with their clinical exploitation. Moreover, further analyses are in progress to assess possible effects due to cryopreservation on cues fundamental for proper cells-ECM interactions.

***Abstract*— In this work we present the design and development of a new bioreactor for supporting the regeneration of the enthesis, the area where the tendon or ligament insert into bone. Specifically, to optimize the proliferation, cell differentiation, and thereby the mechanical properties of a bioartificial construct, the bioreactor is designed to apply cyclic strains on a scaffold over a range of stress. The bioreactor was designed to meet several criteria. It allows applying precise control of the strain field on a scaffold. The hardware design guarantees real-time monitoring of the tensile stress applied to the scaffold and provides data to the user to perform mechanical characterization. It can be placed in standard incubators and provides a simple but effective scaffold clamping system. It ensures an airtight seal during the working phases to avoid contamination of the culture medium and provides a sterile environment during use. Finally, the developed software allows to select both pre-set or customizable stimulation cycles by setting traction frequency and test duration. All the critical specifications were met, so this work sets the stage for testing the proposed device with scaffolds developed in the framework of the TRITONE project, in order to support the biofabrication of autologous enthesis-like constructs.**

I. INTRODUCTION

In the field of orthopedic surgery, tendon and ligament (T/L) injury is one of the most common soft tissue damage [1] Of the approximately 30 million musculoskeletal injuries reported each year, more than half are believed to involve tendons and ligaments [2]. Current surgical approaches to reconstruct the injury and/or defect fail to replicate the structural and functional organization and mechanical properties of these tissues. These limitations may compromise the regeneration process leading to poor bone integration and a high incidence of postoperative failure. Therefore, there is an urgent need to fabricate engineered tissues that are increasingly bioinspired and capable of replicating the spatial inhomogeneity and biomechanical properties of damaged tissue [3]. In tissue engineering, the key elements for engineering a tissue are cells, the vital component essential for obtaining an autologous tissue, scaffolds, three-dimensional structures capable of emulating the extracellular matrix of the target tissue, on which cells are seeded, and a system capable of implementing biochemical and physical conditioning on the cellular construct. Particular attention in the field of T/L engineering is given to the osteotendinous junction, also called the enthesis [4], through which T/Ls insert into the bone. There are two types of enthesis in the human body: i) fibrous and ii) fibrocartilaginous. The latter is characterized by gradients in physicochemical and morphological properties. The enthesis has the task of making soft tissue and bone cooperate by facilitating the transmission of forces during the movement of limbs and joints. Because of this function it is an area of high stress concentration and goes often prone to injury. It is evident from the literature that mesenchymal stem cells (MSCs) appear to be the most promising for this type of application [5]. In addition, the need to provide appropriate biochemical stimuli to promote cell proliferation and viability is coupled with the application of appropriate mechanical stimulation to ensure that differentiation into tenocytes by MSCs is promoted [5]. Tensile stimuli are imposed on the scaffolds in culture using bioreactors. These devices are intended to replicate the in-vivo environment and are characterized by basic components, such as: i) a culture chamber with a tensile system capable of providing mechanical stimulation; ii) a circulation system for the culture medium; ii) monitoring and control system [6]. Each bioreactor is sized according to the type of sample to be stimulated and the mode of stimulus application. The magnitude and regimes of applied forces can therefore vary considerably among configurations. This work focuses on the development of a novel bioreactor that can apply cyclic strains on a cellular construct to improve cell proliferation and differentiation and thereby the mechanical properties of cultured constructs. Specifically, the design choices are the result of an in-depth analysis of the pros and cons of devices present both in the literature and market [7-9].The result of this analysis is summarised in the following specific requirements for T/L and enthesis regeneration: i) capability of providing precise control of the applied strain field on a scaffold biofabricated scaffold; ii) capability of in-line monitoring the tensile stress applied to the scaffolds and providing data to perform any mechanical analysis; iii) possibility to be placed in commercially available incubators; iv) capability of providing an effective fixation system of the scaffolds without causing any damage to them; v) capability of ensuring an airtight seal during to avoid contamination and leakages of culture medium; vi) ensuring a sterile environment during use. The bioreactor was then specifically designed in terms of hardware and software to stimulate the scaffold, developed in the framework of the TRITONE project, with a cyclic frequency and strain required for tendon and ligament regeneration as highlighted in the literature [7-9]. Briefly, these scaffolds consist of an electrospun poly(lactic-co-glycolic acid) (PLGA) zone that interfaces with the tendon and one of polycaprolactone (PCL) obtained by fused deposition modeling (FDM) printing technology. The joining component

between the two parts, obtained by the overlapping of the two materials represents the enthesis. Thus, we are dealing with scaffolds bi-material with structures that have different mechanical and morphological properties [10,11]. However, it is easily scalable, to be used for the stimulation of scaffolds or mechanic excitable tissues.

II. Materials and Methods

A. Bioreactor design

The whole bioreactor is composed of a culture chamber and a cyclic tensile stimulation and monitoring system. All parts were designed using Fusion 360 software and checked for fit in an assembly file. The dimensions of the culture chamber were constrained by the standard-specific dimensions of a TRITONE scaffold (e.g., 30 x 5 x 0.4mm) and by the need to guarantee a low encumbrance inside a commercial incubator.

The design of the culture chamber is shown in Fig. 1. The culture chamber presents an upper cover that was designed to hermetically accommodate a 15 ml of culture medium to ensure the possibility of performing standard biochemical analysis on it.

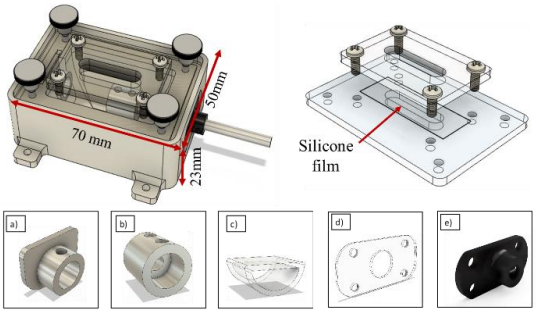

Fig. 1: Top left: CAD model assembly of the culture chamber with external dimensions. Top right: cover of the culture chamber with gas exchange system highlighted. Down: a) fixed coupling system, b) movable coupling system, c) silicone insert, d) silicone gasket, e) flange for compressing the gasket.

To ensure easy and effective sterilization of the culture chamber, all media contact bioreactor parts can be easily disassembled and are made of biocompatible and autoclavable materials (aluminum and Polyoxymethylene (POM)) by milling. Specifically, the culture chamber was made of POM, while the interlocking lid was made up of transparent Plexiglass to allow optical analyses on the cells without opening the chamber. Moreover, a biomedical silicone gasket was foreseen below the covering to isolate the internal environment of the chamber from the external one, and a hole was foreseen on the lid, covered with a 200 µm thick ELASTOSIL® [12] film, to keep the culture properly ventilated.

The cyclic stimulation system is composed of a scaffold anchoring system, a linear actuating system, and a load cell. The anchoring system (Fig. 2) was placed inside the culture and consists of a commercial aluminum-based shaft (4 mm in diameter and 60 mm in length), connected to a movable cylindrical clamp to constrain one end of the TRITONE scaffold, and of a fixed clamp to constrain the second end of the same scaffold. Both the cylindrical clamps consist of a hollow cylindrical element fabricated by milling process from aluminum. Each clamp was provided with a medical grade polydimethylsiloxane (PDMS) (Sylgard 184 with mixing ratio 10:1) insert whose compression via a commercial nylon screw constrained the scaffold without causing any damage (Fig.1 a, b, c).

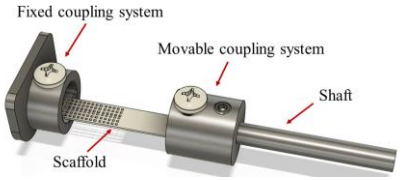

Fig. 2: CAD assembly of the scaffold anchoring system.

The linear actuating mechanism is made up of a stepper motor (Nema 17) and a screw-lead screw coupling (MTSFR8 T-type brass screw nut) to pull the scaffolds during the cyclical stimulation. To prevent the loss of culture medium at the point where the shaft is inserted into the chamber, a PDMS gasket was purposely fabricated (Fig.1(d)) by molding process using Sylgard 184 (10:1 mixing ratio). An aluminum flange was designed and milled to properly fix the gasket to culture chamber's wall (Fig.1(e)). A key component included in the cyclic stimulation system is the load cell (S-type 3kg, sensitivity 2.0 ± 0.05mV/V) that allows real-time mechanical analysis and control feedback based on scaffold changes over time. Finally, a purposely designed component (see Fig. 3) was designed and connects on one side to the cell load and to the other to the shaft, thereby allowing the chamber to be separated from the rest of the system. The whole cyclic stimulation system is solidly attached to a mechanical carriage to allow the anchoring system to move in the direction of stimulation of the sample (see Fig.3).

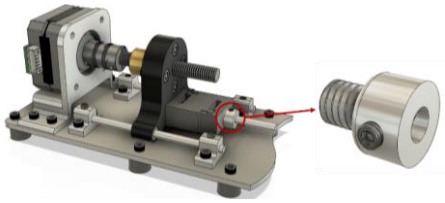

Fig. 3: On the left is the CAD assembly model of the pulling system. On the right the component for connecting the load cell is highlighted.

B. Bioreactor Electronics and Controller

System input and control were implemented in the Arduino development environment to: i) drive the stepper motor and pull the scaffold according to custom or pre-defined stimulation test programs; ii) monitor the tensile stress applied to the scaffold; iii) store data from each stimulation test thus giving the operator the possibility to perform a post-test mechanical analysis. To this aim, an Arduino Uno board (Arduino®) was used to control the stepper motor through a stepper driver (micro-stepping DM240) that translates high/low voltage digital inputs (generated by the Arduino) into appropriate settings (e.g., rotation direction or step resolution) and prescribed rotation steps. The load cell was powered through a JY-S60 board by a DC power supply (24V@5A) which also allows the amplification and transmission of the acquired data to the Arduino board, as an analog signal. To store data during a tensile mechanical stimulation test, a module for reading and writing to micro-SD memory cards was foreseen. The communication of this board with the

Arduino board took place via the Serial Periferal Interface (SPI) communication protocol. Finally, to allow the user to interface with the bioreactor electronics, a display, a rotary encoder, and buttons were provided to choose the type of stimulation protocol from the standard present ones or create a customised one by setting stimulation frequency strain and test time.

C. Leakage tests

Both static and dynamic (with the cyclic stimulation system activated) tests were conducted to assess the tightness of the culture chamber by filling it with 15 ml of deionized water. For tests in a static condition, the chamber was filled and checked after 24h and 48h for leaks. For tests in dynamic conditions, the culture chamber was checked for leaks after activating the cyclic stimulation system for 30 minutes twice a day for 3 days with standard stimulation protocols (e.g., 0.5 Hz 10% strain).

D. Stimulation test

The bioreactor was validated by performing TRITONE scaffold stimulation tests. Twice daily cyclic stimulation sessions were performed on 4 groups of TRITONE scaffolds stored in PBS (phosphate-buffered saline, pH 7.4) for 7, 14 and 21 days, plus a control group (samples in PBS overnight). Tests were conducted in triplicate. The ability of the load cell to monitor the tensile loading applied on samples was also evaluated. Therefore, tensile mechanical tests with a frequency of 0.5 Hz and 10% strain were carried out. Each sample was stimulated for 30 minutes twice at 7-hour intervals. For each group, a stimulation session without sample was carried out to acquire, from the load cell, the voltage values referring only to the effect of friction due to the seal. These values were then subtracted from those obtained from stimulation tests with samples to isolate the voltage values representing the tensile stress applied to the scaffold. Equation (1) was then used to convert these data into Force (Newton) data information for the scaffold under testing.

$$\text{Force} = \frac{\text{Output}_{\text{LoadCell}} \cdot \text{CellRange}}{\text{Sensitivity} \cdot \text{V}_{\text{LoadCell}}} \cdot \frac{\text{g}}{\text{A}} \qquad (1)$$

Where:

- $\text{Output}_{\text{LoadCell}}$ is the load cell output voltage [V];
- CellRange is the max value the load cell can read [kg]
- Sensitivity is the smallest force a load cell can reliably detect [mV/V];
- $\text{V}_{\text{LoadCell}}$ is the input voltage to load cell [V];
- g is gravitational acceleration [9.81 m/s2]
- A is the gain of signal conditioning electronics.

At this point, to obtain the stress-strain curve for the scaffold under stimulation, we convert the data from Eq. 1 into tensile stress (MPa) by knowing the cross-sectional area of the scaffold using the equation 2.

$$\text{Stress} = \frac{\text{Force}}{\text{Section}} \qquad (2)$$

Where:

- Force is calculated via Equation (1) [N];
- Section is the cross-sectional area of the scaffold measured prior to mechanical stimulation [mm^2].

The strain-strain curve was evaluated up to the strain set at the start of stimulation.

III. Result

A. Bioreactor design

Based on the mandatory requirements presented in section I, a bioreactor system was designed and prototyped. The whole bioreactor in its final layout is shown in Fig. 4. As shown in Fig. 4, a plexiglass case (290mm in width, 140mm in depth and 93mm in height) was also designed and fabricated to protect the bioreactor during travel and from dirtiness. All the design choices led to a completely modular bioreactor, where the culture chamber can be mechanically and environmentally isolated from the cyclical stimulation system. Isolating the culture chamber allows modularity in experimental design (e.g., a single the stimulation system several scaffolds can be stimulated in succession within their culture chambers) and enables simple part change-out in case repair is needed. As shown in in Fig. 4 (b), a second chamber was also built for static sample control experiments to verify the effectiveness of stimulation of the TRITONE scaffold.

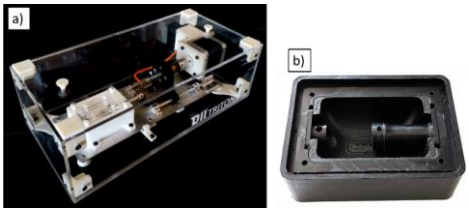

Fig. 4: (a) Bioreactor inside the case, (b) control culture chamber.

B. Bioreactor Electronics and Controller

The electronics and the control system of the bioreactor were designed to manage all the device's operations while ensuring the repeatability of the experimental tests. The electronic components were chosen to properly manage the stepper motor for the tensile stimulation of the scaffold; to select the stimulation program via buttons, rotary encoder, and display, to monitor via load cell the state of the samples during traction and to save the data on a microSD memory card for later analysis. All the electronic components were placed inside a case shown in Fig.5.

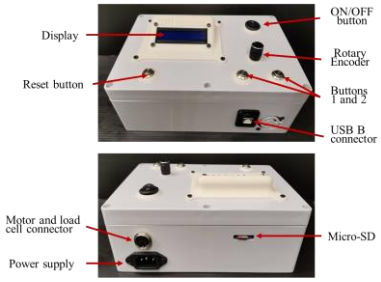

Fig. 5: Electronics case. The two images show the components that allow the user to interface with the electronic part of the bioreactor system.

To control the overall bioreactor system a software was developed with the aim of making the use of the device as simple as possible. Via the buttons on the right-hand side of

the box lid, it is possible to choose from two preinstalled programmes with stimulation frequencies of 1 and 0.5 Hz and the same strain set at 10%, which appear from the literature to be the most commonly used stimulation conditions [4]. It is also allowed the customization of the stimulation program, through the display and the rotary encoder, in terms of the frequency of stimulation, the strain to be applied and the test duration time. The operating workflow initially required the user to calibrate the system by setting a pre-strain of the sample. This is possible by rotating the rotary encoder, whose rotation corresponds to that of the motor. When the load cell reads a value in the set range, is communicated via the display that pre-strain has taken place. The software then waits for the user's choice in the type of stimulation to be performed. A timer then starts counting and when it expires, the system stops. At any time, the reset button can be pressed to stop the motor and restart the menu and a new stimulation test.

C. Leakage tests

Under both static and dynamic conditions, no leaks were detected as a demonstration of the effective functionality of both the chamber covering and the gasket inserted near the shaft. This ensures that the required amount of culture medium is maintained sterile during the mechanical stimulation tests and the possibility to perform any biochemical tests on the culture medium if needed.

D. Stimulation tests

To demonstrate that the bioreactor functions accurately stimulation tests with a frequency of 0.5Hz and 10% strain were carried out. Graphs of the data obtained from the load cell during and store in a memory card stimulation without and with sample are shown in Fig.6. From this data, the stress-strain curve of the stimulated scaffold was obtained as described in section II D. As can be seen in the figure below, the voltage recorded is positive and periodic, so we have demonstrated that the system can stimulate the scaffolds as specified in section 1.

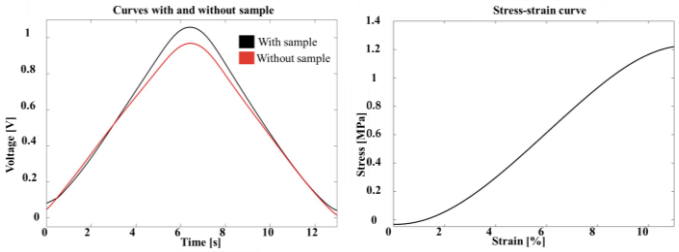

Fig. 6: On left: superposition of one period of the curves obtained from the load cell by performing a tensile mechanical test with and without the sample. In both cases, a filtering of the data by means of moving average filter was applied for smoothing the signal. On right: stress-strain graph curve relating to the tensile of the sample.

IV. Discussion and Conclusion

In this work, a novel bioreactor capable of cyclically stimulating a scaffold with a specific design developed for T/L and enthesis regeneration was presented. Tests carried out on the bioreactor show the capacity to apply constant cyclic traction to the scaffold over time without leakage of the culture medium; moreover, all the critical design specifications identified were meet. Globally, the results obtained demonstrated the potential of the device to stimulate and promote entheses regeneration. Cell culture tests are ongoing to validate the system. Possible future developments may include the modification the culture chamber with inlet/outlet ports to recirculate the culture medium, driven by a peristaltic pump, and thus facilitate long-term experiments.

Abstract*— Recently, oral delivery systems have gained more and more attention and among them oil in water nano-emulsions (O/W NEs) are of particular interest for their capability of loading and delivering lipophilic compounds, improving their pharmacokinetic. Few years ago, our group developed a method to stabilize O/W NEs by adding a polymeric shell on the oil core, using pharma grade formulations. To effectively exploit this formulation as food supplement we tried to enhance muco-adhesion properties of the polymer shell, namely chitosan (Ct) towards the intestinal barrier. However, in the field of food supplements, food grade materials should be used, because of both their safety and cost effectiveness. Therefore, in this work, we first have replaced pharma grade (PG) materials with food grade (FG) ones for the preparation of the polymer coated O/W NEs, namely secondary O/W NEs, performing a comparative study between the two formulations. Then we have modified Ct by adding thiol groups via a simple non-covalent procedure based on N-acetylcysteine (NAC) salification, which is compliant with food supplement formulations. PG and FG formulations were prepared and physio-chemically characterized using different techniques, including DLS, ^{1}H-NMR, ITC, obtaining comparable results. We validated these systems in terms of physiological behaviour. Very importantly, we assessed mucus-adhesion properties of the two polymeric coatings (Ct and Ct-NAC) within a microfluidic device in the shape of an intestine-on-chip device capable of mimicking the *in-vivo* intestinal microenvironment, verifying a significant enhancement in the mucus-adhesive properties of Ct-NAC with respect to Ct due to the presence of thiol groups, as expected. Nonetheless, in-vivo assays are required as a final assessment for the proposed system to be commercialized.

Keywords: Oil in water Nanoemulsions, Intestine-on-a-chip, Mucus-adhesion.

I. Introduction

Food grade nano-formulations are becoming a promising option for the encapsulation of bio-active molecules with limited oral bioavailability, due to the protection they guarantee in the harsh conditions typical of the gastrointestinal tract (GIT) after their ingestion [1-3]. Oil in water nano-emulsions (O/W NEs) are an ideal oral delivery system, thanks to their physicochemical and functional properties, such as high encapsulation efficiency for lipophilic molecules, high bioavailability [4, 5] and time stability. In our group, we were able to implement a remarkable strategy to improve the stability of completely nature-based O/W NEs by optimizing process and composition [6]. In this work, we have proposed a completely food grade (FG) secondary O/W NE for oral delivery of lipophilic substances, comparing it to the pharmagrade (PG) counterpart by means of stability, size distribution and material interactions. Then, taking advantage of a simple yet effective microfluidic platform in the shape of a gut-on-chip device, we assessed mucus-adhesion properties of the nanocarrier. Each PG component of the nano-carrier was replaced step by step and compared with the FG analogous in terms of size distribution (DLS) and in terms of materials interaction, strictly connected to the final stability of the formulation (Isothermal titration calorimetry, ITC). Aiming to enhance Ct-NEs mucus-adhesiveness, we developed a Ct salification reaction with a food grade N-acetyl-cysteine (NAC) [7]. Since salification is not a covalent reaction and does not need activator agents, there is no need to remove secondary reaction products. Firstly, this derivative was employed for building SNEs with an improved mucus adhesive property in substitution of covalent derivatives [7]-[29]. Finally, to assess the improvement in terms of mucus-adhesion, we exploited an organ-on-chip, i.e. a microfluidic cell culture system, with controlled dynamic conditions able to replicate the assembly, function and physiology of a human organs *in vitro* [8]. We designed an Intestine-on-a-chip (InOA-chip) platform composed of a single PDMS microfluidic channel on which human intestinal epithelial cells were cultivated in a controlled environment [9, 10]. InOA-chip platform was produced by culturing human colorectal adenocarcinoma (Caco-2) cell line under dynamic fluid flow on PDMS. In these conditions Caco-2 cells form a polarized epithelial monolayer that can mimic adsorptive enterocytes. Thanks to it we were able to evaluate and compare mucus-adhesion properties of polymeric coated nanocarriers (Ct and Ct-NAC). In the end, confocal imaging was used to qualitatively estimate the transport and localization of Ct and Ct-NAC NEs. This is a key point because muco-adhesiveness is strictly related to the release of the encapsulated active molecule.

II. Results and Discussion

A. Materials characterization

We proposed a non-covalent functionalization of chitosan with NAC, adding thiol groups to it. Since this is a simple salification, we are able to avoid activator agents and, more importantly, elimination of secondary reaction products. For each Ct-NAC, we calculated % NAC, which is related to the

presence of thiol groups, whose concentration was measured by Ellman's test, i.e., a colorimetric assay able to quantify free thiol groups. Ellman's test results show very similar %NAC (average value ≈ 15.8 ± 1.1 %) regardless of FG or PG Ct. To corroborate Ellman's test results, the Ct salification was evaluated by ^{1}H-NMR[11]. Each spectrum shows a triplet signal at 3 ppm (H-2-2'), meaning that there are not any covalent bonds between Ct and NAC, which acts like Ct counter-ion by salification. The Deacetylation degree (%DD) and Acetylation degree (%DA) calculated by ^{1}H-NMR analysis were respectively in PG Ct NAC 81% and 47% and FG Ct NAC 68% and 55%.

B. Nanocarrier assembly and characterization

ITC experiments allowed to identify an exothermic binding event followed by an aggregation for both PG Ct and FG Ct due to electrostatic interaction between the negative O/W NEs and the positive charged Ct. The binding was characterized by unfavorable enthalpic contribution, but favorable entropic contribution to Gibbs energy change, as already found in a previous work [12], where the O/W NE was titrated with PG Ct in similar solution conditions. The ITC proved that the interaction between polymer and NE is not influenced by the grade (FG or PG) of Ct and that the thermodynamic parameters determined for both types of Ct are comparable (**Fig. 1**), corroborating that the typology of Ct did not influence the electrostatic interaction between polymer and NE.

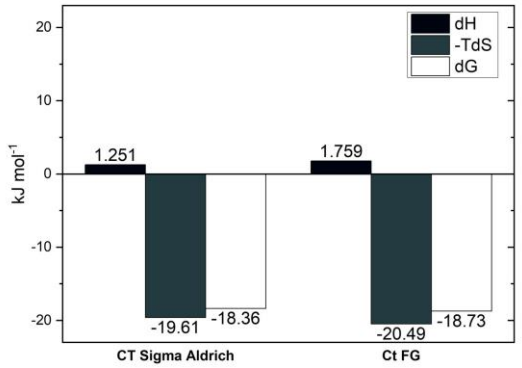

Fig. 1: Diagram of the thermodynamic parameters of electrostatic interaction of 0.7 w/v % PG Ct (**A**) and FG Ct (**B**) into O/W NE 1.1 wt% oil at 25 °C.

After having characterized Ct in all its configurations, we used it to coat primary NEs (**Fig. 2-A**). This coating produces a charge switching from a negative to a positive ζ-potential value. In all cases, we observed a little increase of the hydrodynamic diameter of NE droplets, although remaining monomodal, a symptom of the formation of a nanometer shell around the oil core. On the overall, we observed no difference, especially in terms of stability, between FG and PG formulations, confirming the possibility of exploiting entirely FG based O/W Ct NEs, enabling the nanocarrier for a possible entry in the food industry. Furthermore, FG Ct and Ct-NAC NEs (10 wt % oil and 0.1 w/v % polymer) loaded with curcumin (CUR) were also prepared and checked by DLS showing maintenance in values (**Fig. 2-B-E)** (Particle size distribution of 94.17 ± 0.30 nm; PDI value of 0.01 ± 0.02; ζ-potential value of 43.3 ± 0.6 mV for curcumin loaded Ct-NAC NEs; Particle size distribution of 87.16 ± 0.62 nm; PDI value of 0.07 ± 0.02; ζ-potential value of 43.3 ± 0.6 mV for curcumin loaded Ct NEs) with results which are comparable to FG empty formulations **(Data not shown)** (Particle size distribution of 98.58 ± 0.70 nm; PDI value of 0.099 ± 0.004; ζ-potential value of 39.5 ± 2.0 mV for empty Ct-NAC NEs; Particle size distribution of 93.03 ± 0.9 nm; PDI value of 0.088 ± 0.001; ζ-potential value of 35.0 ± 0.9 mV for empty Ct NEs). The DLS data were corroborated by Cryo electron transmission microscopy (CRYO-TEM) which showed a nanosized distribution for both Ct-NEs and Ct-NAC NEs CUR loaded formulations (**Fig 2 -C and D**).

Data are reported as mean (n = 3) (s.d.).

C. Mucus-adhesion properties in InOA-chip

Finally, we tested the muco-adhesive properties of Ct-NAC in comparison with simple Ct. This has been assessed through an InOA-chip device in which we culture Caco-2 cells that, given the dynamic fluid flow and shear stresses typical of the intestine, formed a monolayer. In literature it is possible to find many *in vitro* approaches to quantify mucus permeation [13], among them microfluidic systems able to reproduce the formation of the intestinal dynamic mucus architecture are of great interest [14]. Moreover, this gives the possibility of have human-like mucus without the effort of 3D Intestine *in vitro* models, which are more complex and obtained from biopsies of human intestinal tissues [15]. We used this functional microfluidic platform for the first time to monitor *in situ* real-time the intestinal microenvironment formation and to simulate Ct and Ct-NAC NEs interaction with intestine. For this purpose, we implemented confocal analysis to detect the FITC, with which we labelled the polymer coating of NEs as to monitor the cellular uptake and retention of nanoemulsions on the mucus layer [16]. The Caco-2 monolayers treated with FITC-Ct NEs and FITC-Ct-NAC NEs showed a tight junction-modulation, due to chitosan ability to open the intercellular tight junctions enhancing paracellular permeability [17] (**Fig. 3-A,B**), differently from the not treated Caco-2 monolayer (**Fig. 3-C**). In addition, we observed a spread signal of FITC in Caco-2 monolayers treated with Ct NEs (**Fig. 3-D**) compared with Ct-NAC NEs in which, together with the strong FITC signal, there were some fluorescent spots due to monolayer aggregates (**Fig. 3 -E**). We continued monitoring FITC signal for both formulations for over 140 min (**Fig. 3-F**).

They reached the same plateau after 1 h of treatment, probably due to a saturation in the signal of FITC that did not permit to detect any difference in fluorescence intensity during the treatment. Knowing this and aiming to assess muco-adhesion, we washed the channel to remove the excess of the two systems and re-analyzed the fluorescence intensity of FITC in Ct NEs and Ct-NAC NEs. The images show almost no FITC signal, representative of few Ct NEs linked to mucus produced by Caco-2 cells **(Fig. 3-G**), compared to the higher signal of Ct-NAC NEs (**Fig. 3-I**), shown also in the high magnification insets (**Fig. 3-H** and **J**), indicating much higher adhesion for this system. After washing, the intensity of Ct-NEs signal decreased whereas Ct-NAC showed a greater intensity due to a steady adhesion to the mucus layer (**Fig. 3-K)**.

We believe that the enhanced mucus-adhesions properties of Ct-NAC NEs are due to the formation of covalent S–S bonds by free thiol groups of Ct-NAC and cysteine from mucus domains, further enhanced by the electrostatic interactions between the positively charged Ct and the negatively charged mucosa layer, as it has been reported in literature for covalent bounded Ct-NAC nanocarriers [7], [17, 18],[7, 19].

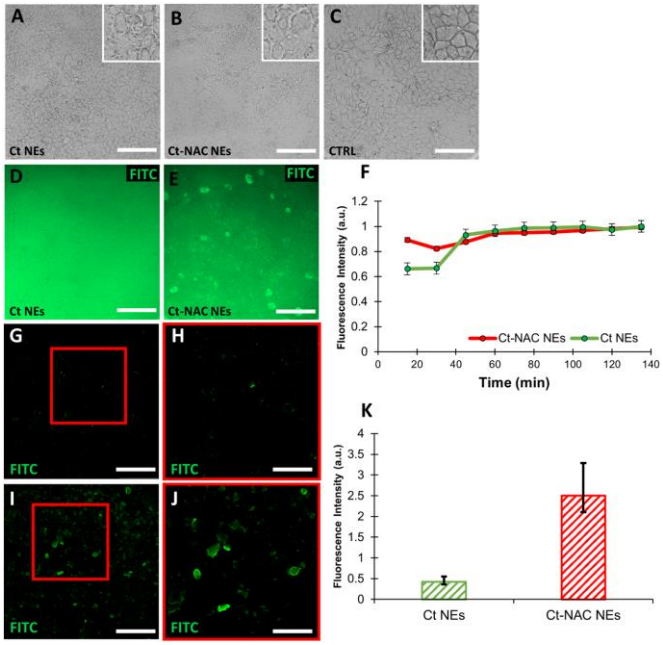

Fig. 3: Analyses of mucus adhesions properties of Ct-FITC NEs and Ct-NAC-FITC NEs. Bright-field images of **A**) Ct NEs, **B**) Ct-NAC NEs and **C**) CTRL with high magnification views of Caco-2 monolayers; FITC images of Caco-2 monolayer treated with **D**) Ct NEs and **E**) Ct-NAC NEs; scale bar 100 µm. **F**) Graph of fluorescence intensity of Ct-FITC NEs and Ct-NAC-FITC NEs time-dependent. FITC images of **G**) Ct NEs and **I**) Ct-NAC NEs after washing and fixing and high magnification views shown in red squares (**H**, **J**); scale bar 100 µm and 70 µm. **K**) Graph of fluorescence intensity of Ct-FITC NEs and Ct-NAC-FITC NEs after washing and fixing.

Recently, we have also started to work on the replacement of acetic acid with citric acid for a matter of taste improvement and thus patient compliance and at least in the first 20 days the size is perfectly stable (**Table I**). Size stability is under monitoring.

TABLE I: TIME STABILITY OF CT NES IN CITRIC ACID

Day	*Size (nm)*	*PdI*	*Z-potential(mV)*
0	106.7±0.2	0.074±0.2	16.2±3.27
2	107.1±0.5	0.081±0.3	22.9±3.24
10	98.6±7.6	0.108±0.4	26.2±3.73
20	108.8±0.2	0.1±0.4	28.1±3.37

III. CONCLUSION

To conclude, we presented for the first time, a full FG delivery system based on a secondary O/W NE coated with Ct-NAC obtained by non-covalent bound thiols that in turn enhance mucus-adhesion properties. FG and PG formulations have been morphologically, thermodynamically, and chemically compared. The are no differences between them from both size and stability perspectives. Last but not least, the Ct and Ct-NAC mucus adhesive properties were compared for the first time within an innovative and accessible intestine-on-chip platform, InOA-chip, proving that thiolated Ct NEs possess much better mucus adhesive properties, as a consequence of S-S bonds formation with the mucin produced by the Caco-2 monolayers. The proposed totally FG system opens a new route in nutraceutical field, being a novel emulsion-based formulation with enhanced mucus-adhesiveness thanks to the Ct salification with NAC. Nonetheless, the chosen non-covalent thiol functionalization of chitosan opens the door to an immediate use of such formulation with no need for safety clinical tests.

***Abstract*—The co-culture of the human gut microbiota and eukaryotic cells is still a great challenge in biomedical research. Direct exposure to microbes could in fact cause cell infections or death, as microbial metabolites may have cytotoxic effects. Moreover, cells and microbes usually require different culture conditions. Accordingly, this work presents the design, development and performance of a novel micro-dialyser to allow the microfluidic co-culture of eukaryotic cells and microbes thereby assessing their crosstalk while preventing their direct contact.**

***Keywords*—Microfluidic device, dialysis, gut microbiota.**

I. Introduction

THE gastrointestinal tract houses an extremely variable microflora called "human gut microbiota" (HGM), which constantly impacts the state of health and disease of the host [1]-[3]. The symbiotic interaction between the HGM and the host has considerable effects both locally, due to the HGM's intimate contact with the intestinal cells, and systemically, as the alteration of the HGM's composition towards a pathologic profile (*i.e.*, dysbiosis) has been associated with numerous disorders and diseases, from allergies to neurodegenerative diseases and even cancer [2], [3]. To better understand dysbiosis-associated diseases and the related therapeutic strategies, it is essential to deepen our knowledge of the HGM, its symbiotic interaction with the host, and the role of intestinal dysbiosis in the disease's onset. Among the common HGM study approaches the analyses of human and animal faeces are not fully representative of the microbial composition in the different intestinal districts and results from in vivo animal models have limited translatability to human applications due to inter- and intra-species variability [3]-[5]. Additionally, the 3Rs European directive is increasingly encouraged [3], [5]. In vitro culture models represent powerful tools to recapitulate the specific anatomical, physiological and environmental conditions in which the HGM proliferates and to investigate its cross-talk with the host [1]-[5].

Bioengineering is currently aiming to develop novel in vitro culture devices, which can integrate microbial fermentation technologies with advanced systems for the in vitro co-culture of HGM and host cells [6]. In this perspective, a selective filtration system becomes crucial as some HGM's metabolites have beneficial effects on eukaryotic cells (*e.g.*, short-chain fatty acids [4], [7]) while others can be cytotoxic (*e.g.*, colibactin) [7].

Accordingly, this work presents the design and fabrication of a novel micro-dialysis system that can be used in a co-culture microfluid system for allowing the chemical crosstalk between eukaryotic cells and microbes and investigating host-HGM interactions without allowing their physical contact.

II. Materials and Methods

A. Design and fabrication of the micro-dialysis system

The micro-dialysis system consists of two symmetrical parts (upper and lower) (Figure 1b, Figure 2h) and a dialysing membrane between them. The upper part allows the flow of the HGM's culture medium, while the lower part allows the flow of the dialysed fluid. A schematic representation of the device and its coupling with the hydraulic circuit is presented in Figure 1.

Both the lower and upper parts were fabricated by casting, using Sylgard 184 (Dow Corning, USA), a biocompatible silicone [8]; a ratio of 10:1 w/w was used for the base agent and curing agent, respectively. Each batch of silicone was degassed before use for removing trapped air within the mixed materials. A 30% w/v Pluronic F-127 (Sigma-Aldrich, USA) hydrogel was prepared through the procedure described in [9] and used at room temperature as a sacrificial material to create microfluidic channels in the silicone part. The mould for the lower and upper part of the device was fabricated by firstly printing the microfluidic channels (200 μm height, 200 μm width) and tubing entry guides using the pluronic-based sacrificial ink into a petri dish (60 x 15 mm) using an INKREDIBLE 3D printer (CellInk, USA). Different printing models were designed using Solidworks CAD software and then converted into a G-Code file using Slic3r with 0.2 mm layer height,100% infill and 260 μm conic nozzle diameter. Thereafter, the degassed silicone mixture was poured into the mould up to the mid-height of the petri dish. After a 30 min curing process at 60°C, commercial silicone tubes were inserted into the previously-printed Pluronic-based guides and additional silicone was poured in until complete filling of the petri dish, which was then left at 60°C for 30 min. The mould was placed at 4°C to allow the Pluronic liquefaction and its subsequent removal. The entire procedure is summarised in Figure 2.

To guarantee the hydraulic sealing of the microfluidic device, once a 14 kDa dialysing membrane (Sigma-Aldrich, USA) is placed between the silicone parts, two different ABS sealing systems (Figure 3) were designed and fabricated using an FDM printer (Stratasys 250 MC, USA): a bolted closure system and a snap-fit closure system.

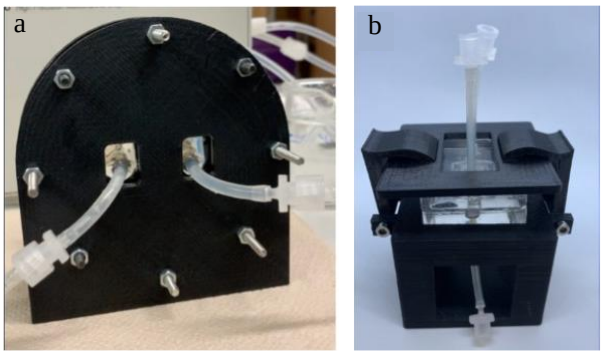

Fig. 3: Prototype of the closure systems. a) Bolted system. b) Snap-fit system.

B. Testing of different microfluidic circuit geometries

Different microfluidic circuit geometries (*i.e.*, with spiral, hexagonal, and serpentine paths) were designed and tested: a dye was dissolved in deionised water (dH_2O), which was then flowed through the microfluidic system using a peristaltic pump (Ismatec IPC, Fisher Scientific). The performance of the two sealing systems was evaluated, as well.

C. Finite element simulations

Finite element simulations were performed using COMSOL Multiphysics 5.5 software to highlight the most time-efficient combination of the different circuit geometries and dialysing configurations (*i.e.*, co-current and counter-current).

The adopted geometry is composed of three domains, modelling the upper compartment, the dialysing membrane and the lower compartment. The "Laminar Flow" and "Transport of Diluted Species in Porous Media" modules were used and coupled via the fluid velocity field. The liquid media and the dialysing membrane were modelled as water and a porous medium, respectively. A fluorescent marker (5(6)-Carboxyfluorescein, CF, Sigma-Aldrich, USA) solution's diffusion through the membrane was simulated with Yamashita's model [10]. A closed-loop circuit configuration was adopted, as recirculation increases fluid velocity and improves mass transfer [11], and was modelled with the periodic condition. A 5 ml/min flow was set and a time-dependent model was implemented over a 22 h (79200 s) period of time with an 1800 s time-step that simulates the periodic sampling of the dialysed fluid.

D. Micro-dialyser efficacy tests

To evaluate the dialysing ability of the microfluidic system, two dynamic experimental tests with fluorescent markers were carried out, using the dialysing membrane.

The first test involved a 2500 nM CF solution in PBS 1X, while the second test involved a 100 µg/ml albumin-fluorescein isothiocyanate (AFI) (Sigma-Aldrich, USA) solution in dH_2O. The CF is expected to diffuse across the dialysing membrane, while the AFI's diffusion is expected to be prevented, as their molecular weights are, respectively, lower and higher than the membrane's cut-off.

For each experiment, the calibration curve was first derived and then a 22-hour dynamic test was carried out with the hexagonal micro-dialyser in the counter-current configuration. For both dynamic tests, the setup (Figures 4 and 5) involved the peristaltic pump for setting a 5 ml/min flow, the printed microfluidic device (hexagonal shape) and two beakers, one containing 20 ml of the fluorescent marker solution and the other containing 20 ml of dH_20.

Samples with a 300 µl volume of the dialysed fluids were taken at 0, 30, 60, 90, 180, 240, 360, and 1320 min. Then, 100 µl aliquots of those samples were placed in a 96-well plate and scanned with a plate spectrofluorometer (SpectraMax Gemini™ XPS/EM Microplate Reader, Molecular Devices).

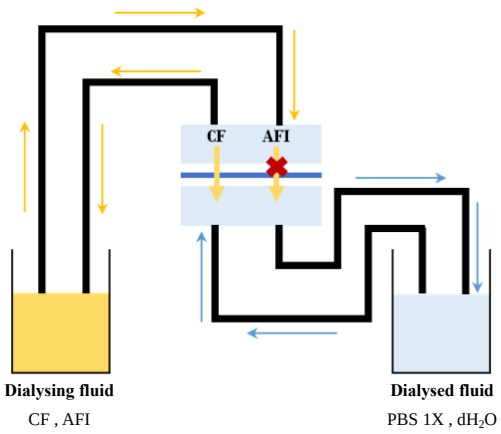

Fig. 4: Schematics of the experimental setup.

Fig. 5: Image of the dialysis setup.

III. Results

A. *Testing of different microfluidic circuit geometries*

Fig. 6: The fabricated micro-dialysis system.

The completely assembled micro-dialysis system is shown in Figure 6.

Both closure systems showed optimal hydraulic sealing for 24 h under a 5 ml/min fluid flow. Nevertheless, the snap-fit closure system was adopted since it simplified the assembly and disassembly procedures. Concerning the circuit geometry, in the hexagonal-shaped and serpentine-shaped circuits the liquid filled the channels completely and by following the path, while in the spiral-shaped channel, the liquid flowed from one channel to the other without following the default path (Figure 7). Thus, this latter configuration was discarded.

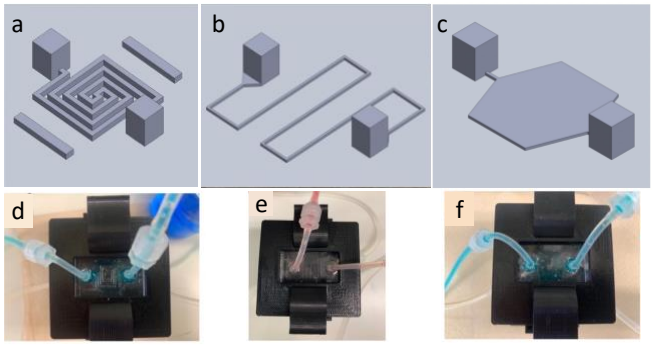

Fig. 7: Different circuit geometries CAD models. a) Spiral. b) Serpentine. c) Hexagonal. d, e, f) Results of the tests for the spiral, serpentine and hexagonal configurations.

B. *Finite element simulations*

The effectiveness of hexagonal and serpentine-shaped dialysers in both the co-current and counter-current configurations was compared. The steady-state achievement was evaluated as the ratio between the concentration at a specific time t and the equilibrium concentration.

The hexagonal-shaped dialyser in the counter-current configuration is the first to reach the steady state (Figure 8). In fact, the counter-current configuration contributes to a better maintenance of the concentration gradient between the two compartments [12], [13] and the greater exchange area between the two compartments of the hexagonal-shaped dialyser increases the device's clearance [14].

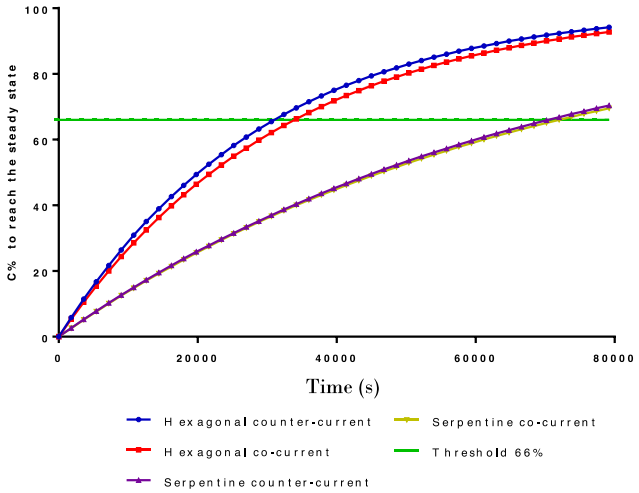

Fig. 8: Steady-state achievement comparison between the two circuit geometries (*e.g.*, hexagonal and serpentine) in the two different configurations (*e.g.*, co-current and counter-current).

C. *Micro-dialyser efficacy tests*

As expected, the tests resulted in the CF's diffusion through the membrane, as its concentration in the dialysed fluid rose (Figure 9a) and the AFI's retention, as its concentration in the dialysed fluid is always almost comparable to 0 (Figure 9b). Moreover, the experimental data on the CF's concentration over time showed no statistical differences with FE-computed CF's concentration over time (Figure 10), therefore validating the computational model described in section II C.

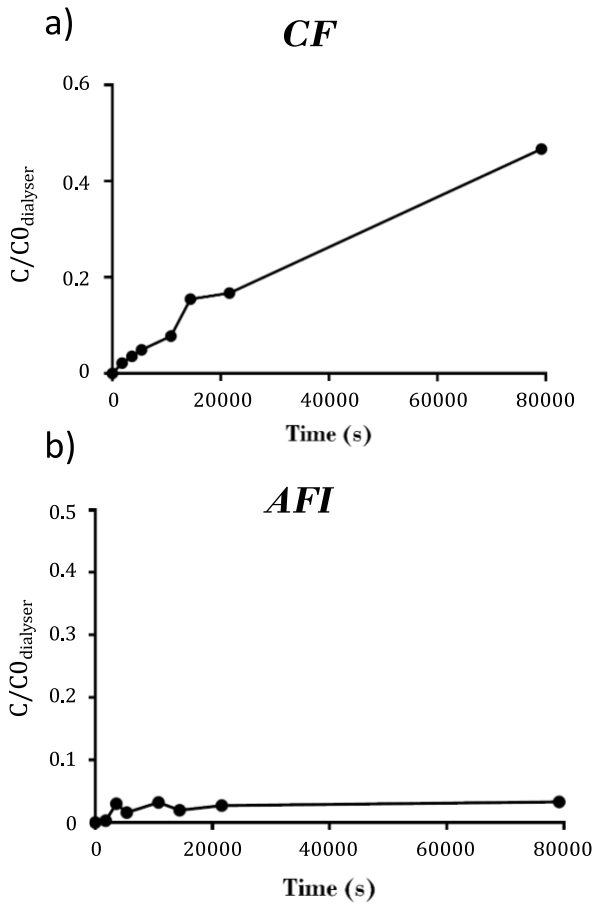

Fig. 9: Fluorescent markers' concentrations in the dialysed fluids over time. a) CF concentration over time. b) AFI concentration over time.

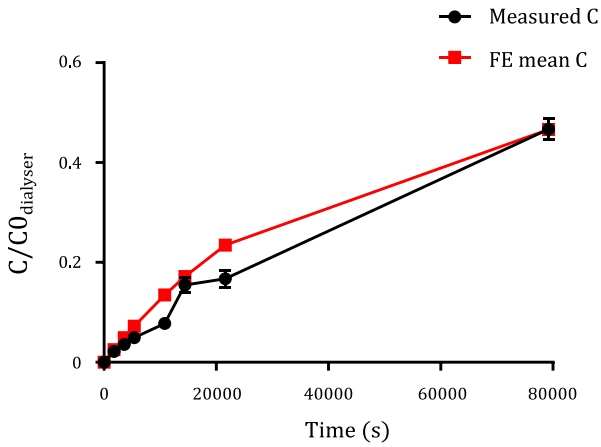

Fig. 10: Comparison between the experimentally and computationally obtained CF's concentration over time in the dialysed fluid.

IV. Conclusion

The fabricated novel micro-dialyser guaranteed the total absence of leaks in all tests and an optimal dialysing ability, as observed in the experimental dialysing tests described in sections II D and III C. Those experiments assessed also the better performance of the hexagonal-shaped microfluidic circuit in the counter-current configuration compared to the alternatives. This outcome is in line with the results obtained with numerical simulations, thereby validating the designed FE model.

Among the future perspectives, the micro-dialysis system represents a promising tool to evaluate the indirect effects of the HGM's metabolites on eukaryotic cells, by simply exposing them to the dialysed surnatants of the HGM in vitro culture. Additionally, other circuit geometries could be considered to further improve the device's dialysing ability and dialysis membranes with different cut-offs could be used to give deeper insights into the different HGM metabolites and how they impact eukaryotic cells' metabolism or viability. Future design optimizations of the device could include bubble-trap systems to limit cell membrane damage or even cell death due to air bubbles. Finally, a specifically designed culture chamber could be integrated into the system to perform the dynamic in vitro culture of the HGM and the dialysis process simultaneously. An external chamber could moreover enable the generation and maintenance of anaerobic environmental conditions and the connection of the microfluidic platform with external cell compartments and, consequently, the analysis of the HGM-tissues/organ interactions.

***Abstract* – 3D bioprinting techniques are rapidly increasing their relevance in the field of tissue engineering as potential tools for the fabrication of complex 3D structures that could find applications as therapeutic patches or *in vitro* models. In this work, we investigated the use of alginate and gelatin based bioink for cardiac tissue engineering. The hydrogels were developed through an internal gelation mechanism, allowing 3D printing of uniform self-supporting fibres without the need for post-crosslinking or the use of support materials. Varying gelatin content, bioinks with tuneable rheological properties were developed. Biological validation showed that the bioinks were biocompatible and promoted cell adhesion.**

Keywords - Alginate dialdehyde, gelatin, bioink, internal gelation

I. INTRODUCTION

Cardiovascular diseases (CVDs) represent a social and economic worldwide burden, causing about 18 million deaths per year [1]. New resolutive therapies are highly demanded as heart transplantation still remains the only effective therapeutic option in case of end stage heart failure.

3D bioprinting techniques are gaining tremendous attention in tissue engineering and regenerative medicine as the precise and controlled deposition of bioinks can be exploited for the fabrication of complex 3D structures [2]. In cardiac tissue engineering, bioinks can be employed to develop scalable and reproducible bioprinted constructs as therapeutic patches for cardiac regeneration or *in vitro* models for preclinical validation of new advanced approaches.

Alginate (Alg)-based bioinks have been widely investigated thanks to their tuneable properties and cost-effectiveness [3]. Alg-based materials are currently being investigated in clinical trials for cardiac regeneration. Algisyl-LVR™ is an Alg-based injectable hydrogel designed to confer mechanical support to the left ventricle to prevent or reverse the progression of heart failure [4].

Alg-based hydrogels are usually obtained through physical crosslinking of Alg chains with polyvalent cations (e.g., calcium ions, Ca^{2+}). The sol/gel transition of Alg occurs under physiological conditions and almost instantly [5].

Alg 3D bioprinting usually exploits an external gelation mechanism, by the extrusion of an Alg sol phase into Ca^{2+} enriched supporting bath [6]. The crosslinking is fast and non-homogeneous, localized at the interface between the printed filament and the coagulation bath [7]. A thermosensitive supporting bath containing calcium ions derived from dissociations of salts, such as calcium chloride ($CaCl_2$), has been proposed to achieve higher 3D spatial resolution and shape fidelity, in the so-called "FRESH" method [8], [9].

Recently, internal gelation of Alg chains has been investigated to develop 3D self-standing constructs without the use of a supporting bath [10]. In this case, a water-insoluble calcium salt (e.g., $CaCO_3$) is dispersed within the Alg sol phase, and Alg crosslinking is triggered by pH-induced progressive release of Ca^{2+} promoted by the addition of an acidifying compound (e.g., glucono-d-lactone - GDL). [7] Internal gelation results in homogeneous gel and allows the 3D printing of uniform self-supporting fibers without the need for post-crosslinking or the use of supporting materials or bath. 3D printing based on this crosslinking mechanism has been limited to Alg-based bioinks. Even though Alg is biocompatible, non-immunogenic and non-toxic, its applications are restricted due to the lack of cell-adhesive motives and poor *in vivo* degradation [4]. To overcome such limitations, herein we investigated the use of oxidized alginate or alginate dialdehyde (ADA) to improve materials degradability, and its combination with gelatin (Gel) to promote cell adhesion and enhance biological properties. In this work, novel Alg-ADA-Gel hydrogels based on internal gelation mechanism were optimized for applications as bioinks for prospective applications in *in vitro* cardiac tissue engineering.

II. MATERIALS AND METHODS

ADA was produced through partial oxidation of sodium alginate via sodium metaperiodate following the protocol by Sarker *et al.* [11]. The oxidation degree was calculated through a starch-iodine method, measuring the unconsumed sodium metaperiodate as described by *Sarker et al.* [11]. Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) and ^{13}C CPMAS (cross polarization/magic angle spinning) NMR of alginate powder and ADA lyophilized samples were carried out to investigate the successful formation of aldehyde groups in the alginate chains. Molecular weight of ADA and Alg were determined through viscometric analysis using an Ubbelohde viscometer.

Alg-ADA-Gel hydrogels were optimized maintaining constant ADA, $CaCO_3$ and GDL concentration and varying the polymer weight ratios of Alg:Gel (% w/w) from 100:0 to 50:50 keeping

the final content of Alg + Gel equal to 3% w/v. Rheological characterizations were performed at 37°C using MCR 302 rheometer (Anton Paar) equipped with a parallel plate geometry with a diameter of 25 mm.

In vitro water absorption and dissolution tests were carried out by immersing bulk hydrogels in phosphate buffered saline (PBS) at 37°C to investigate their stability as a function of time. At each time point, the weight of the samples was measured both in wet state and, then, in dry state after freeze-drying. Water absorption degree was calculated as the percentage of water absorbed by hydrogel samples *versus* time. Dissolution degree was calculated as the percentage of dry sample weight loss *versus* time.

Hydrogel printability was assessed using RegenHU - 3D Discovery^{TM} bioprinter by optimizing printing parameters. Model filaments and grid geometries were printed. To investigate changes in printability over time, grid structures were printed at selected time points (from 10 to 90 min). Images were collected with Nikon Eclipse Ti2 spinning disk and NIS-Elements software (Nikon) and the data were analysed using ImageJ software.

In vitro cytocompatibility studies on printed cells-laden Alg-ADA-Gel hydrogels were performed using adult human cardiac fibroblasts (AHCFs), according to ISO 10993-5. Cell viability of AHCFs embedded in printed hydrogel filaments was assessed by Live/Dead assay. Briefly, AHCFs were dispersed in PBS and incorporated in the bioinks with the dual syringe mixing method. 3D bioprinted grid structures were obtained on a 12-well plate, maintained in a humified incubator at 37 $^{\circ}$C, 5% CO_2 and images were collected using Nikon Eclipse Ti2 fluorescence microscope equipped with a spinning disk.

III. Results and Discussions

Alginate dialdehyde was successfully prepared through partial oxidation of alginate via sodium metaperiodate with an average production yield of 75% and an average oxidation degree of 25%. ATR-FTIR and ^{13}C CPMAS NMR spectra further confirmed aldehyde groups formation and successful ADA production. Furthermore, 93% decrease in the viscosity average molecular weight of ADA respect to Alg was measured. Aldehyde groups of ADA are expected to undergo Schiff base reaction with primary amino groups in Gel. On the other hand, ADA carboxyl groups may electrostatically interact with calcium ions.

Initially, the effect of the addition of ADA into Alg-based hydrogels was investigated. The relative amount of the polymers in Alg-ADA hydrogels was optimized to achieve a stiffness value similar to that of Algysil and close to that of cardiac tissue (i.e., G': 1-3 kPa) [12]. The presence of ADA in the selected Alg-ADA hydrogel compositions caused an increase in the hydrogel dissolution rate compared to initial Alg-hydrogels: after 21 days of incubation in PBS, a weight loss of 42% *vs* 25% was measured in bulk Alg-ADA vs. Alg hydrogels, respectively.

Then, Alg-ADA-Gel hydrogels were prepared by optimizing Gel amount to confer cell-adhesive properties to the samples. Alg-ADA-Gel hydrogels preserved cardiac tissue-like viscoelastic properties by properly tuning Gel concentration.

Rheological tests showed a decrease in storage modulus G' as a function of Gel content. Moreover, printability studies of Alg-ADA-Gel hydrogels, moreover, evidenced that all the compositions possessed time-dependent shear thinning properties suitable for 3D bioprinting and influenced by Gel content. Alg-ADA bioinks alone (without Gel) underwent a rapid crosslinking, forming self-standing scaffolds with a printability window of up to 30 min. For bioinks containing Gel, cross-linking time increased, hence the printability interval increased consistently as a function of the amount of Gel in the bioinks, reaching 90 min for samples with 50:50 of Alg:Gel ratio. Within the printability windows, optimal printability times were identified for each hydrogel composition, depending on crosslinking time. Exemplary images of printed grid structures are reported in Fig.1.

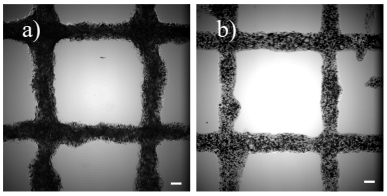

Fig. 1: Representative optical microscopy images of printed grid-shaped structures using: (a) Alg-ADA ink and (b) Alg-ADA-Gel ink with 50:50 Alg:Gel weight ratio. Structures were printed at the optimal printability times for each composition. The scale bar is equal to 250 um

Furthermore, *in vitro* tests showed that viability of AHCFs in contact with the analyzed samples was high (ISO-10993-5) and an increase in Gel content also improved cell adhesive properties of hydrogels.

Finally, the production of cell-laden constructs was investigated using a bioink with the highest content of Gel (1.5% w/v) tested in this work. As shown in Fig. 2, Live and Dead staining performed on a bioprinted cellularized hydrogel grid demonstrated the absence of death cells suggesting the biocompatibility of the bioinks and biofabrication conditions.

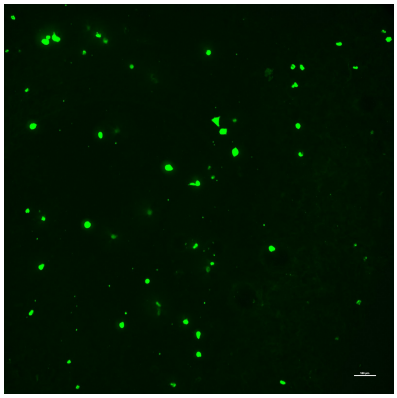

Fig. 2: Live/Dead stained AHCFs in 3D bioprinted constructs visualized after an incubation time of 1h Scale bar equal to 100 um.

IV. Conclusion

In this work, novel Alg-ADA-Gel inks based on internal gelation mechanism were developed to provide suitable properties for bioprinting in cardiac tissue engineering. Specifically, the incorporation of Gel through ADA was investigated to improve the biological features of Alg-based hydrogels and to study the influence of Gel on the cross-linking mechanism. Shear thinning inks with biomimetic viscoelastic properties, cell adhesion ability and tunable stability in physiological conditions were obtained by varying ADA and Gel contents. Printability studies showed that increasing Gel content delayed the cross-linking time of the hydrogels widening the printability window and increasing the optimal printing time. *In vitro* cell tests demonstrated the biocompatibility of Alg-ADA-Gel bioinks. Finally, 3D cell-laden constructs were printed using a selected Alg-ADA-Gel bioink containing AHCFs. In the future such bioink could be exploited to design *in vitro* models of cardiac fibrotic tissue. Alternatively, by changing the types of encapsulated cells, the bioink could be used for the biofabrication of patches for cardiac tissue regeneration.

Abstract **Childhood visceral myopathy (VM) is one of the most severe and life-threatening pathologies affecting intestinal tone and motility. There is currently no cure. Novel engineering solutions are urgently required to provide longer life expectancy and quality to people with VM. In this context, replicating gut anatomy and mechanics is fundamental for pre-clinical studies. However, replicating complex gut anatomy and its combination with intestinal mucosa is still challenging. For this reason, we designed and fabricated a multiscale phantom-based model reproducing the bowel anatomy and mechanical properties of a 10-year-old child. PDMS was used as a material to mimic intestinal wall mechanics, while alginate with type II mucins was selected for the luminal lining. The luminal content was also replicated using pectin solution mimicking physiological viscosity ranges.**

Keywords **Phantom, peristalsis, lumen content, viscosity, pH.**

I. Introduction

THE bowel is a vital organ that acts as a barrier protecting the body from pathogens while digesting food, absorbing nutrients, and eliminating waste. These processes depend on coordinated intestinal muscle contraction and relaxation [1] along a long-twisted tube with variable diameter. The intestinal wall consists of five overlapping tissue layers: serosa, longitudinal and circular smooth muscle, submucosa, and mucosa, from external to inner, respectively. Longitudinal muscles shorten or lengthen bowel segments while circular muscles narrow or widen the bowel lumen. At functional level, these muscles are controlled by the enteric nervous system, enabling segmentation, peristalsis, and other complex movements. Segmentation is a series of directionless contractions and relaxations that mix intestinal contents, while peristalsis is a wave of unidirectional contractions that push the luminal contents along the bowel [2]. These physiological processes can be disrupted by various pathologies affecting gut function and motility. Among the most severe disease bowel motility disorders are visceral myopathies (VM), typically genetic diseases characterised by profound bowel, bladder, and uterine smooth muscle weakness [3], [4]. The most severe form is called megacystis microcolon intestinal hypoperistalsis syndrome. All VM causes marked bowel dilation, prolonged dependence on intravenous nutrition, and often causes death in childhood. Current therapy is purely supportive, inadequately relieves symptoms, and leaves children at risk for dangerous complications of prolonged intravenous nutrition (e.g., sepsis, vessel thrombosis).

Pre-clinical studies with intestinal phantoms are thus fundamental for the identification of strategies to support gut wall tone and motility. Table I summarises the intestinal phantoms in the literature according to the intestinal portion addressed, and the materials used to model gut wall, mucosa, and intestinal contents.

TABLE I: Current solutions to mimic the gut

Author	*Gut portion and shape*	*Material for intestine and luminal content models*	*Mucosa layer*
Suzuki et al [5]	Intestine, straight tube	Phantom: rubber latex and carbonium fibres Luminal content: water	No
Wrigth et al [6]	Duodenum, tube with un-physiological loops	Phantom: acrylic cylinder and dialysis membrane Luminal content: protein isolate and arabic gum [7]	Presence of mucins in the lumen content but without a real mucus layer
Ashigaki et al [8]	Small intestine, straight tube	Phantom: nitrile rubber Luminal content: polybutadiene with hydroxyl radicals	No
Tharakan et al [9]	Small intestine, straight tube	Phantom: cellulose ester membrane Luminal content: guar gum [10]	No
Minekus et al [11], Blanquet et al [12]	From stomach to colon, tube systems	Phantom: glass and silicone Luminal content: guar gum	No
Guerra et al [13]	Stomach and small intestine, straight tube	Phantom: polycarbonate Luminal content: diethylenetriamin epentaacetic acid in water [14]	No
Hribar et al [15]	Small intestine, straight tube	Phantom: silicone Luminal content: polyethylene oxide and water	No
Wang et al [16]	Stomach and duodenum, tube with un-physiological loops	Phantom: silicone Luminal content: beef stew and orange juice [17]	No

However, most of these studies do not accurately reproduce small intestine anatomy, the presence of an inner mucosa layer and/or mechanical properties in physiological or pathophysiologic conditions. Moreover, although different examples of artificial intestinal mucosa can be found in the literature [18], their integration with intestinal phantom is still missing.

The aim of this work is to address current limitations, engineering an advanced intestinal phantom or 'physical twin' for a 10 year-child preserving shape, complexity, size of the bowel and deformation capabilities.

II. Material and Methods

○ *Phantom*

The phantom was designed according to the following specifications, focusing on the small bowel:

- Anatomy: duodenum with physiological loops, as shown in fig 1. The size is based on a 10-year-old child (length 185 mm, diameter 21 mm and thickness 1.4 mm). These dimensional parameters were obtained by extrapolating adult data [1], [2] through scaling, keeping the ratio of tube diameter to thickness constant.
- Mechanical properties: elastic modulus of healthy tissue is approximately 2-3 MPa [19-20]. The value may be lower in people with VM due to loss of tone or higher due to fibrosis [3].

A realistic simplified version of the phantom was developed using CAD (Computer Aided Design) software (Fusion 360). Polydimethylsiloxane (PDMS) was selected to mimic gut mechanical properties. The properties of this material can be modulated according to monomer - crosslinking agent ratio to replicate the different properties of pathophysiological gut walls. In particular, the following ratios were selected: 4:1, 5:1 and 6:1 [21]. Solutions were then degassed for 15 minutes and, after casting in custom moulds (obtained thanks to fused deposition modelling in Acrylonitrile Butadiene Styrene - ABS), samples were cured at 60°C for 6h. Tensile tests were performed at a strain rate of 6 mm/s using a universal testing machine (*Zwick-Roell, Z005 ProLine)*. A 60% maximum deformation was selected corresponding to the limit beyond which the muscle, at a physiological level, remains in the elastic regime and therefore does not exceed the critical deformation that leads it to leave the elastic region [19-20]. PDMS was silanized with (3-Aminopropyl) tiethoxysilane (APTES) to increase surface wettability and coupling with the mucosa layer. PDMS samples were soaked for i) 5 minutes in a 1% of APTES v/v - 50% ethanol solution with, ii) 3 minutes in a 33% v/v acetic acid solution and iii) dried for 1 minute in a vacuum chamber. The wettability of silanized-PDMS and PDMS samples was tested with 1% alginate solution with a tensiometer (*Biolin scientific*), measuring the contact angle over time for 10 minutes.

○ *Luminal content modelling*

Replicating small bowel luminal content rheology at different pH values is also fundamental to testing the efficiency of the technology in assisting luminal content propulsion within the bowel. As food moves from the stomach into the duodenum, the pH changes from a range of 1.5-3.5 to 5-6 as the acidic gastric contents are neutralised by pancreatic secretions. pH increases to 8 at the end of the intestine [22]-[24]. The intestinal tract's viscosity also changes because of nutrient absorption. Numerous studies use animals and predictive models to estimate viscosity due to the difficulty in measuring it [25], [26]. In the intestine physiological shear rate (1-10 s^{-1}), the estimated viscosity values fall between 0.1 and 10 Pas [26]. Buffers were obtained by dissolving 0.681 % w/v potassium dihydrogen phosphate and 0.022, 0.1164, and 0.187 % w/v sodium hydroxide in distilled water, obtaining solutions at pH 6, 7 and 8, respectively, to reproduce the different portions of the small intestine. pH values were assessed with a pH meter (*Hanna, Edge series).*

Different materials were then dissolved in the buffer solutions (pluronic from 15 to 20% w/v, pectin from 0.5 to 5% w/v). Viscosity measurements were performed using a *Brookfield DV-II+PRO* Viscosimeter.

○ *Mucosa layer modelling*

0 to 0.7% Alginate was selected for its ability to adhere to the intestinal mucosa thanks to polymer chain length and the presence of ionisable groups. [27]. Type II Mucins, present in the physiological mucus, were added to alginate solutions at a concentration of 0.5, 1, and 1.5%. Solutions with different concentrations of alginate and mucins were tested in terms of viscosity. Viscosity was measured as described in the previous subsection.

III. Results

Fig. 1 shows the CAD design for the phantom, while Fig. 2 reports CAD designs of the moulds for two sections. The phantom is finally obtained by coupling the different PDMS sections.

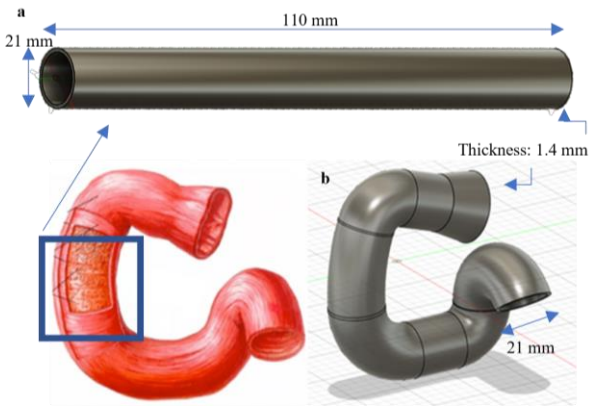

Fig. 1: Comparison between physiological duodenum and technical drawings of a) simplified mould, b) realistic mould.

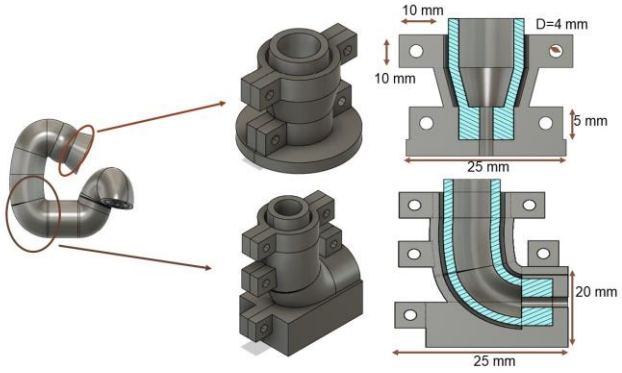

Fig. 2: Technical drawing of the moulds of two different parts of the duodenum.

Mechanical results are shown in Fig. 3. the 5:1 ratio apparent elastic modulus (2.09 ± 0.17 MPa) resulted close to the desired range (2-3 MPa [19-20]) and was selected for phantom fabrication. However, ratios and curing times can be further optimised to better match both diseased tissues.

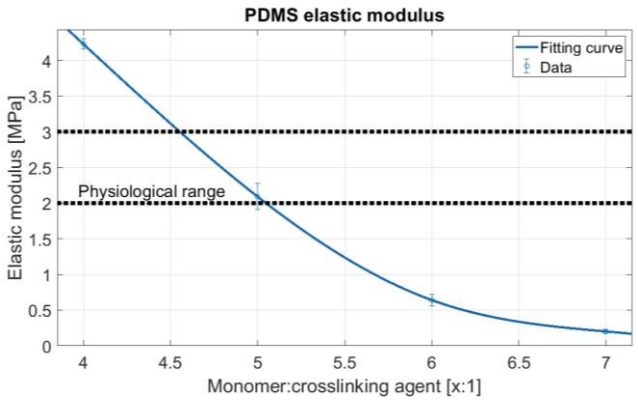

Fig. 3: PDMS elastic modulus with different ratios.

Moreover, the wettability results in Fig. 4 show that the contact angle on silanized PDMS is significantly decreased with respect to the untreated PDMS, confirming the improvement of the wettability of the substrate.

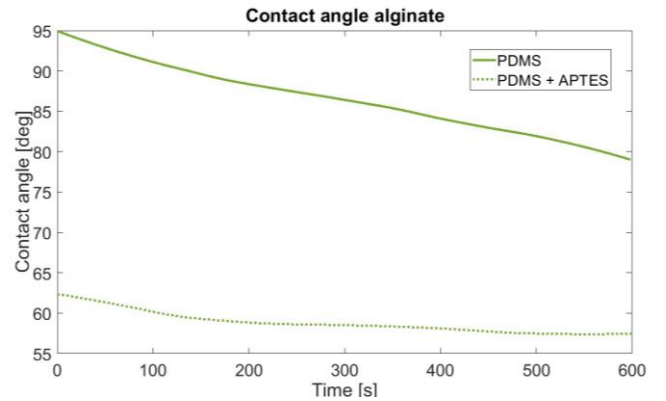

Fig. 4: Contact angle of 1% alginate on silanized PDMS and PDMS over time.

Table II shows that pluronic cannot be used to reproduce the luminal content because the viscosity values do not cover the entire physiological range at 37 °C (0.1-10 Pas [26]). Indeed, pluronic gelling temperature increases with increasing concentration. Thus, solution viscosity was not measurable at 18 and 20% w/v.

TABLE II: PLURONIC VISCOSITY AT PH6 AND 37°C

Concentration [% w/v]	*Viscosity [Pas]*
15	0.0657
17	0.37
18	Not measurable
20	Not measurable

Differently, pectin viscosities (Figure 5) fall within the desired physiological range at all pH. Moreover, it was also observed that viscosity decreases as the pH increases. This behaviour can be related to hydrogen bonding between protonated carboxylic acid groups on the pectin backbone [28].

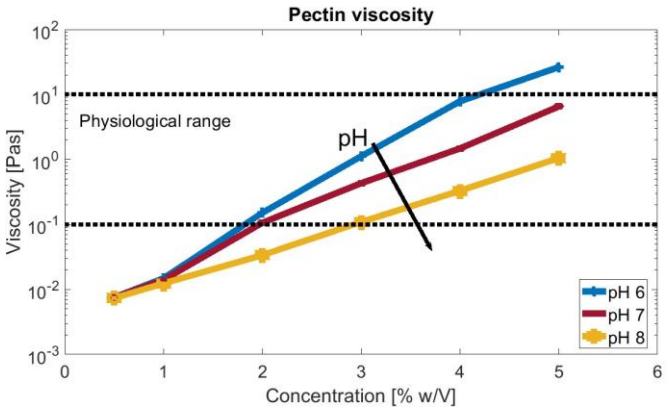

Fig. 5: Pectin viscosity in buffer solutions with different pH, plotted in logarithmic scale with respect to pectin concentration.

Finally, the viscosity of alginate as a function of polymer and mucin concentration is shown in Figure 6, demonstrating its compatibility with the physiological mucus range (3.8 and 25.8 mPas [29]).

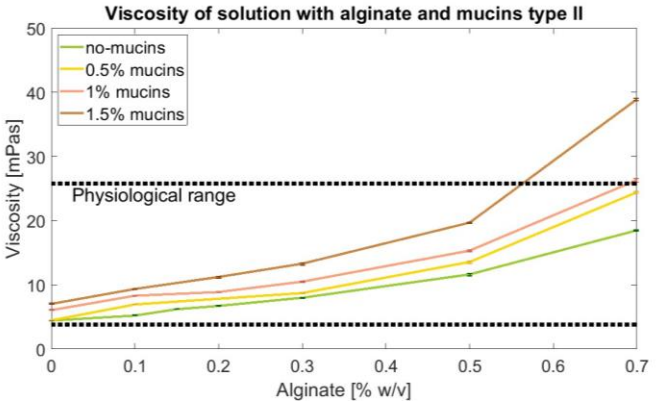

Fig. 6: Alginate with mucins viscosity in buffer solution at pH 7.

IV. CONCLUSION AND FUTURE DEVELOPMENTS

In this work, the first steps toward the design and fabrication of a physiologically relevant intestinal phantom were presented. PDMS was used to match healthy intestine mechanical features and functionalised to improve the coupling with an artificial mucus layer. The materials to reproduce the mucosa layer and luminal content were also characterised in terms of pH and viscosity properties.

We are currently investigating further conditions to replicate diseased conditions. Future studies will also involve the further development of digital twins by combining computational models with endoscopic images of bowel motion to inform the design of a magnetic actuation field. Developing non-animal phantoms, this work is also in line with 3R principles (Reduction, Refinement and Replacement of animal experiments as prescribed by EU directive 2010/63 and national legislation).

***Abstract*—Bacterial colonization and biofilm formation on medical devices is one of the most pressing current healthcare issues, posing serious threats to patients health other than having a great economic impact on national healthcare systems. Smart and tailored biomaterials for the fabrication of medical devices are needed to contrast this problem, in particular the development of surface modification strategies, preventing bacteria adhesion and proliferation into mature biofilm. Layer-by-layer (LbL) assembly technique allows for easy, reproducible and specially designed surface modifications, providing the material with the desired antibiofilm activity. More interestingly, LbL coatings can also display smart, stimuli-responsive features to favour a controlled, on-demand antibacterial response which is triggered only when bacteria are present (self-defensive coatings).**

***Keywords*— antibacterial coating, layer-by-layer technique, surface functionalization, responsive behaviour**

I. INTRODUCTION

One of the main criticalities associated with short and long-term use medical devices is bacterial colonization with subsequent formation of biofilm. Among the most problematic medical devices we find invasive ones, both implantable such as dental [1] and orthopaedic prostheses [2], cardiac valves and pacemakers [3]-[5], silicone prosthesis used in multiple surgical procedures [6]-[8], catheters used for several anatomical districts [9] [10], endotracheal tubes for pulmonary ventilators [11], suture threads [12], and also non-implantable ones like ophthalmological contact lenses [13]. The incidence of nosocomial and medical device-associated infections is still unacceptably high [14], given that biofilm formation on such devices and implants leads to severe functional and medical problems, not to mention aesthetical discomfort in some cases. These malfunctions, along with the infection itself, can seriously threaten patients health and well-being, apart from weighing on healthcare costs because of prolonged hospital stays, revisions of surgeries, new production of devices and frequent clinical visits [15]. It is impossible to completely eliminate all potential causes of contamination, spreading from surrounding environment, human skin, administered intravenous fluids, unsterile instruments, poorly aseptic medical procedures, difficulty of cleaning/treating complex or hidden anatomical regions. The increasing resistance of microorganisms to antibiotic drugs and the inadequacy to eradicate them when in the biofilm mode of growth [16] have boosted research to develop new smart and specifically designed antimicrobial biomaterials. An interesting solution is offered by surface treatments and coatings that do not affect bulk material properties, allowing to limit the antibacterial action only to the region actually colonized by biofilm formation. Such approaches should focus both on prevention of bacterial adhesion (antifouling action) and treatment of bacterial infections (antimicrobial action), preferably exerting their antimicrobial action in a smart and controlled way. In fact, current antibacterial strategies for biomaterials aim at preserving their antimicrobial potency until actual bacteria have adhered on the surface, thus avoiding premature loss of efficiency and potential side effects to surrounding living tissue. Among such useful surface modifications that allow bacteria-triggered antibacterial activity, layer-by-layer (LbL) surface deposition technique in particular stands out as a simple, versatile technique which is able to incorporate a plethora of antimicrobial agents like antibiotics, antimicrobial peptides (AMPs) or nanoparticles and be applied to a wide range of different substrate chemistries and geometries. This work has the aim of introducing the most interesting and innovative LbL antimicrobial strategies recently developed, focusing on coatings that exert their action in response to stimuli specifically linked to the bacterial colonization microenvironment present at the site of infection.

II. THE GENESIS OF BACTERIAL BIOFILM

Bacterial microorganisms do not only exist as planktonic, single floating entities. On the contrary, they tend to aggregate and organize themselves in colonies in order to improve their adhesion, nutritional support and resistance to environmental stresses. For medical device-associated biofilms such external threats could be host immune response, antibiotic therapy or antimicrobial agents in general. Once adhered on the device surface, the attachment can be considered a trigger for biofilm organization and thus the bacteria start to produce biopolymers like polysaccharides, DNA, proteins and lipids which constitute their extracellular matrix (ECM), becoming embedded in it [17] [18]. The ECM is the major component of the resulting biofilm, holding together the developing microcolonies. The process of biofilm formation is supported and controlled by constant communication within and between bacterial species (e.g. quorum sensing). It can be divided in four essential steps (Fig. 1) [19]:

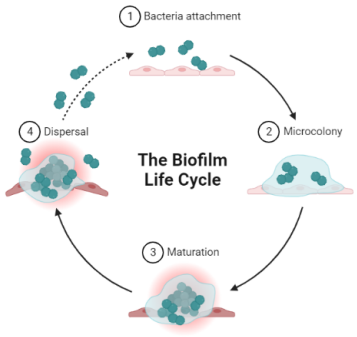

Fig. 1: the essential four steps in biofilm formation
Reprinted from "The Biofilm Life Cycle", by BioRender, November 2022, retrieved from https://app.biorender.com/t-636d1940a2064909c86a9b8c-the-biofilm-life-cycle
Copyright © 2023 by BioRender.

1) initial reversible attachment of bacteria through several mechanisms that guarantee a stable anchorage;
2) aggregation in microcolonies, mainly through bacterial replication and adhesion of new cells, leading to spatial expansion and irreversible attachment;
3) maturation of biofilm, tridimensional growth and proliferation secured by the ECM stability and protection;
4) dispersal of cellular aggregates from the biomass into the surrounding environment, probably because of increased cellular density within the biofilm.

Given the possibility of detachment and dispersal of bacteria after maturation, it is clear that medical device-associated biofilms constitute a health risk not only at the site and time of contamination but expose the patient to possible chronic infection and/or sepsis. This is one of the main reasons why strategies for prevention and treatment of biofilm are extensively investigated when dealing with medical devices. Such antibiofilm strategies could be grouped in four main categories on the basis of their action [17]:

1) prevention of microbial adhesion (antifouling surfaces);
2) inhibition of bacterial communication (quorum quenching);
3) killing of adhered microorganisms;
4) disruption of early stages biofilm formation.

All of these strategies could be pursued by means of surface modifications. In the first line of defence, antiadhesive surfaces are obtained both through physical parameters modification (changes in roughness, wettability) and also functionalization with antifouling moieties e.g. polyethylene glycol (PEG). Regarding the second, third and fourth approach, the design of surface coatings comprising specific active molecules (quorum sensing blockers e.g. furanones, antimicrobial peptides/nanoparticles/drugs, degradative enzymes e.g. dispersin B) represent the preferential line of action, either by immobilization of such molecules on the surface or through release systems.

III. Possible Solutions through Surface Functionalization

Since microorganisms proliferating inside mature biofilm are extremely difficult to extinguish because of the protective layer provided by the ECM, the best way to avoid bacterial colonization of medical devices is to prevent its formation. In order to do so, the device surfaces must exert an antibiofilm action. Surface functionalization of biomaterials could provide the necessary antifouling and antimicrobial activity, whether it be inhibition of bacteria adhesion, inhibition of their growth from the surface or direct bacteria suppression [17]. Self-defensive coatings stand out as an extremely interesting solution, being able to exert their antimicrobial action only when bacteria are actually colonizing the surface: thus, the antibacterial efficacy is preserved and readily available when needed. One of the key features of such innovative coatings is represented by their capacity of tuneable antibiotic release in response to specific triggers found in bacterial colonization microenvironment, mainly acidic pH and presence of degradative enzymes [20]. During bacteria metabolism, production of organic acids like, for example, lactic acid for *S. Aureus* or acetic acid for *E. Coli* leads to local acidification of pH. Moreover, bacteria release virulence factors that assist them in host colonization by evading/suppressing host immune response and allowing them efficient cellular adhesion and nutrition. Out of all these factors, degradative enzymes, e.g. hyaluronidase (HAS) and chymotrypsin (CMS), are frequently secreted. Among the plethora of surface modification techniques, LbL self-assembly stands out as a very versatile fabrication method, able to yield coatings that display antiadhesive properties and/or incorporate therapeutic agents while retaining their biological activity. Such LbL coatings could be easily rendered self-defensive: through incorporation of weak polyelectrolites, acidic pH would trigger an increase in permeability and/or direct disruption of the coating with subsequent release of antimicrobial agent [21] [22]; alternatively, if the LbL building blocks are sensitive to enzymatic degradation the presence of the afore-mentioned enzymes would lead to delamination of the coating with subsequent elimination of adhered bacteria and controlled release of integrated antibiotic drugs [20].

A. LbL surface functionalization

LbL self-assembly is one of the most popular bottom-up nanostructured surface modification techniques due to its reproducibility, efficiency, robustness and flexibility. The deposition results from spontaneous assembly of multivalent building blocks which are complementary thanks to the specific interaction between them (electrostatic attraction is very common, but also hydrogen bonds, covalent bonds, hydrophobic/charge-transfer/host-guest/biologically driven interactions) [23]. The process requires mild conditions, avoiding extreme temperature/pH or aggressive solvents, thus making it easy, cost-effective and suitable for a wide range of substrate chemistries and geometries. Its versatility also lies in the variety of molecules that can be incorporated as building blocks, allowing a targeted design of the coating features for the final application. The fabrication process, in the case of oppositely charged polyelectrolytes, is illustrated in Fig. 2: briefly, the substrate is alternatively exposed to the chosen polyanion and polycation solutions, a step of washing before each layer deposition is needed to eliminate residual unbound polyelectrolytes. Also, a preliminary step of substrate

processing could be necessary to allow suitable interaction with the first polyelectrolyte layer [24].

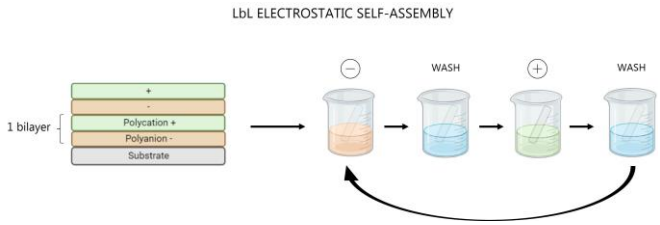

Fig. 2: LbL electrostatic self-assembly fabrication scheme

B. Bacteria-triggered antimicrobial response in LbL coatings

In the last decade, several self-defensive antibacterial LbL coatings have been developed exploiting acidification of pH or degradative enzymes as possible bacteria-related triggers. Wu et al. [25] incorporated two polycations such as 1,2-ethanediamine (EDA)-modified polyglycerol methacrylate (PGMA) and lysozyme, which provide multivalent interactions with bacterial membranes, in a LbL coating together with hyaluronic acid (HA) acting as a substrate for HAS and therefore, able to delaminate in its presence . Such coating was deposited on silica nanoparticles containing antibiotics, hence the delamination triggered the release of drug only in presence of bacteria. Another LbL coating that incorporates HA was developed by Wang et al. [26] and deposited on medical silicone substrates. The coating was composed of montmorillonite (MMT) and HA, both of which could electrostatically interact with gentamicin (GS) leading to successful high loading of antibiotic. The progressive degradation of HA by HAS leads to drug release but also film peeling, exerting a dual antimicrobial-antifouling action (Fig. 3).

A very similar approach was proposed by Xu et al. [27] but using poly-L-lysine (PLL) in combination with MMT and gentamicin. In this case, the degradation and delamination of the coating with subsequent drug release was due to CMS acting on PLL. Moving on to pH triggers, there has been extensive investigation that unfolded several interesting solutions. Employing weak polyelectrolytes that become poorly ionized at acidic pH determines weak electrostatic interactions with incorporated antibiotics and thus, slow diffusion of drug from the coating. Such sensitive building blocks could be natural polymers such as polyphenols [28] and chitosan [29] [30], synthetic polycarboxylic acids [31] but also inorganic compounds such as polyphosphazenes [32]. A peculiar strategy is represented by LbL hydrogel coatings made of poly (2-alkylacrylic acids) which were used for electrostatic adsorption of antibiotic [33] or simply as tuneable hydrophobic coatings with intrinsic antibacterial properties [34]. Both works use polyacids and the LbL technique in order to achieve an open molecular structure of polymeric cross-linked hydrogel. In the first study, the coating permitted self-hydration, which hinders bacterial adhesion, and loading of cationic antibiotics that could be released upon acidification of pH thanks to weaker electrostatic interactions. In the second, hydrogels were constituted of poly(2-alkylacrilic) acids with increasing hydrophobicities and acidic pH triggers could yield charge and water content changes thus interfering with the membrane of adhered bacteria.

IV. Summary and Future Perspective

Medical device-associated biofilm and infections are currently one of the open challenges in biomedical research. Self-defensive coatings stand out as an innovative and smart solution which is able to activate its antibacterial action only in presence of initial bacterial colonization, thus preventing coating premature loss of efficiency, antibiotic resistance and potential damage to surrounding tissues/cells. A particularly beneficial surface functionalization method able to yield such coatings is LbL deposition, allowing for a wide range of building blocks and possible geometries/chemistries of substrates, not to mention the possibility of incorporating several antimicrobial features (e.g. bactericidal and antifouling properties) in one coating. A step further in this direction, worthy of future investigation, would be to synthesize customable polyelectrolytes specifically designed for the application of interest. Making them responsive to a trigger of choice and imparting them with biomimetic or bioactive features for better biocompatibility or tissue integration are just a few of the possible interesting strategies.

***Abstract* — Vascular tissue engineering aims to regenerate vessels "at the target site" using cell-free synthetic scaffolds supporting endogenous regeneration. This approach aims to harness the natural wound healing process. This physiological response involves a complex series of events that could lead to detrimental outcomes, such as fibrosis and chronic inflammation. A critical aspect impairing the success of endogenous regeneration is the fine balance between functional neo-tissue formation, haemodynamic stimuli, and scaffold degradation.**

With the aim of investigating the biomechanisms at the basis of the interplay among these factors, we have developed an advanced *in vitro* culture system able to mimic *in vivo*-like physiological wall shear stress and pulsatile pressure. In the present work, we performed first biological tests to validate the device functionalities, in particular cell seeding and conditioning of a vascular graft.

This novel culture system will make possible to achieve fundamental insight concerning cell-graft interaction, synthetic scaffold colonization, and their response to haemodynamic cues.

***Keywords* — advanced culture system, *in vitro* model, hybrid fibroin/polyurethane vascular graft, vascular tissue engineering.**

I. Introduction

Recent developments in vascular tissue engineering strategies show a shift towards *in situ* vascular tissue engineering while using cell-free synthetic scaffolds promoting tissue regeneration inside the human body [1,2]. Ideally, the regenerated tissue is remodelled, guided by physiological hemodynamic loads, to resemble a vessel with native-like structural and functional properties, while the graft slowly degrades [3,4]. Despite encouraging *in vivo* proof-of-concept studies [5,6], intimal hyperplasia, early stenosis, and aneurysm formation remain prevalent complications in vascular graft implantation. These adverse events are often attributed to a mismatch between graft properties (e.g., microstructure, geometry, and mechanical properties) and haemodynamic induced mechanical loading, resulting in aberrant inflammation and pathological tissue deposition [7]. Nevertheless, the biomechanisms underlying tissue maladaptation remain elusive.

With the aim of investigating these phenomena, *in vitro* and *ex vivo* models are becoming increasingly more relevant as alternatives to *in vivo* animal tests, that up to now remain the standard [8]. The newly conceived *in vitro* models allow reproducing controllable hemodynamic, tuneability of single parameters - thereby avoiding neurohormonal effects-, none of which are possible *in vivo*. Controllability of the mechanical and chemical environment is also possible. Therefore, an advanced *in vitro* model could be a helpful tool for studying cell and tissue responses to graft implantation, applying mechano-chemical *in vivo*-like stimuli [9]. Moreover, the extensive use of such in vitro culture systems would significantly reduce costs in the preclinical and clinical phases, while not being subject to the ethical burden of animal experimentation and in accordance with the principles of the so-called three Rs principle: Replacement, Reduction and Refinement.

The aim of this project is indeed to develop a new device to fulfil the major requirements of an ideal system that allows simultaneous seeding, conditioning, and perfusion under *in vivo*-like stimuli for long-term experiments. So far, we succeeded in developing an advanced and versatile culture system able to host a cell-free vascular graft on which human endothelial cells can be seeded and grow properly in culture under perfusion conditions. Currently, experiments with different seeding and culture conditions and related biological analyses are ongoing to verify the suitability of the system to be used in a cell culture lab and its performances under different experimental protocols.

Its extensive use will enable the investigation of the mutual role of mechanical cues on cells-mediated neotissue formation.

II. Methods

A. Culture system design

The main design requirements are semi-automatic cell seeding, *in vivo*-like stimuli (fluid dynamic stresses and chemical factors), versatility of use, and compactness for being easily used within a standard incubator. Moreover, components that are in direct contact with cell media, cells, and/or tissues need to be suitable sterilizable.

The system main components are: a culture chamber, a rotating mixer for semi-automatic cell seeding, a pinch-valve to generate controlled pressure circumferential stress on the sample, and two fluid dynamic circuits – one for the luminal compartment and one for the extraluminal compartment – each one composed by a roller pump, a reservoir and an air chamber to dampen the pump's pulsatility (Figure 1A-D).

The culture chamber is adaptable to different vessel lengths (30 – 120 mm) and diameters (1.6 – 6.4 mm) and its geometry is optimized for nutrient and oxygen transport through fluid dynamics simulations thanks to the Comsol Multiphysics® software. All peripheral devices are managed by four microcontrollers which are set up through a custom wireless graphic user interface (GUI) developed in Labview® (Figure 1E); the communication between them is through TCP/IP protocol, allowing a stable and fast remote wireless control.

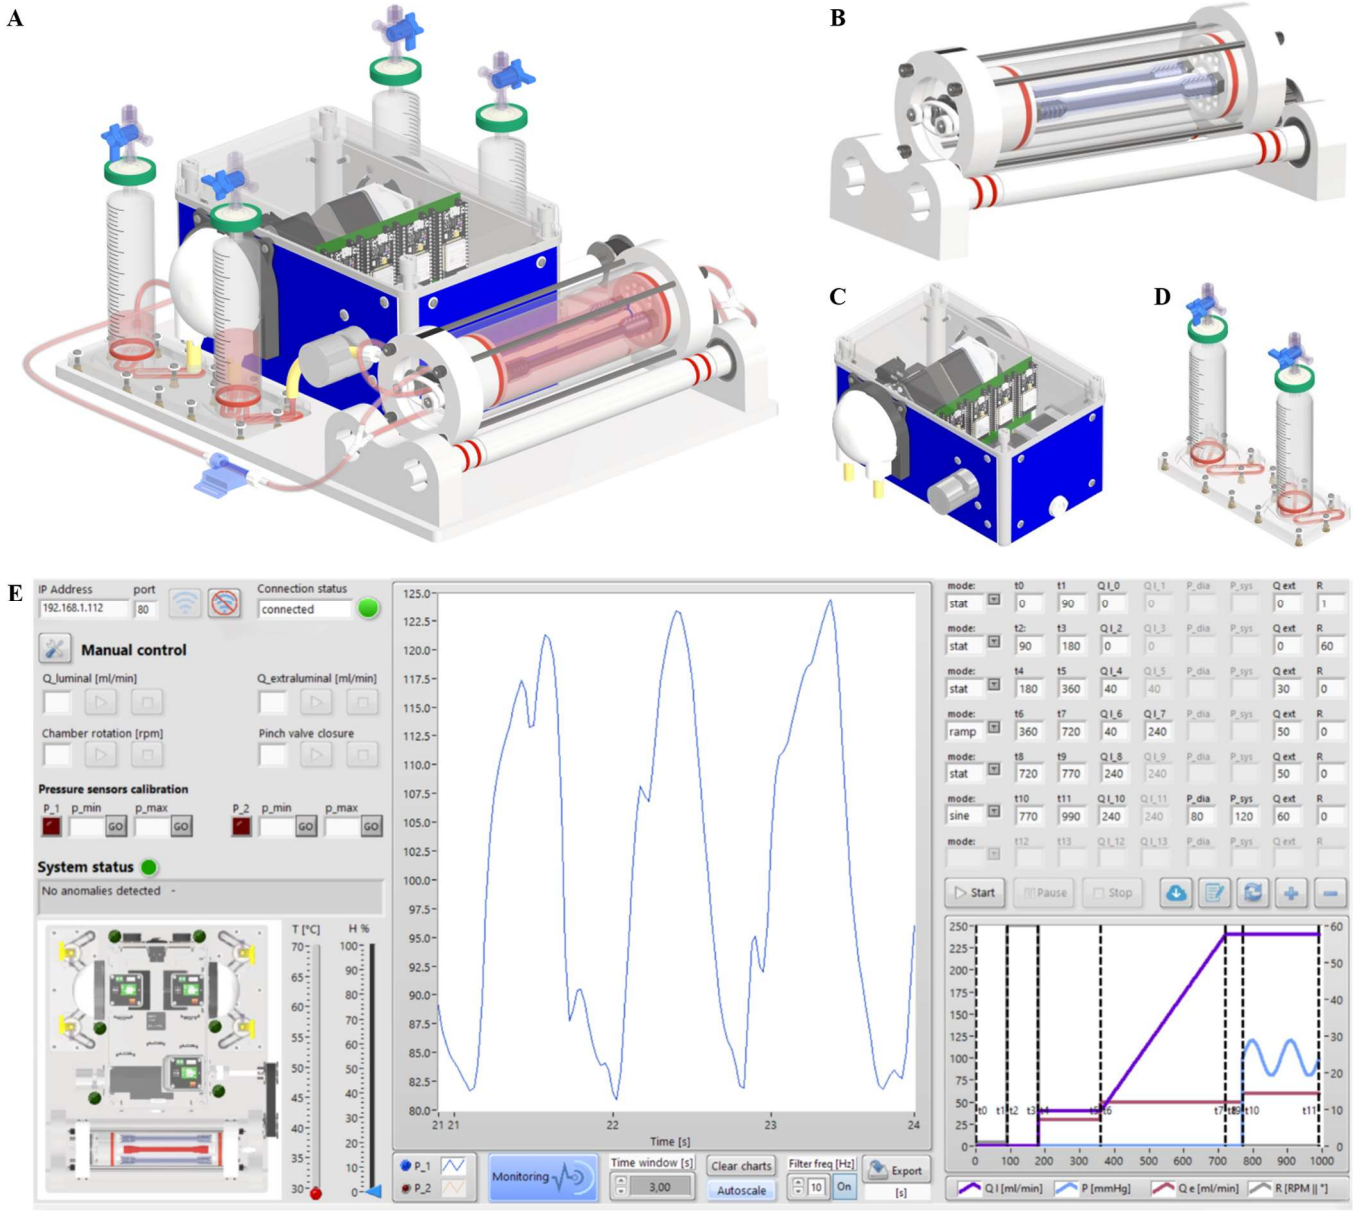

Fig. 1 (A) Culture system assembly CAD; (B) Culture chamber and rotating mixer; (C) Electronic control unit containing the peripheral devices (pinch-valve, roller pumps and stepper motor); (D) Syringe base with reservoir and air chamber; (E) Custom wireless graphic user interface developed in Labview®

Through the GUI it is possible to act on each peripheral device in manual control or to set an experiment by specifying the duration, the pumps' flow rate, the pressure regime, and the culture chamber's rotation speed for the seeding. The control unit constantly monitors the physical variables (pressure, bioreactor's rotation, temperature, and humidity inside the control unit case) and when unexpected events are detected (by pre-setting of parameters' thresholds), the execution of each peripheral device is interrupted, thus guaranteeing an elevated safety grade during system's use.

B. Cell-free hybrid graft

Three-layered electrospun grafts ($Ø_{in}$ = 6 mm, l = 60 mm), composed of a nanometric mesh of silk fibroin (SF) and polyurethane (PU) enclosed within SF layers, were manufactured and used for these tests [10].

C. Cell seeding and conditioning protocol

The first requirement to biologically validate our system is to obtain a homogenous cellular monolayer on the graft luminal side setting appropriate cell seeding and cell conditioning parameters. To reach this goal, the identification of an effective cell seeding protocol is crucial.

The cell culture experimental protocol consists of the human umbilical vein endothelial cells (HUVECs) seeding through an *ad hoc* semi-automated procedure. HUVECs were isolated from human umbilical cords and characterized, as previously described [11]. Cell seeding (10^6 cells/ml) was achieved using discrete rotations (4 angular position, each kept for 30 minutes). Concerning the conditioning protocol, initially we applied a steady WSS of 0.1Pa for 12h, we gradually increased WSS up to 0.4Pa during 24h, and we applied a steady WSS of 0.4Pa for 12h.

D. Morphological and functional analyses

To accurately verify the critical steps of cell seeding and graft colonization, small ring samples of the graft ($Ø_{in}$ = 6 mm, l = 5 mm) were taken at different time points: after seeding phase (1 ring sample), after conditioning phase (3 ring samples at different positions) (Figure 2A).

Cell morphology was investigated by immunostaining of graft pieces and subsequent imaging through a fluorescence wide-field Zeiss Axio Imager microscope, equipped with the Apotome module (structured illumination). As markers, we selected DAPI (nuclear staining), phalloidin (actin cytoskeleton), and cell adhesion molecules. The latter, including VE-Cadherin, pFAK, paxillin, and ZO-1, will allow an initial assessment on the functionality of the tissue. Afterwards, we will evaluate flow-induced changes on HUVECs morphology, function, and gene expression (e.g., KLF-2, vWF).

III. Results and Discussion

A. Culture system bench tests and validation

The system was successfully subjected to bench tests to verify the no cytotoxicity of all components that are in direct contact with the sample and cell medium, the compatibility with the assembly procedures under laminar flow hood, the hydraulic sealing (up to 400mmHg), and the maintenance of sterility inside an incubator up to 21 days.

We believe that the versatility and easiness of use are the features that most distinguishes the culture system here developed and presented from those commercially available or present in the state-of-the-art. Indeed, the system is robust and reliable in setting and exploit different seeding and stimuli protocols and allow to carry out cell colonization experiments in a precise and controlled way, allowing to perform a fine tuning of the experimental procedures both in terms of rotary seeding and fluid dynamic conditions.

B. Cell seeding and conditioning results

According to previously published data [11], initial cell seeding protocols revealed the high affinity of HUVECs for the chosen hybrid electrospun vascular graft. Cell adhesion occurred rapidly following injection of cell suspension within the graft. Although the luminal surface was not entirely populated, the first morphological analyses are highly promising. We observed that HUVECs almost completely covered the graft (*i.e.,* without leaving empty spaces between them) and establish a complex cell-graft and cell-cell interaction network (Figure 2B-C). Of note, the staining of cell nuclei show that a complex architecture generated by the cell-graft binomial and composed of a compact cellular monolayer. All these observations endorse the possibility to obtain a functional cell-populated graft to subject to physio-pathological environments of fluid flow.

Following cell seeding, we applied a venous-like wall shear stress (up to 0.4Pa). Compared to the sample taken after seeding, only few cells were observed 48 hours after starting perfusion. We hypothesize that this is mainly due to conditioning protocol itself: WSS maximum value of 0.4Pa attained after 36h and maintained for 12h could be too high or applied too quickly in combination with a not yet optimal adhesion of all cells to the graft after seeding phase. Furthermore, given the intrinsic permeability of the electrospun graft, we found extravasation which could affect the stress state of the cell layer.

Currently, we are carrying out a fine optimization of the conditioning protocol parameters, mainly acting on the WSS maximum value and application duration.

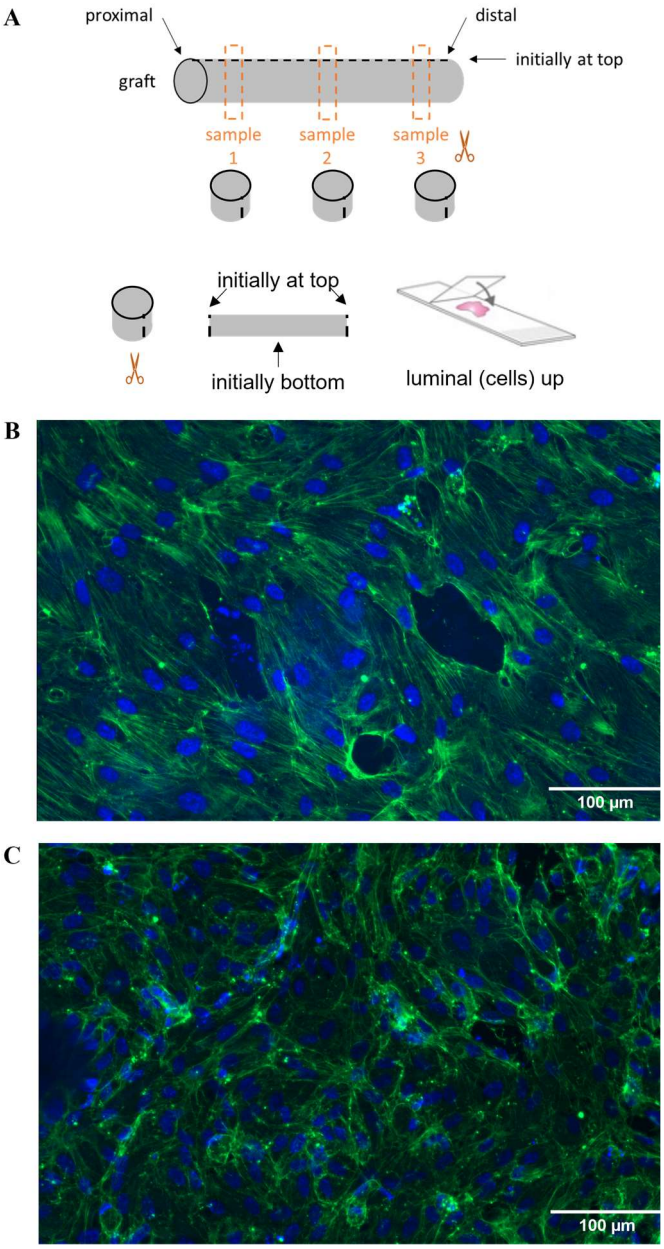

Fig. 2 (A) Representative scheme of sampling method for the cultured graft (proximal and distal respect to the cells injection site); (B)-(C) Immunostaining images (DAPI (blue), phalloidin (green)) at different sample position.

Once a completely circumferentially colonized graft will be achieved, it will be possible to fine tune the wall shear stress parameters to study the effects of haemodynamic conditions on vascular cells, as well as the process of inflammation *in vitro* (with the addition of other components into the cellular system, e.g. immune cells) and pathological tissue deposition or adaptation.

IV. Conclusion

In this study, we successfully developed an advanced culture system to investigate *in situ* biomechanisms of electrospun vascular prosthesis. We demonstrated its effectiveness in allowing semi-automatic seeding followed by finely controlled fluid dynamic stresses. The encouraging biological results that we obtained represent a preliminary, but crucial step. Indeed, obtaining a reproducible graft colonization is fundamental for

the exploitation of a custom-made culture system for blood vascular grafts. Now we are testing how a combination of circumferential deformation and WSS affect HUVECs cytoskeleton organization, as well as protein regulation and gene expression. In the future, the system shall be used to perfuse also native vessel harvested by slaughterhouses, under controlled arterial and venous haemodynamic conditions. In this way, it will be possible to investigate whether native vessel cell functions respond differently to physical stimuli, and their mechanobiology. In experiments with native vessels, as read out, we will consider matrix growth, tissue remodelling, and gene expression, and early pro-pathological markers.
In perspective, through the developed advanced culture system and the drafting of *ad hoc* protocols for both graft cellular colonization and native vessel experiments, it will be possible to establish an accurate *in vitro* model that allows to investigate the complex biological interactions that occur in vascular tissue engineering.

***Abstract*—In this work we propose a novel nanocomposite hydrogel formulation, composed of food waste-sourced polymers (gelatin and pectin) and nanosytems (multiwall carbon nanotubes), and produced by extrusion-based 3D printing, to lay a foundation for nanostructured 3D printed drug testing platforms.**

***Keywords* — 3D printed hydrogels, carbon nanotubes, tissue engineering, drug testing**

I. Introduction

Natural polymer-based hydrogels, three-dimensional hydrated polymeric structures, are extensively used in tissue engineering studies for their extracellular matrix mimicking properties, biocompatibility, and biodegradability [1]. Drug investigation urgently requires advanced *in vitro* models to investigate and test new pharmacological options. In fact, current in silico or *in vitro* approaches and animal models can't replicate the morphology, functionality, and biochemistry of certain complex human tissues, such as the pulmonary blood/air barrier or the blood-retinal barrier [2].

Recent progress in tissue engineering has led to the development of advanced 3D hydrogel systems. The complexity of human tissues requires tissue engineering practices to ensure precise control over architectural cues and cell activity, viability, and stress [3], [4].

Nanosystems have caught the scientific community's interest for their capability of improving hydrogel structural stability, shape fidelity, cell-interaction, and viability, while maintaining scaffold biocompatibility. Moreover, they can allow a more efficient drug delivery, by enhancing cellular uptake and bioavailability while reducing adverse side effects [2], [5], [6]. Nanosystems exist in different structures (2D and 3D), organizations, and nature, such as carbon-based (nanotubes and graphene), polymeric (nanoparticles and micelles), silica oxides, metal oxides, nanocrystals, lipids (liposomes and solid lipids), and quantum dots [7].

Among nanomaterials, carbon nanotubes (CNTs) present appealing physicochemical properties, easily tuneable by surface functionalization. The functionalization of CNTs with various biomolecules has allowed interesting drug delivery applications [8]. CNTs have in fact been employed to trigger drug release in a hydrogel system thanks to their sensitivity to near infrared radiation (NIR) or UV light [6], [9]. However, the introduction of nanosystems could affect the matrix hydrogel's printability [10].

In the present study, an eco-friendly biodegradable biomaterial ink, printable by extrusion-based 3D printing (EBP), was designed for the development of a 3D tissue-engineered drug testing platform. The aim was to investigate the properties of the material and the effect of the addition of multi-wall carbon nanotubes (MWCNTs) on the printability and post-printing stability. The biomaterial ink was based on a blend of two natural polymers, namely gelatin and pectin. MWCNTs functionalized with -COOH groups (MWCNT-COOH) were added to the polymeric biomaterial ink solution. The 3D printed hydrogels were crosslinked using a genipin solution. Morphological analysis, mechanical characterization and degradation tests were carried out.

II. Materials and methods

A. Materials

Gelatin from porcine skin (type A, gel strength 300g bloom) was acquired from Sigma Aldrich (Saint Louis, MI, USA). Pectin from fruit waste (classic CU 701, DE 36%, MW 100-400 kDa) was acquired from Herbstreit&Fox (Neuenburg, Germany). Genipin (98% purity HPCL), was acquired from Challenge Bioproducts Co. LTD, CBC (Taiwan). Multi wall carbon nanotubes (93%wt purity) were acquired from CNT Co. LTD (South Korea) and functionalized with carboxylic groups (-COOH) in a nitric acid tank (68% HNO_3, Sigma Aldrich) for 50 hours at the Technology University of Warsaw, by Professor Leszek Stobinski. Dulbecco's phosphate buffered saline (DPBS) 1X (9.55 g/l in deionized water) was acquired from Biowest (Meda, Italy), and Tween 20 was acquired from Sigma Aldrich (Italy).

B. Preparation of the gelatin/pectin solutions

The polymeric solution GelPec (5% gelatin and 1% pectin w/v in DPBS) was prepared by mixing polymer powders in the solvent at 70°C under stirring at 700rpm for 60 minutes.

C. Preparation of the GelPec/MWCNT solutions

Tween 20 (100µl) was added to the MWCNT-COOH powder, which was then diluted in PBS (0.1%w/v) and sonicated in a cold environment for two hours at 59kHz and 2W power (Vibra Cell 130, Sonics&Materials Inc., Newton, MA, USA) to produce a dispersion. Three MWCNT-COOH/GelPec solutions were created (0.3%, 0.9%, 1.2% w/w, respectively) adding the gelatin and pectin powders to the MWCNT dispersion (beforehand stirred at 70°C, 700 rpm for 15 minutes), diluting accordingly in DPBS and stirring for 60 minutes at 700 rpm at 70°C.

D. 3D printing and crosslinking of the scaffolds

All solutions were left to cool at room temperature before printing. Disposable syringes were loaded with the gels and inserted in a NEMA17 motor driven 3D printing platform. Depending on the characterization method, different CAD designs were printed: woodpile (square based, 25% infill, six 3-by-3 crossed 250µm layers) and filled (65% infill, three 250µm layers, various base areas). The extruding nozzle diameter was 400µm. The speed of the extruder on the x-y plane was 8 mm/s. CAD designs were produced with Autodesk Fusion 360 and the G-code was generated with Repetier Host. Samples were printed on laboratory slides or acetate sheets depending on their dimensions. Figure 1 displays some printed woodpile and filled samples.

E. Crosslinking optimization

Samples were solvent casted in a multiwell plate (13mm well diameter) at 4°C, cut to 5mm heights and crosslinked in different solutions: genipin 0.5% w/v in ethanol or genipin 0.5, 0.25 and 0.2% w/v in DPBS. The samples were completely submerged in the solutions. The crosslinking took place in two phases: room temperature overnight and 40°C for 24h.

F. Scaffold characterization

1) Degradation test

Woodpile samples were printed, weighed, crosslinked, kept in water at 40°C (hydration phase) and weighed again at set timepoints during a 9-day test span. Genipin-crosslinked pure gelatin samples were included as a control. Average post-crosslinking weight and relative weight loss (printed vs crosslinked sample) were analysed by ANOVA.

2) Morphological characterization

Printed woodpile samples were analysed (Leica Microsystems srl, Varese, Italy) before and after the crosslinking and during the hydration phases. Dimensions were extracted from microscope photos with ImageJ at set timepoints (as printed, crosslinked, hydrated for 24h). ANOVA analysis was used to evaluate the effect of carbon nanotubes percentage and timepoints on line and pore features.

3) Mechanical characterization

Filled samples were printed, crosslinked, and tested on a uniaxial tensile texting machine (Zwick Roell ProLine Z005, Zwick Gmbh & Co, Germany). Young's modulus, breaking stress and strain were calculated. A pretension was set at 0.005N and testing speed was set at 2.6 mm/s. Average nominal length and surface of the samples were respectively 26.7mm and 5.4 mm^2.

III. Results

GelPec resulted in a printable and crosslinkable biomaterial ink exhibiting post-printing stability. The printability of GelPec biomaterial ink was not affected by the addition of carbon nanotubes. Genipin 0.2% in DPBS showed the best crosslinking results in terms of integrity and stability of the hydrogel (Figure 1 and Figure 2).

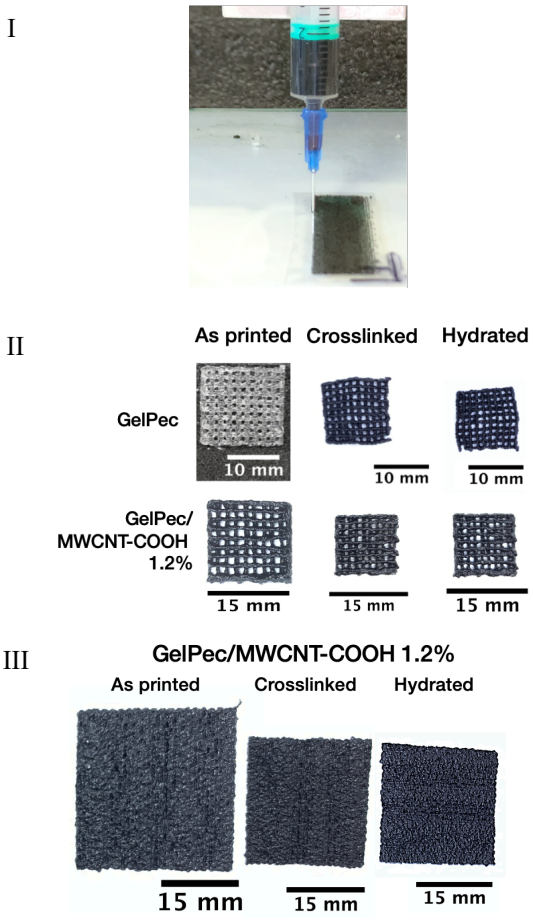

Fig. 1: The images display I) a photograph from a 3D printing process of a filled GelPec/MWCNT-COOH sample II) a woodpile 3D printed GelPec and GelPec/MWCNT-COOH sample right after being printed, crosslinked, and hydrated for 24h and below, III) a 3D printed filled GelPec/MWCNT-COOH sample during the three mentioned phases

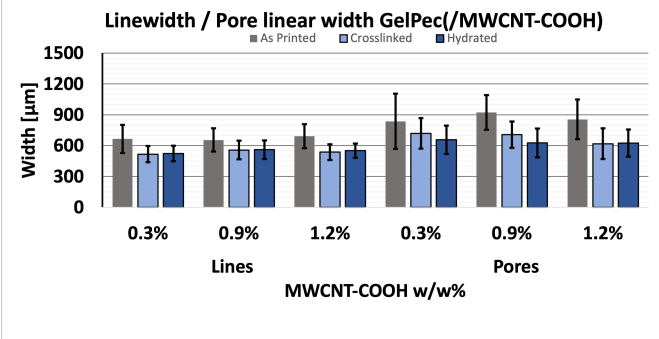

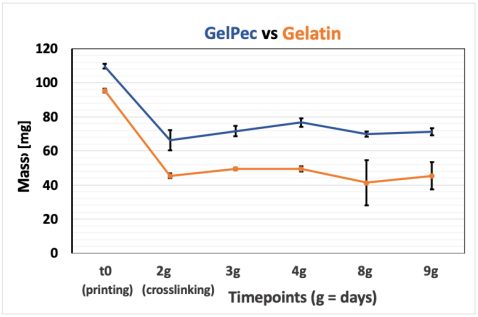

Fig. 2: The image displays the linewidth (left) and pore linear width (right) of 3D printed woodpile GelPec and GelPec/MWCNT-COOH samples over three timepoints (as printed, crosslinked, and hydrated for 24h)

As expected, the degradation test showed that control gelatin hydrogels were poorly stable while GelPec hydrogels were able to better maintain their shape. Therefore, pectin seems to act as a structural stabilizer of gelatin. GelPec samples added with MWCNT-COOH showed a significantly higher weight loss with respect to unloaded GelPec (Figure 2).

I

II

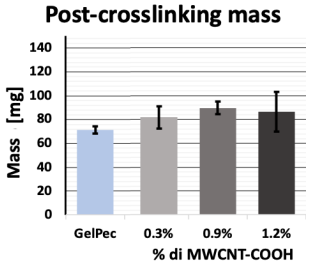

Fig. 3: The images display I) a graph of GelPec and gelatin samples' mass over time, II) GelPec and GelPec/MWCNT-COOH samples' mass following the crosslinking process

GelPec hydrogel had a Young's modulus of 400kPa, breaking strain of 20% and breaking stress of 80kPa. The elastic modulus of GelPec is agreement with data reported in literature for human choroidal tissue [11].

Mechanical properties of hydrogels loaded with MWCNT-COOH (1.2% w/w) did not show statistical difference with respect to those of unloaded hydrogels, while for hydrogels loaded with lower amounts of MWCNT-COOH (0.3% and 0.9% w/w) mechanical parameters, apart from breaking strain, decreased (Figure 4). This indicates the need for testing different embedded percentages of nanotubes, both greater and lower than 1.2%.

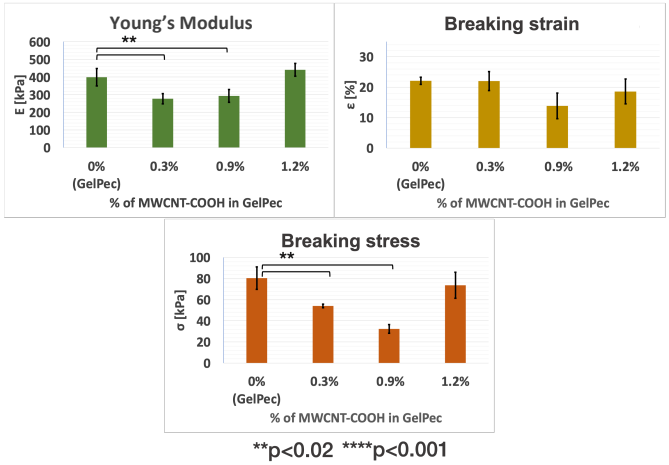

Fig. 4: The image displays histograms of the values of Young's modulus, breaking strain and breaking stress of 3D printed GelPec and GelPec/MWCNT-COOH samples.

IV. Conclusions

We successfully produced a gelatin/pectin biomaterial ink for potential application as 3D tissue-engineered drug testing platforms. The material resulted optimally extrudable and able to maintain the programmed architecture after genipin crosslinking. The loading of carbon nanotubes in the GelPec biomaterial ink does not affect the printability and post-printing stability of the material. Given the promising results obtained with the designed nanotubes incorporation protocol, a future development may include the use of different nano-fillers, in particular polymeric nanoparticles loaded with specific drugs, to evaluate the use of the GelPec hydrogel as a drug testing platform.

***Abstract* — With the aim of studying the cardiotoxic effect of different compounds on cardiac tissue, in this work a microfluidic platform (uHeart) was exploited to generate 3D cardiac models from different cell sources (i.e., chick embryo CMs and human iPSC-CMs), developed by exploiting different stimulation set-ups (i.e, mechanical and/or electrical stimulation). uHeart enabled to analyze 3D cardiac microtissues through combined readouts (e.g. video acquisition and electric field recording). A comparison between uHeart and commercially available MEA systems, the gold standard for 2D cardiac electrophysiology, was then performed by evaluating functional parameters (e.g. spontaneous beating onset time, synchronicity, electrophysiological parameters). Finally, a drug screening was carried out to preliminarily assess the ability of uHeart to be used as a predictor of cardiotoxicity, such as MEA systems.**

***Keywords*—Heart on chip, cardiac toxicity, drug screening.**

I. INTRODUCTION

CARDIOTOXICITY still represents one of the most important side effects in the drug development pipeline. According to different studies drugs may disturb the delicate orchestration of cardiac ions fluxes [1]. To reduce incorrect termination of compound development and to prevent market withdrawal for unpredicted cardiotoxic effects in humans, regulatory agency recently developed new guidelines (International Committee on Harmonization, ICH S7B) to better determine TdP [2]. In such a context, pre-clinical in vitro cardiac models developed by combining human induced pluripotent stem cells derived cardiomyocytes (hiPSC-CMs) and Organs-on-Chip (OoC) technology have emerged as promising predictive and reliable tools [3]. hiPSC-CMs represent predictive and relatively easy-to-handle source of human cells, despite they have been often reported to lack the typical myocardial maturation in classical 2D culture systems. To overcome this limitation, OoC are advanced cell culture setups able not only to recapitulate in vitro the key aspects of the in vivo cardiac physiology with an unprecedented level of accuracy [4], thanks to a combination of biochemical and biophysical stimuli, but they can also integrate multifunctional readouts. Being inserted in the safety screening field, the aim of the present work was to develop and validate an experimental set-up (uHeart) able to predict functional cardiotoxicity of compounds by exploiting 3D engineered cardiac microtissues, benchmarked against state-of-the-art 2D Multi Electrodes Array (MEA) based models. uHeart was first developed from an animal source and then validated with iPSC-CMs, and integrated a combination of readouts (i.e., motion analysis, calcium imaging, viability assays and field potential recordings).

II. MATERIALS AND METHODS

A. Platforms

At first, a comparison between a commonly used 2D platform (MEA, Fig. 1a) and an advanced 3D culture system (uHeart, 1b) was performed.

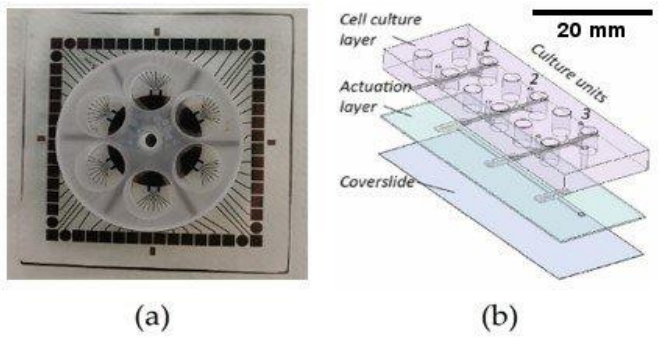

Fig. 1: (a) MEA and (b) uHeart platforms

MEAs (Multi Channel Systems MCS GmbH, Germany) have an arrangement of 60 surface electrodes which are meant for extracellular field potential (FP) recording, since the cells are cultivated in 2D directly on them. uHeart platforms consist in three layers: 1) an upper cell culture layer, where the cells are seeded embedded in a fibrin gel and are feed thanks to two lateral channels filled of medium by four wells per chamber, 2) an intermediate actuation layer which provides a means to mechanically stimulate (i.e., uniaxial strain of 10%, 1 Hz) the 3D microtissue through a pneumatic actuation system and 3) a bottom coverslip. uHeart platforms can additionally hosts electrodes to provide electrical stimulation, alone or in combination with the mechanical one, or to measure the electrical activities of the cells (Fig. 2). Specifically, the electrical stimulation was provided through the implementation of a pair of coaxial guides which allow the insertion of microelectrodes in correspondence of the lateral channels, while the electrical measurement through electrodes positioned in the central channels, in contact with the microtissues. uHeart platforms were produced by replica molding. Briefly, PDMS (Syligard 184 Sylicon Elastomer Kit), made by mixing in 1:10 ratio the curing agent and the pre-polymer, was poured on previously fabricated acrylic resin

molds (10 10 CFS, C-system) to obtain the culture layer. The same process was performed on a micropatterned wafer to obtain the actuation layer. In the case of uHeart platforms the two layers were then bonded through a plasma treatment (Harrick Plasma, PDC-002) and a glass coverslip was finally bonded to the actuation layer. For the electrical devices, the culture layer is directly bonded on a PDMS membrane, 800 µm thick.

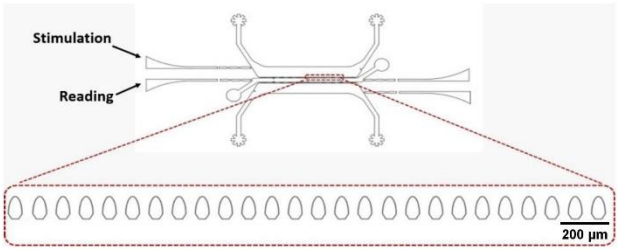

Fig. 2: electrical platform encompasses four electrode guides: two for stimulation and two for reading. The semihexagonal pillar shape was optimized to allow cell-laden gel confinement during injection.

B. Cell sources and models generation

For the first part of the work embryonic chicken cardiomyocytes were isolated from 13 days old embryonic chicken hearts, by enzymatic and mechanical digestion. The so obtained single cells were then seed on MEAs and uHeart by means of different protocols. In first case 4µl of cell suspension (density 20000 cells/µl in 3% FBS medium) was seeded onto the nitrocellulose-coated electrode surface. In second case CMs were seeded into the devices after embedment in a fibrin gel (i.e., 10 mg/ml of fibrinogen and 2.5 U/ml of thrombin) at a final density of 100 x 10^6 cells/ml. in uHeart, the mechanical actuation was started at Day 2 [5]. For the human models, hiPSC previously differentiated in CM were thawed (Day 9) and used after 2 days of pre-culture (Day 11). CM were mixed with human cardiac fibroblasts in a 3:1 ratio (i.e., 75% CM and 25% of hCF), embedded in different hydrogels (i.e., Geltrex or fibrin gel 10 mg/ml of fibrinogen and 2.5 U/ml of thrombin) at a final density of 100 x 10^6 cells/ml and inoculated into uHeart platforms.

C. Readout set-up development

The evolution of microtissues in terms of morphology, viability and functionality was assessed by means of different ad-hoc readouts, singularly exploited.

1) Cell viability

Calcein, AM (Thermo Fisher Scientific Inc., USA) and Propidium Iodide (Sigma; P-4170) were used to stain living and dead cells respectively. A solution of PBS containing propidium 3.3 µM was mixed with Calcein AM 1 µM and it was inoculated in the platforms after a cell wash with PBS and incubated for 1 hour before performing the imaging through a reverse microscope (Life Technologies EVOS® FL).

2) Contractility

Time series images were acquired at 25 fps through an inverted microscope and were analyzed with "MUSCLEMOTION" software [6], which assessed the development, the synchronicity and the beating properties of microtissues by measuring four standard parameters (i.e., beating period-BP; contraction duration–CD)

3) Electrophysiology

The electrical activity of samples cultured in MEAs was assessed by means of MEA2100-Systems. In uHeart platforms the signal recordings were performed thanks to a custom-made set-up. Briefly, working and reference electrodes were manually inserted in the platforms and connected to an extracellular amplifier (Ext-10C, Npi Electronic GmbH, Germany). Electrical signals were acquired at 2 kHz by means of an electronic board (Analog Discovery 2, Digilent, Washington, USA) connected to a personal computer through the "Scope" function included in the software of the instrument. The acquired signals were then elaborated through MATLAB to derive the relevant parameters, such as RR interval, and the Field Potential Duration (FPD).

D. Drug test

As for the chicken cardiac microtissues, the responsiveness of the cardiac samples to a commonly recognized IKr blocker drug (E4031) was assessed. An increasing ramp of concentration (i.e., 0 nM, 5 nM, 50 nM, 250 nM and 500 nM in medium) was administered to the samples and after 15 minutes of incubation, the specific readout (i.e., calcium transient, motion analysis or FP recording) was performed. Human 3D cardiac microtissues were administered with a non-selective β-adrenoreceptor agonist (Isoprenaline), usually used to treat bradycardia or heart block since it has positive inotropic and chronotropic effects. A cumulative dose administration was followed, testing different concentrations (i.e., 0.1 nM, 10 nM and 1 µM).

III. RESULTS

A. Chicken cardiac models

After the isolation of CMs from the primary tissue, the cells were cultured in the platforms. The 2D culture in MEAs (Fig. 3a) differs from 3D microtissues in uHeart (Fig. 3b) in terms of morphology. 2D cardiomyocytes well spread at the bottom of the wells, while in the 3D configuration more branched cells were evidenced. Spontaneous beating onset was detected at Day 4 for 2D samples cultured on MEA and at Day 2 for 3D samples in uHeart.

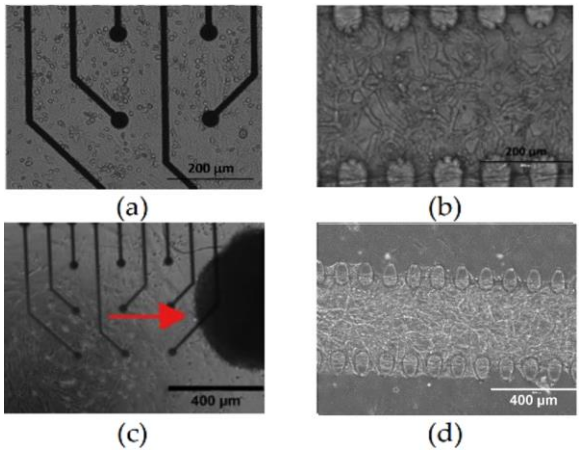

Fig. 3: comparison of morphology between 2D culture on MEA (a) and 3D in uHeart (b).

After a prolonged culture (i.e., ten days), 3D microtissues maintained their branched architecture (Fig. 3d), while 2D microtissue formed differently sized cluster of cells after the detachment from the substrate (red arrow Fig. 3c). Viability assays at Day 1 didn't evidence any difference between the samples in the different platforms, while a larger difference emerged at Day 10 (Fig. 4), with static and dynamic uHeart platform having higher viability (78.02 ± 4.62 % and 77,83 ± 3.72%, respectively) than MEA (60.7 ± 9.71%).

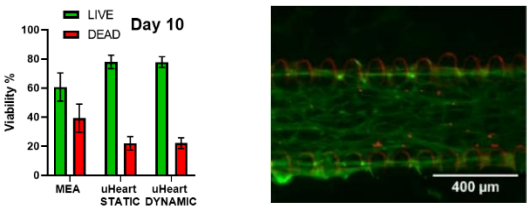

Fig. 4: viability results at day 10 (left) and an example of L/D assay on uHeart platforms.

Since in 2D the cells clustered together after a prolonged time in culture, functional readouts were performed at Day 4 to compare the conditions (2D and 3D). Motion analysis accomplished to determine the synchronicity of the beating throughout the microtissues (Fig. 5), calculated as correlation coefficient of the effective overlap of all the contraction peaks (Fig. 5a). The highest values were detected for actuated 3D microtissue (97%), followed by 2D culture (94.6%). The lowest score was obtained in static uHeart, showing a correlation coefficient of about 56.2%.

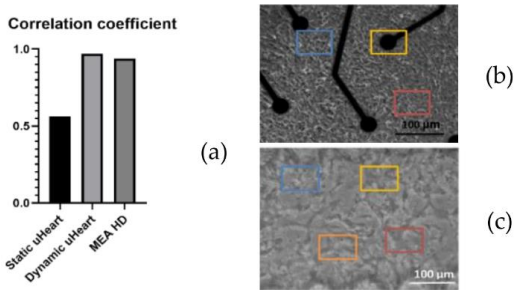

Fig. 5: (a) correlation coefficient computed by analyzing the trace of CA in different zones if the same microtissue in MEA (b) and uHeart (c).

The same trend was obtained by computing the correlation coefficient derived from the calcium transient analysis. Thanks to its well-established method of FP recordings, MEAs were used to assess the relation between electrical parameters and motional ones. In particular, the comparison between RR parameter and the corresponding BP carried out on the same day on the same samples (n=5) yield to a correlation coefficient of 0.996. Since the different readouts resulted consistent, they were exploited to assess the effect of E4031 on cardiac microtissue. In all the samples a concentration higher than 5 nM induced an increase in BP and CD with respect to controls without drug (red, Fig. 6), both if analyzed by means of video analysis (Fig. 6), or through calcium transient. The same results were obtained also with the computation of RR interval through FP recordings, while it wasn't possible to determine the FPD since the huge noise in the signal covered the repolarization wave. A further administration of 250 nM induced the arrest of the beat in all the samples, except in 33% of dynamic ones, which were subjected to a further increase in BP and CD. Another exception was found in one 2D sample, in which the highest dose yield to an arrhythmic event.

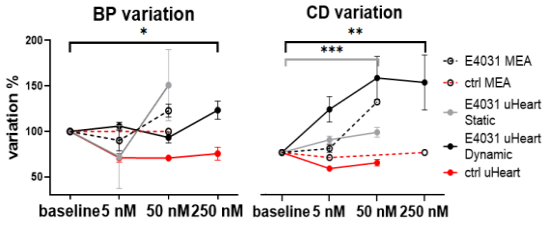

Fig. 6: variation of BP and CD, computed by means of motion analysis, induced by the dose escalation of E4031 in all differently cultured samples.

B. Human Cardiac Models

3D cardiac microtissue model were developed by seeding hiPSC-CM in uHeart and their development was monitored daily to assess the effect of mechanical and/or electrical stimulation compared to a static culture. Video analyses revealed a gradual decrease in BP from Day 3 (1245.68 ± 37.49 ms) until Day 11 (784.84 ± 42.94 ms), while from this time point a huge variability among samples occurred in all models. The mechanically actuated samples emerged as the most capable to keep a stable and constant pace of CM, while both mechanical and electrical stimulation allowed to induce a precise pace after 10 days of training. The implementation of the setup to achieve FP recordings allowed to combine it with video analysis. The incremental administration of isoprenaline yielded in a decrease of both BP/RR and CD/FPD computed through both MUSCLEMOTION and FP recordings.

IV. DISCUSSION

In the first part of the work a comparison between an innovative OoC platform and the platforms currently used as gold standard (i.e., MEA) for new studies of cardiotoxicity screening was carried out using chick embryo CMs as animal model to preliminary validate the setup. Since after the isolation from the native 3D myocardium, cell–cell contacts are disrupted and extracellular matrix is destroyed, causing cells to lose extra cellular network connections, it is fundamental to recapitulate these aspects in vitro, to recover physiological cellular functions. A combination of architectural (i.e. three dimensionality and cell density), biophysical (i.e. mechanical stimulation) and environmental (the substrate) cues was thus demonstrated to be fundamental and the combination of different developed readouts allowed to determine that 3D stimulated microtissues have higher capability to get faster a more mature and synchronous beating with respect to both 2D and 3D static samples. This was reflected on the highest correlation coefficient relative to the beating motion of different area of the same sample obtained by the stimulated 3D CM. The 3D environment resulted fundamental to elicit an early onset of spontaneous beating, that was detected after just 48h from the seeding in 3D

platforms and after 72/96h for 2D models. Calcium imaging corroborated the results obtained from motion analysis, with the highest score of correlation obtained by dynamic uHeart (0.962), followed by MEA HD (0.498) and static uHeart (0.398). On the other hand, this analysis yielded to discover a mild electrical activity in MEA LD, which was not detected in video analysis, confirming the advantages and importance to have the possibility to couple different readouts in the same platform. The FP recordings carried out at Day 4 on different 2D samples through MEA confirmed the presence of the synchronous beating, showing the presence of some BP variability between different samples. The different developed readouts resulted fundamental and were further preliminary validated to accomplish the drug test on all three types of platforms. FP recordings, calcium imaging and motion analysis were performed to screen the effect of an administration at incremental concentration of E4031. In both 2D and 3D models, all the readouts yielded a negative chronotropic effect, with an increase of BP for concentration > 5 nM. Moreover, the chicken cardiac models stopped beating within a range of concentration of [50-500 nM] in all the platforms. Interestingly, only in case of mechanically stimulated microtissues in uHeart, the stop of the beating occurred only with the highest concentration (i.e., 500 nM), while in static devices the threshold was lower (i.e., 50 or 250 nM). This may be due to the higher grade of maturation of the actuated cardiac microtissues, since younger CMs have an action potential more sensitive to the IKr blockade having less density of repolarizing currents [7]. A further confirmation was the onset of an arrhythmic event only in case of 2D microtissue, in which the blockade effect of E4031 is most prominent and could more easily induce early afterdepolarization events.

After having the preliminary validation, a new biological campaign was carried out on uHeart platforms equipped with electrical stimulation capabilities that could be used alone or in combination with the mechanical system. Human iPSC-CMs were co-cultured with supportive human cardiac fibroblasts. As for animal model, two days of stimulation (i.e., mechanical, electrical or combined) resulted sufficient to drive an interconnected and branched shape of cardiac microtissues, while a delay of few days was observed in the static control samples. The development of cardiac functionality was monitored for a longer interval and with more timepoints with respect to the previous experiments to observe the evolution of the hiPSC-CMs microtissues. The monitoring of functional parameters such as the BP and CD was achieved through motion analyses. The decrease in BP of actuated samples from Day 3 to Day 11 might be due to the actuation, acting not only as a training in their maturation but also as a pacing system. In fact, the devices mechanically actuated with a frequency of 1 Hz reached at Day 14 a beating period of 855.4 ± 92.3 ms, while electrically stimulated one passed from 1361.8 ± 81.3 ms of the Day 3 to a BP of 735.7 ± 231.2 ms at Day 14. Furthermore, as compared to Day 3 and Day 7, the later time points resulted in higher variability between samples, with a standard deviation substantially increased in Day 11 and 14. This behavior may be due to a different degree of maturation of the construct between samples [7]. The most variable samples were the hybrid ones, while the most stable during all the time of culture were the mechanically actuated, suggesting that a continuous mechanical pace at a constant frequency yield different effect respect to an increasing frequency stimulation (electrical and hybrid conditions).

To further validate the capability of this setup to assess chronotropic and inotropic effects induced on the CMs by drugs, isoprenaline was administered with increasing concentration. Both video and electrical recordings were used, by means of the optimization of a multi-parameter setup which allowed to record at the same time FP and video imaging. The trend highlighted through these combined readouts confirmed the results in literature as regards the chronotropic effects of the drug [1,4], with the BP/RR and CD/FPD decreasing by increasing the administered dose of isoprenaline. Conversely, it wasn't possible evaluate the inotropic effect, which can be revealed by means of motion analysis [5,8], since the values of CA achieved weren't consistent with each other, maybe due to the sensitivity on luminosity of the tracking software.

V. CONCLUSIONS

Intending to develop a system allowing for combined readouts to assess drug cardiotoxicity, this work exploited different platforms to culture cardiac microtissue models with different architectures (i.e., 2D and 3D), species origin (i.e., chicken embryo and human) and incorporating several analysis systems. The comparison between video, calcium transient analyses, and FP recordings on MEAs, showed a clear superimposition and consistency in their results obtained from animal models. The validity was proved through a drug test with a potent hERG channel blocker (E4031), which brought the expected results. The setup was further tested in human cells, after the implementation of an electrical readout. The experiments highlighted the capability of uHeart platforms to be not only a very useful and reliable system in achieving more advanced and highly functional cardiac microtissues from different cells sources (i.e., chick embryo CMs and hiPSC-CMs) but also in allowing a higher number of combined readouts, potentially evaluated at the same time, compared to other commercially available systems (i.e., MEA).

***Abstract*—Polyetheretherketone (PEEK) is a polymer that has been widely employed as bone implant thanks to its biocompatibility and mechanical properties. However, its bio-inertness does not induce bone integration once the material is implanted. In this work, the surfaces of 3D-printed PEEK disks were functionalized with the fragment (48-69) of BMP2 protein (GBMP1α) proved to significantly enhance calcium deposition and expression of genes involved in osteoblast differentiation. Different chemical methods were evaluated for covalently grafting the peptide onto PEEK surface: (a) anchor through specific covalent bond via oxime chemistry; (b) anchor through photoactivation of an azido group. All functionalized PEEK samples were characterized by water contact angle (WCA) measurements, atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). The biological results showed that the peptide GBMP1α anchored through the two different methods is able to increase human osteoblast proliferation at 1 and 21 days with higher calcium deposition.**

Keyword – PEEK, surface functionalization, human osteoblasts, bone implant.

I. Introduction

THE clinical need for biomaterial therapies for bone is unrelenting. Polyetheretherketone (PEEK) is an ideal substitute material for bone tissue engineering. PEEK is a semi-crystalline polyaromatic linear polymer with (–C_6H_4–O–C_6H_4–O–C_6H_4–CO–)n chemical formula. It is finding popularity in bone replacement as it has been shown to have bio-mechanical properties close to human bones. It represents a promising polymeric alternative to metal implant components thanks to its excellent property combinations, of strength, stiffness, toughness, and environmental resistance. The Young's modulus of PEEK is much lower than any metallic material employed in common bone implant and is tunable through additive inclusion. It may increase up to 18 GPa, which is similar to the values of the cortical bone (18.4–20.7 GPa) [1], avoiding the effect of the stress shielding. PEEK is a thermoplastic polymer and in the range of its melting temperature, it can be processed using 3D-printing. The possibility to use PEEK polymer in the 3D-printing process has increased scientific interest and impact future development [2]. Furthermore, PEEK has interesting biological properties: it is highly resistant to thermal degradation, to the attack by organic and aqueous environments, and to biodegradation. Therefore, PEEK implants are biocompatible and biologically inert [3]. However, inertness has constrained PEEK potential applications. PEEK has a hydrophobic surface, which neither allows protein absorption nor promotes cell adhesion [4]. The aim of this research project is improving its biological properties. PEEK disk surface was functionalized with a bioactive peptide: the fragment (48-69) of BMP2 protein (GBMP1α) proved to drive a greater calcium deposition, to guide osteogenic differentiation of mesenchymal stem cells, and to promote human osteoblasts' (HOB) proliferation and expression of genes involved in osteoblast differentiation [5], [6]. Covalent bonds were realized through two different chemical strategy. The former occurred with a reaction between an aminooxy groups inserted in the peptide N-terminus and the ketone groups of the PEEK surface [7], the second one includes photoactivation of an azido group (also inserted in the peptide N-terminus) that can binds several sites of PEEK monomer [8].

II. Methods

A. Sample Preparation

Aoa-x-GBMP1α (sequence: H-Aoa-(7-aminoheptanoic acid)-Pro-Phe-Pro-Leu-Ala-Asp-His-Leu-Asn-Ser-Thr-Asn-His-Ala-Ile-Val-Gln-Thr-Leu-Val-Asn-Ser-NH_2) and N_3-x-GBMP1α (sequence H-Phe(p-N_3)-Gly-γAbu-Phe-Pro-Leu-Ala-Asp-His-Leu-Asn-Ser-Thr-Asn-His-Ala-Ile-Val-Gln-Thr-Leu-Val-Asn-Ser-NH_2) were synthesized using the solid phase peptide synthesis (SPPS). The peptide was purified by reverse phase-high performance liquid chromatography (RP-HPLC) (at least purity grade 95%) and characterized by analytical RP-HPLC and its identity was determined by mass spectrometry (SCIEX TOF-TOF 4800 instrument).

AutoDesk Fusion 360 (Autodesk, California, USA) computer-aided-design (CAD) software was used to design PEEK disks 10mm in diameter and 4mm in height and exported in a stl format into Simplify 3D software (Simplify3D- USA, OH, USA). The files were then sliced to generate printer ready G-code and printed using an Apium P155 PEEK filament printer (Apium Additive Technologies GmBh, Willy, Germany). The resulting 3D-printed PEEK disks possess a flat surface and a patterned one.

PEEK scaffolds were covalently functionalized with all the peptides. The linkages between the aminooxy group on the N-terminus of the peptide chain and ketonic groups in PEEK surface are realized by means of chemoselective ligation. Each peptide was dissolved in 40 mM monobasic sodium phosphate at 6 pH and left to react with PEEK samples for 24 hours at

room temperature. Peptide concentration used was 10^{-4}M. After that, the disks were rinsed three times with buffer and three times with MilliQ.

Functionalization through azido group occurred as in [8]. The peptide was dissolved in MilliQ with concentration equal to 1mg/ml.

B. Surface characterization

X-ray photoelectron spectroscopy (XPS) analysis was performed with a homemade instrument, consisting of preparation and analysis UHV chambers separated by a gate valve. The spectra were energy referenced to the C1s signal of aromatic and aliphatic C atoms having a binding energy BE = 284.7 eV. Curve-fitting analysis of the C1s, N1s, O1s, F1s spectra was performed using Gaussian profiles as fitting functions, after subtraction of a Shirley-type 219 background. Atomic ratio values were calculated from peak intensities.

Atomic force microscopy (AFM) analyses were carried out on different functionalized PEEK disks at room temperature in order to evaluate separately the effects of the peptides on the mechanical properties of interfaces. The Young's modulus was calculated from the collected force–distance curves measured with the NTEGRA AFM (NT-MDT, Moscow, Russia). Stiff single crystal silicon cantilevers with a symmetric tip shape were used (model Tap300Al-G, BudgetSensors, Bulgaria: nom. Frequency 300 kHz, nom. Spring constant 40 Nm−1, tip radius < 10 nm). For adhesion force measurements, Au-coated silicon nitride tips were used. AFM measurements were made in triplicate.

The surface wettability was traced by measuring the static water contact angle (WCA). An OCA30 instrument (Dataphysics) was used at 25 °C and 65% relative humidity. At least three measurements were made for each sample and then averaged.

Superficial characterization analyses were performed on flat PEEK surfaces.

C. Biological assays

All biological studies were performed on the patterned surface of the 3D-printed PEEK disks. Human osteoblasts (HOB) were used to evaluate the functionalized PEEK disks. Prior to seeding, PEEK specimens were sterilized in 70% ethanol for 24 hours and then washed with PBS. Cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) containing, 10 ml of 1 M HEPES, 5 ml of 200 mM L-glutamine, 5 ml of 100x penicillin/streptomycin, 50 ml of Fetal Calf Serum (FCS), 5 ml of minimal essential medium and 0.075 g of solid ascorbate acid. HOB cells were microseeded onto the surfaces of the disks at a density of $1x10^5$ cells per disc. Seeded samples were incubated at 37°C and 5% CO2 for the time duration required or all tests performed. For gene expression evaluation, a density of $2x10^5$ HOB cells/per disc was used. Culture media was changed every three days for optimal growth conditions.

Cell viability was assessed using a LIVE/DEAD™ Viability/Cytotoxicity Kit (Thermo Fisher Scientific, Waltham, MA, USA) after 48 hours of cell culture. Images were captured with an Olympus IX51 fluorescent microscope. ImageJ software was used to display and process images of living cells (green fluorescence at 530 nm) and dead cells (red fluorescence at 600 nm).

Morphology of HOB cells after 48 hours from seed on the 3D printed PEEK structures were observed using SEM (Zeiss Gemini SEM 360) at a voltage of 10kV.

Calcium deposition was evaluated by Alizarin Red S staining on HOB cells. Alizarin Red S is an anthraquinone dye that reacts with calcium and forms an Alizarin Red S/calcium complex that is birefringent. HOB cells were cultured for 21 days. The results were achieved using a microplate reader (Opsys MRTM 96-well microplate reader, Dynex Technologies, VA, USA) at 570 nm.

The proliferation of osteoblasts cultured on functionalized and non-functionalized PEEK disks was assessed at 1, 4, 7, 14, or 21 days using AlamarBlue™ kit. For each sample three replicates were measured with the same microplate reader, which measured the fluorescence values at 570 nm test wavelength and 630 nm reference wavelength.

Specific mRNA transcript levels coding human SRY-Box transcription factor 9 (Sox9), Runt-related transcription factor 2 (Runx2), Alkaline Phosphatase (Alp), and Osteocalcin (Oct) were quantified in osteoblast cells cultured for 24 hours on functionalized and non-functionalized PEEK. Data were quantified by the ΔΔCT method using human Gapdh as the reference gene.

All assays were performed at least in triplicate and all values are reported as mean ± standard deviation. Data were analyzed and processed with Prism (GraphPad Software 9). Alizarin Red S results were compared by using one-way analysis of variance (ANOVA) test. Tukey's multiple comparisons test was carried out to confront every condition. AlamarBlue™ and gene expression results were compared with two-way ANOVA tests, followed by Tukey's post-hoc test. The significance level applied was 5%.

III. RESULTS

A. Surface characterization

XPS measurements were performed to confirm the presence of peptide on the surface of PEEK indicated by nitrogen increase. Table I shows the ratio nitrogen/carbonium (N/C) on the functionalized and non-functionalized PEEK. In non-functionalized PEEK, nitrogen was detected, while in functionalized PEEK it was. Also, Table I reports that peptide grafted through azido group was more available on the surface than through oxime chemistry.

TABLE I: XPS EVALUATION. QUANTIFICATION OF N/C RATIO FOR EACH FUNCTIONALIZED SCAFFOLDS AND NOT FUNCTIONALIZED SCAFFOLD.

Sample	*N/C*
PEEK-Control	/
PEEK+Aoa-x- GBMP1α	0.14
PEEK+N3-Phe-x-GBMP1α	0.17

AFM analyses achieved Young's modulus and adhesion force values on the surface of PEEK. As shown in Fig.1a, all functionalizing conditions induced an increased stiffness denoted by a higher value of the surface Young's modulus. The increase of surface rigidity with the functionalization of the PEEK substrate may be explained in terms of the expected stronger interchain. Fig.1b shows the adhesion forces measured on the bare and peptide-functionalized surfaces. All the functionalizing conditions show enhanced adhesion tip-sample forces, compared to non-functionalized PEEK, since the peptide at the interface promotes intermolecular interactions with the tip.

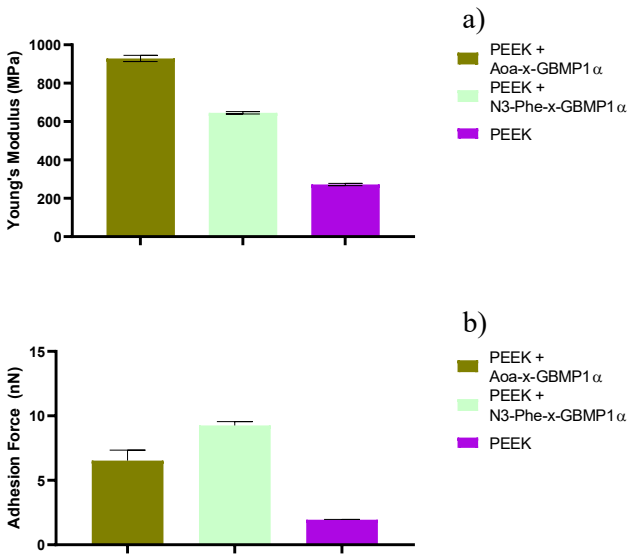

Fig. 1: AFM analysis of functionalized PEEK. (a) Surface Young's modulus and (b) adhesion forces for the bare and functionalized PEEK. Values are reported as mean ± SD.

WCA (Fig.2) showed how differently the functionalization through azido and aminooxy affected the superficial behavior of PEEK. PEEK functionalized with Aoa-x-GBMP1α slightly increases the hydrophobicity of the surface. While the samples functionalized through azido group increase the hydrophilic behavior of PEEK.

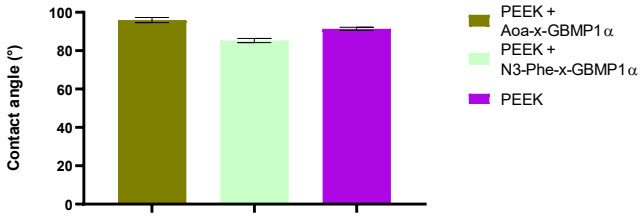

Fig. 2: WCA analysis on bare and functionalized PEEK. Values are reported as mean ± SD..

B. Biological assays

Cell viability tests (Fig.3) showed that HOB colonized all test samples. Generally, no cell death (red cells) was observed on test surfaces after 48 hours in culture, demonstrating that there was no cytotoxic effect, only non-functionalized PEEK showed a few dead cells.

The SEM analysis (Fig.4) at 48 hours from cell seed showed a homogeneous cell layer on the material surface. Focusing on PEEK functionalized with Aoa-x-GBMP1α (Fig.4b) overlapped cell multilayers are present.

As reported through Alizarin Red assay in Fig.5, all the conditions significantly increased the deposition of calcium ions after 21 days in culture. Also, functionalization through azido statistically improved the mineralization over the functionalization through aminooxy.

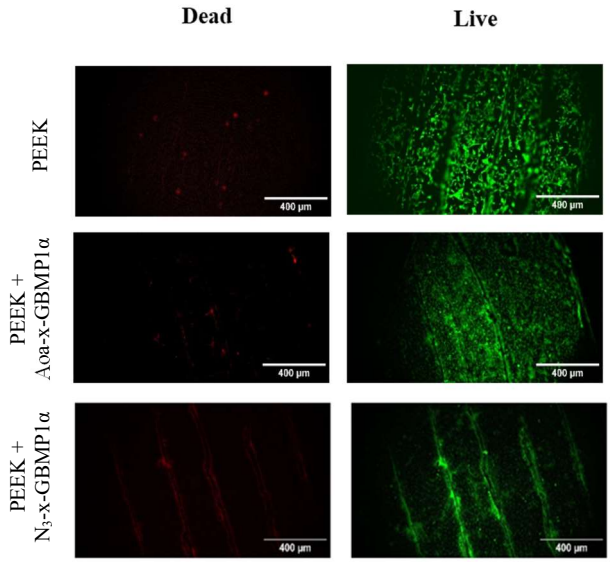

Fig. 3: Live and Dead staining of HOB cultured for 48 hours on non-functionalized and functionalized PEEK at 48 hours. Mag = 10x. Scale bar = 400 µm.

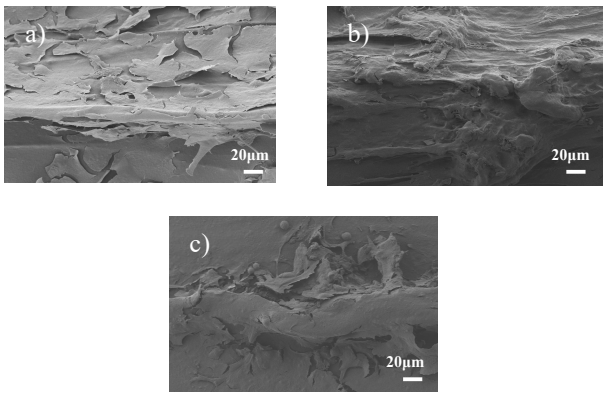

Fig. 4: PEEK sample (a) PEEK-Aoa-x-GBMP1α (b), and PEEK-N3-x-GBMP1α (c). Mag = 3.00 K X. Scale bars = 20 µm.

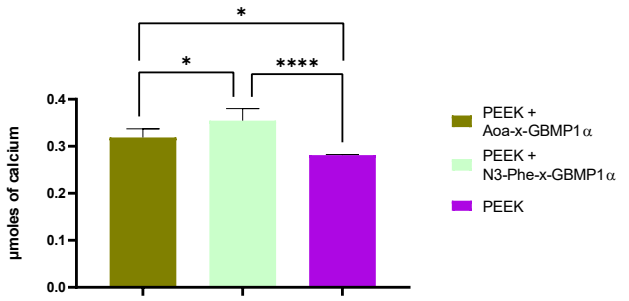

Fig. 5: Mineralization assay. Evaluation of calcium deposition on differently functionalized PEEK disks, at 21 days. *p-value < 0.05, **p-value < 0.01, ***p-value < 0.001, and ****p-value < 0.0001.

HOB proliferation on differently functionalized PEEK samples was evaluated at 1, 4, 7, 14, and 21 days from cell seeding using AlamarBlue™ kit (Fig.6). All the functionalizing conditions showed a significant increase over non-functionalized PEEK in cell proliferation at day 1 and 21.

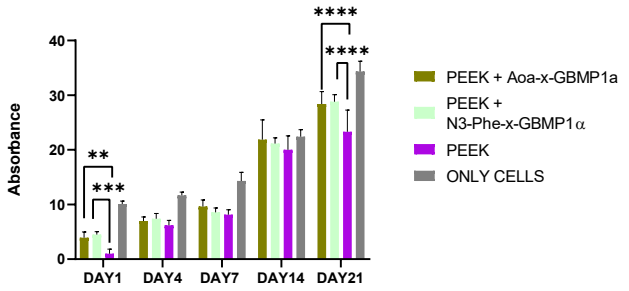

Fig. 6: HOB proliferation assay. Results were achieved at 1, 4, 7, 14, and 21 days from cell seeding. *p-value < 0.05, **p-value < 0.01, ***p-value < 0.001, and ****p-value < 0.0001.

From Gene expression assay (Fig.7), it is underlined that Sox9, and Alp gene was up-regulated with respect to the other conditions at day 1 by Aoa-x-GBMP1α. Functionalized samples had statistically significant increase over non-functionalized PEEK in Oct at day 14 and 21.

IV. Conclusion

We investigated the effect of functionalizing PEEK to determine whether performance could be enhanced. Our studies have shown that the biological properties of PEEK can be enhanced, and this combined with its other properties, makes PEEK a favourable material for applications in bone tissue engineering.

Functionalization of PEEK with GBMP1α showed that can allow a control of material surface behavior in wettability, Young's modulus, and force adhesion and can induce improvements in both calcium deposition and cell proliferation. Moreover, grafting peptide through azido group instead of via oxime have shown a higher N/C ratio (as index of peptide presence of PEEK surface), a higher hydrophilicity of the material, and a higher deposition of calcium on the scaffold.

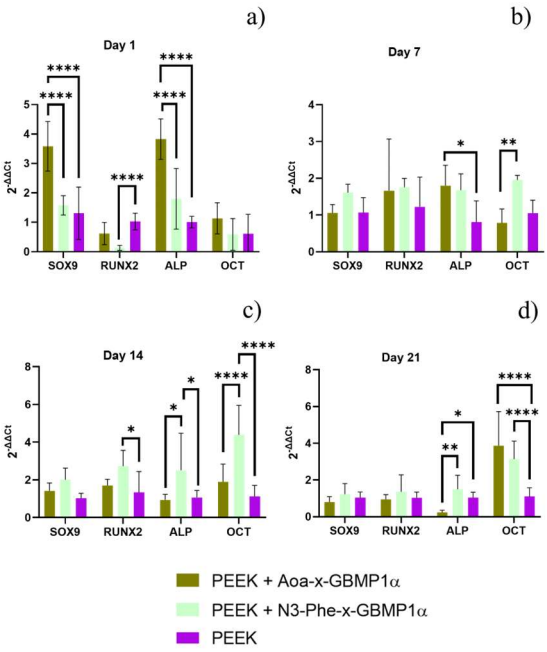

Fig. 7: qRT-PCR assay. Gene expression of Sox9, Runx2, Alp, and Oct, was evaluated on differently functionalized PEEK samples at 1 day (a), 7 days (b), 14 days (c), and 21 days (d) from HOB seeding. *p-value < 0.05, **p-value < 0.01, ***p-value < 0.001, and *** *p-value < 0.0001.

Acknowledgement

The authors thank Ilaria Vignato and Francesco Tolomei for their help in synthesizing the peptides and preparing the functionalized scaffolds.

***Abstract*—Recent years have witnessed the use of microfluidics to shape different types of nanoparticles, such as gene delivery complexes. Herein, we developed a user-friendly microfluidic cartridge for the fast and repeatable preparation of non-viral gene delivery complexes at different N/Ps and their storage.**

***Keywords*—non-viral gene delivery, microfluidic device, polyplexes, reproducibility.**

I. Introduction

NON-VIRAL gene delivery (i.e., transfection), the process of introducing exogenous nucleic acids (NAs) into target cells, is the cornerstone of (nano)medicine, for the prevention[1] or treatment at a genetic level of several diseases,[2] and (nano)biotechnology, for the production of recombinant proteins.[3]

Cationic lipids and polymers, collectively called transfection reagents, are very popular because they are reasonably effective in transfecting cells. Indeed, they spontaneously assemble with anionic NAs in a vial to form lipoplexes and polyplexes, respectively, which are next dripped onto cell cultures to deliver their payload intracellularly.[4] Polyplexes are typically prepared in a vial, following one of these procedures: (i) dripping the solution containing one component into the other (i.e., bulk mixing of transfection reagent and NA solutions), eventually followed by (ii) vortexing the test tube, or (iii) manual mixing of the two solutions through pipetting.[5] However, intra- and inter-individual imprecision in pipetting is likely to be a source of poor data reproducibility to be seriously reckoned with in daily laboratory practice. Moreover, because of the clinical quest for an ever-larger quantity of nanocomplexes, the development of tools for scaling up and standardizing the production of gene delivery particles cannot be delayed further.[6]

As microfluidics allows the most accurate manipulation of small amounts of fluids by simply tuning the experimental parameters such as species concentrations and flow rates, this technology has thus been extensively used to produce optimally tailored gene delivery nanoassemblies.[7]

Nevertheless, to the best of our knowledge, none has addressed the most impellent quest for the simultaneous generation of multiple polymer-to-NA ratios (N/Ps). Specifically, N/P is the mole ratio of the amino groups (N) borne by the cationic polymer used to complex the phosphate groups (P) of a given amount of NA.[3] Driven by the need to fill this gap and motivated to address the lack of standardization in test procedures underpinning the low reproducibility of results,[8] we herein describe the development and validation of a polydimethylsiloxane (PDMS)-made microfluidic cartridge. This platform enables the fast and repeatable preparation of non-viral gene delivery complexes at different N/Ps, their recovery, and storage until use[9].

II. Materials and Methods

A. Architecture of the microfluidic device

The chip layout was designed using CAD software (AutoCAD, Autodesk Inc.). Briefly, the device encompasses four different units (Fig. 1): *i)* a serial dilution generator (SDG) for the increasing dilution of the polymer solution; *ii)* a NA divider to dispense the DNA solution to a downstream region; *iii)* a mixing area made up of seven mixing units in which the polymer and DNA, coming respectively from the SDG and the NA divider, are mixed to give polyplexes. These are collected within *iv)* a storage area consisting of seven different tanks, which are eventually punched to make the outlet ports (O_1–O_7) and recover the polyplex suspensions.

B. Fabrication of the microfluidic device

The master mold was patterned through standard photolithography and consisted of integrated two layers of SU8 negative photoresist (MicroChem, Westborough, MA, USA) composed of *a)* a 100 μm-thick layer for fluidic channels and tanks and *b)* a 36 μm-thick layer for herringbone grooves (HBGs), placed on the top of *i)*. Microfluidic devices were obtained by replica molding of PDMS on the master mold. Briefly, PDMS was cast on the mold (10:1 (w/w) of pre-polymer to curing agent). After degassing at room temperature (r.t) and curing at 65 °C for 3 h, the input (I_1–I_3) and output (O_1–O_7) ports were obtained using a biopsy puncher with a 1.5 mm-diameter tip (Harris Uni-Core™). PDMS was bonded to a glass slide (75 mm × 50 mm × 1 mm) through an air plasma treatment (Harrick Plasma), and next heated at 80 °C for 15 min.

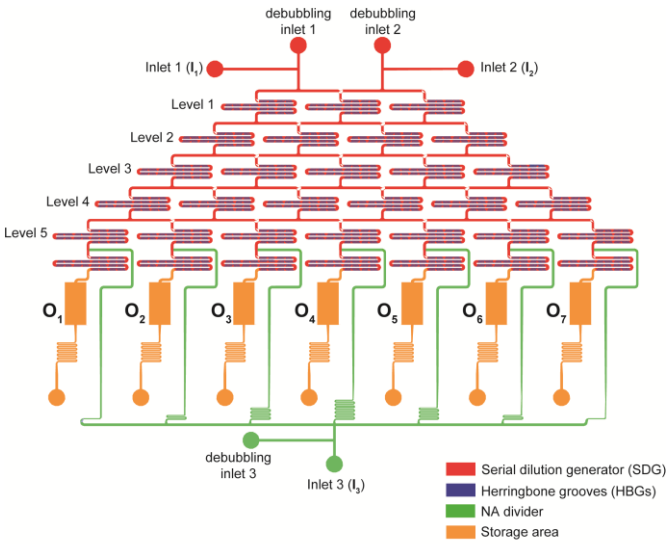

Figure 1. The microfluidic cartridge consists of *i)* an upstream 5-level serial dilution generator (SDG) integrated with herringbone grooves (HBGs), *ii)* a NA divider, *iii)* a mixing area, and *iv)* a storage area. The polymer solution and the water-based medium are injected into the two main inlets (inlets 1 and 2, I_1 and I_2) through the SDG and moved to the downstream area. An additional inlet (I_3) allows for the addition and distribution of the DNA solution to the seven mixing units, where the polymer and DNA are mixed to give rise to polyplexes. These are collected into the storage tanks.

C. Validation of the SDG and the NA divider

The proper mixing of a cationic polymer solution within the SDG was assessed using the commercial transfection reagent jetPEI-FluoF® (λ_{ex} = 490 nm, λ_{em} = 520 nm). Briefly, equal volumes of the polymer solution (prepared by adding 5 µL of jetPEI-FluoF® to 995 µL of 150 mM NaCl) and 150 mM NaCl were injected through I_1 and I_2 of the SDG, respectively, utilizing a two-channel syringe pump (World Precision Instrument, model AL 1000), each set at a flow rate of 25 µL min^{-1} and then the fluorescence intensities of the polymer solutions recovered from O_1–O_7 were measured. Data were expressed in terms of RFU and normalized to the fluorescence value of the jetPEI-FluoF® solution in the syringe, which was taken as 100%, as follows (eq (1)):

$$RFU\ (\%) = \frac{RFU_{sample}}{RFU_{jetPEI-FluoF}} \times 100 \quad (1)$$

Experiments were run with three different cartridges (n = 3).

The effectiveness of the NA divider to split the same volume in each mixing unit was assessed by fluorescence analysis. Briefly, a fluorescently labelled DNA solution was prepared by mixing 1 : 1 (v/v) salmon sperm DNA (ssDNA; 1 µg μL^{-1} in 0.1× TE buffer) with 200× SYBR Green I dye (λ_{ex} = 497 nm, λ_{em} = 520 nm), and pumped through I_3 into the NA divider utilizing a single-channel syringe pump set at a flow rate of 50 µL min^{-1}, while 10 mM HEPES buffer was injected through I_1 and I_2 using a two-channel syringe pump (flow rates = 25 µL min^{-1}). Next, 20 µL of the DNA solution were recovered from O_1–O_7 and analyzed. Data were expressed in terms of relative fluorescence units (RFU) and normalized to the fluorescence value of the DNA solution loaded into the syringe, which was taken as 100%, as follows (eq (2)):

$$RFU\ (\%) = \frac{RFU_{sample}}{RFU_{DNA}} \times 100 \quad (2)$$

Experiments were run with three different cartridges (n = 3).

D. Polyplex preparation with the microfluidic device

Equal volumes of a 25 kDa *l*PEI solution (prepared at a concentration of 0.017 µg μL^{-1} in 10 mM HEPES, corresponding to an amine concentration ([N]) of 0.4 mM) and 10 mM HEPES were first injected into the chip through I_1 and I_2 (flow rates of 25 µL min^{-1}), respectively, and then flowed through the SDG to obtain seven different polymer concentrations. Such polymer solutions and a fluorescent DNA solution, injected through I_3 (flow rate = 50 µL min^{-1}), were simultaneously mixed to give rise to polyplex suspensions at N/Ps from 0 to 6. Right after complexation, micrographs of the mixing units containing the polyplexes were taken by means of a fluorescence microscope and processed using ImageJ software. Next, 20 µL of polyplexes were recovered from O_1–O_7 and analyzed. Data were expressed in terms of relative fluorescence units (RFU) and normalized to the fluorescence value of the fluorescent DNA solution loaded into the syringe, which was taken as 100%, as follows (eq (3)):

$$complexed\ DNA\ (\%) = \left(1 - \left(\frac{RFU_{sample}}{RFU_{DNA}}\right)\right) \times 100 \quad (3)$$

Experiments were run with three different cartridges (n = 3).

E. In vitro transfection experiments

Mycoplasma-free L929 cells were routinely cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 1 mM sodium pyruvate, 10 mM HEPES buffer, 100 U mL−1 penicillin, 0.1 mg mL−1 streptomycin, 2 mM glutamine and 10% (v/v) fetal bovine serum (FBS) (hereafter referred to as complete culture medium), at 37 °C, in a humidified atmosphere and under constant supply of 5% (v/v) CO_2 (hereafter referred to as standard culture conditions). L929 were seeded in 96 multi-well culture plates at a density of 2×10^4 cell/cm^2 and cultured under standard culture conditions for 24 h. For transfection assays, cells were challenged with polyplexes prepared as described above by complexing 320 ng pDNA per cm^2 with PEI solutions. Briefly, the microfluidic device was used to prepare polyplexes at seven different N/Ps (i.e., 0, 10, 20, 30, 40, 50, and 60) that were used right after collection. The final DNA concentration of every polyplex suspension was invariably 20 ng μL^{-1}.

Twenty-four hours after polyplex delivery, the cytotoxicity was evaluated by means of the AlamarBlue® assay. Briefly, the culture medium was replaced with 100 µL per well of 1× resazurin dye solution in complete culture medium. Next, plated cells were kept in the dark for 2 h under standard culture conditions, and then the fluorescence was read using a Synergy H1 reader (λ_{ex} = 540 nm; λ_{em} = 595 nm). The viability of non-transfected cells was assigned to 100% and the cytotoxicity was determined according to the following (eq (4)):

$$cytotoxicity\ [\%] = 100\% - viability\ [\%] \quad (4)$$

Transfection efficiency (TE) was evaluated by measuring luciferase activity in the culture media. Briefly, 20 µL of cell supernatant were mixed with 50 µL of the corresponding assay substrate and the luminescence signal (expressed as Relative Light Units, RLU) was measured using the Synergy H1 reader.

The transfection efficiencies of complexes prepared with the cartridge were compared to those of manually-prepared ones (n = 3 operators).

F. Statistical analysis

Statistical analysis was carried out with Minitab® 21.1.1 statistical software. All data were initially analyzed using the Kolmogorov–Smirnov normality test. As an indicator of reproducibility and repeatability of the results, comparisons among groups were performed with the test for two variances using Bonett's method to test whether variances of transfection efficiencies and cytotoxicities were homogeneous or not. Statistical significance was retained when the p-value < 0.05.

III. RESULTS AND DISCUSSION

A. Design of the microfluidic device

The cartridge encompasses four functionally distinct modules: *i)* a chaotic serial dilution generator (SDG); *ii)* a NA divider; *iii)* a mixing area; *iv)* a storage region (Fig. 1). The *i)* SDG features two input ports (inlets 1 and 2, I_1 and I_2) and is based on a resistive flow model consisting of a symmetric microfluidic network[10] arranged on 5 levels of 240 µm-wide and 100 µm-high channels. Their length was properly dimensioned to mix and split the stock solutions (i.e., an aqueous medium and a polymer solution) and give rise to seven linearly diluted solutions (from 100% stock to 0% in steps of 16.7%), independently addressed to the iii) downstream mixing area. Optimized staggered herringbones grooves (HBGs)[11] are integral to the ceiling of each channel, and each channel encompasses 12 serial HBG units. Besides, the *ii)* NA divider area was based on a one-input (I_3) resistive flow model of seven microfluidic channels, designed and properly sized to enable equal partition of the stock DNA solution into the mixing area. As for the SDG, the seven polymer–NA mixing units that make up the mixing area were dimensioned in length to mix the polymer solutions at different concentrations from the SDG with those from the NA divider. Each mixing unit is a 1.64 mm-long channel encompassing 12 serial HBG units. Furthermore, a *iv)* storage area comprising seven parallelepiped-shaped reservoirs was designed downstream to collect the polyplex suspensions.

B. Validation of the SDG and the NA divider

Since the SDG was designed to mix and split (poly)cations, the function of this area was assessed using a solution of the polymeric transfectant jetPEI-FluoF®. The linear decrease in fluorescence from O_1 to O_7 ($R^2 = 0.96$) (Fig. 2) meant that the polymer was linearly diluted while passing through the SDG.

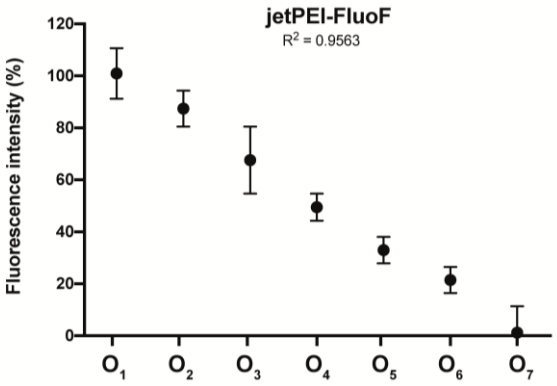

Figure 2. Fluorescence was recorded at each of the seven outlets (O_1–O_7) of the SDG after injecting the jetPEI-FluoF®. Fluorescence intensities were expressed as percentage fluorescence loss in comparison to the fluorescence of jetPEI stock solutions. Results are expressed as mean ± SD (n = 3).

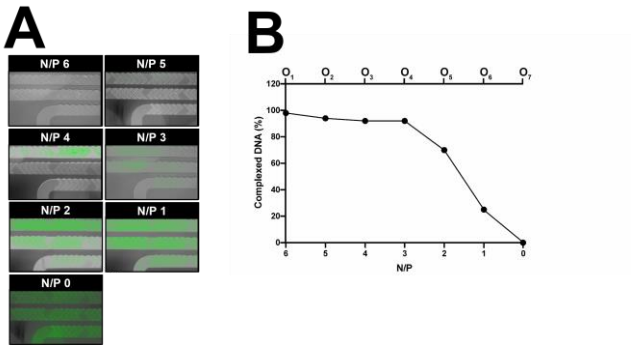
These results highlight that the device was well suited to serially dilute the transfection reagents to be next used to prepare polyplexes at different N/Ps.

To assess the effectiveness of the NA divider to dispense a DNA stock solution to the seven polymer–DNA mixing units, the DNA was made detectable using the SYBR Green I fluorescent dye. Of note, we noticed no significant difference in fluorescence intensity between the DNA solutions harvested from O_1–O_7, meaning that the NA divider operated properly. In summary, we validated the function of the individual chip areas, which are operated by microsyringe pumps controlling the flow rate of the solutions injected into the cartridge.

C. Assessment of the polyplex preparation with the microfluidic device

We took advantage of the DNA complexation assay to assess the effectiveness of the microfluidic cartridge for the simultaneous production and recovery of polyplexes at different N/Ps. The polymer used in the present study is a gold standard transfection reagent known to fully complex the NAs at N/P ≥ 5. Under these conditions, the polymer completely displaces the fluorochrome while binding to the DNA, such that no fluorescence is detected once the samples are excited.[3] To spot any difference in DNA complexation between the mixing units, we imaged them using a fluorescence microscope (Fig. 3A), and the fluorescence signal of every polyplex suspension recovered from the cartridge was quantified with a spectrofluorometer (Fig. 3B). Of note, as *l*PEI and DNA were blended and the complexation took place while moving downwards through the mixing units, the fluorescence steadily decreased (by way of example, refer to N/P 2 in Fig. 3B). In good agreement with the literature,[12] N/Ps 6 and 5, which correspond to the mixing units O_1 and O_2, showed maximal DNA complexation due to the large excess of the cationic polymer. Of note, the extent of DNA complexation was also rather high at N/Ps 4 and 3, as the residual fluorescence was less than 10% of the pristine DNA shown in O_7 (N/P 0) (Fig. 3B). Afterward, the percentage of complexed DNA decreased as the N/P decreased, meaning that there was more and more uncomplexed DNA in O_5 and O_6. These results point to the potential of using the microfluidic cartridge described herein to obtain gene delivery complexes over a given range of N/Ps.



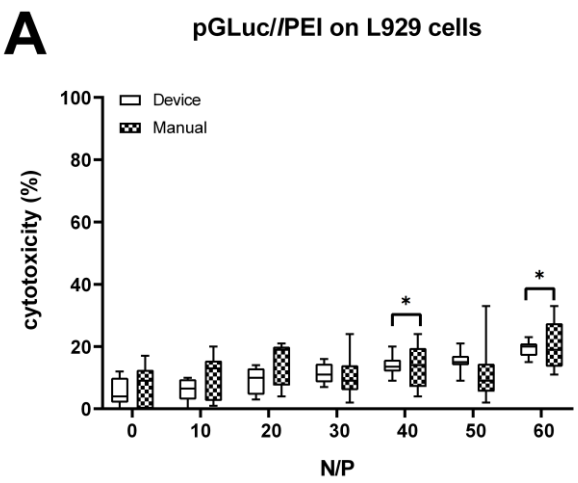


Figure 3. A) Acquisition of fluorescence images of the seven different mixing units. The fluorescence increases as the N/P decreases. Polyplexes at different N/Ps are next collected in the downstream storage tanks that may feature outlet ports (O_1–O_7). B) Complexed DNA (%) in each outlet port was evaluated by monitoring the fluorescence as a function of the N/P (n = 3).

D. Evaluation of polyplex efficacy in vitro

25 kDa *l*PEI and the pGLuc plasmid encoding the secreted luciferase enzyme were complexed through the device and manually using different polymer concentrations to yield a linear N/P scale spanning from 0 to 60 with N/P steps of 10 and dripped onto L929 cells (Fig. 4A and B). The cytotoxicities and transfection efficiencies given by polyplexes produced with the microfluidic cartridge were remarkably homogeneous. Indeed, it is apparent at a glance that each dataset shows very short whiskers and small box sizes, indicating data points consistently hovering around the center value. Besides, the results of microfluidic preparations were more repeatable than the manually-prepared counterparts.

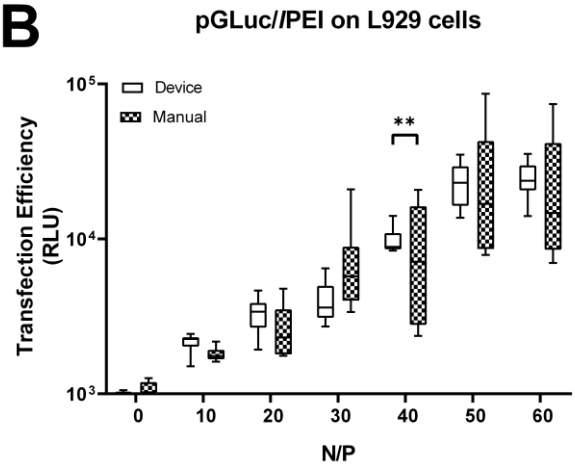

Figure 4. A) Cytotoxicity and B) transfection efficiency of polyplexes prepared with the microfluidic mixing (empty boxes) and by manual pipetting (checked boxes), mixing variable amounts of *l*PEI and a constant concentration of pGLuc in 10 mM HEPES buffer to give different N/Ps (0, 10, 20, 30, 40, 50, and 60). Results on L929 are displayed as box and whisker plots (n ≥ 3). *p < 0.05, **p < 0.01, and ***p < 0.001 between microfluidic and manual preparations (n = 3 operators) (in test for two variances).

IV. CONCLUSIONS

This work addresses the on-chip production of non-viral gene delivery assemblies across a range of N/Ps. Here above, we described the development and validation of a user-friendly, dual-mode microfluidic cartridge that enables the repeatable preparation, recovery and storage of non-viral gene delivery assemblies at desired N/Ps.

***Abstract*—*In vivo,* mechanical cues are fundamental in promoting cell and tissue development and in maintaining homeostasis. Thus, the use of advanced investigation platforms able to mimic and combine native-like physical stimuli is crucial for studying *in vitro* the cellular behaviour under defined mechanical stimuli. Here, we designed, characterized and tested a biomimetic platform, based on a flexible substrate and a previously developed stretch bioreactor, for exposing adherent cells to controlled uniaxial stretch culture protocols in view of mechanotransduction studies.**

***Keywords*—Flexible substrate, Stretch bioreactor, Mechanotransduction, Digital image correlation.**

I. Introduction

MECHANICAL forces play a crucial role *in vivo*, with consequences in cell differentiation, tissue renewal and homeostasis, as well as in pathogenesis [1, 2]. Although it is well known that most cells are able to sense mechanical stimuli and to respond by a set of biological responses that critically impact (patho)physiology, when it comes to laboratory experiments the mechanical stretching experienced *in vivo* by the cells is not often replicated, limiting the relevance of the experimental model results [3].

In this scenario, investigation platforms designed for mimicking *in vitro* the physical stimuli of the native environment have the potential to pave the way for advanced mechanotransduction studies [4-8], for ultimately unravelling the cellular biological responses to specific physical culture conditions. In this study, we developed, characterized, and tested an automated biomimetic investigation platform for culturing adherent cells under controlled uniaxial stretch. The platform is based on a customized flexible substrate to be used in combination with a tunable stretch bioreactor previously developed [9, 10]. As a preliminary biological application, we used the platform for culturing periodontal ligament-derived stem cells (PDLSCs) and adipose-derived stem cells (ASCs) under controlled uniaxial stretch. The final aim of the study was to investigate the role played by mechanical stretching on different cell types in view of exploiting the obtained advancement of knowledge for future tissue engineering applications.

II. Materials and Methods

The biomimetic investigation platform is composed of a stretch bioreactor, previously developed [8-10] and an appositely designed flexible substrate to be clamped in the bioreactor culture chamber. Briefly, the bioreactor is based on two opposite clamps which grasp the substrate and, since one clamp is connected to a stimulation unit motor, allows stretching the substrate and consequently stimulating the adherent cells.

The flexible substrate has been designed (Solidworks) with two parallel rectangular wells (Fig. 1A), for allowing experiment parallelization and optimization of the culture medium volume. Finite element (FE) analyses (Abaqus) were performed for defining the optimal substrate geometry suitable for guaranteeing planar and uniform uniaxial strain. In detail, the substrate was modelled with linear tetrahedral elements (size 0.1mm) and a uniaxial displacement of 3 mm (15% of strain), mimicking the bioreactor stretching, was imposed on one side of the substrate, while constraining the opposite one. Once the optimal design was identified, a corresponding mold was designed, 3D-printed, and used to cast the flexible substrate (Fig. 1B) in polydimethylsiloxane (PDMS, Sylgard 184), cured at 60°C for 6 h.

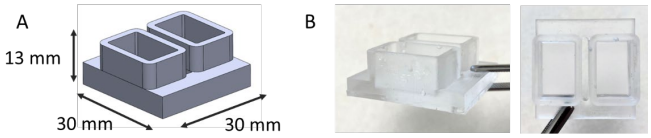

Fig. 1. Flexible substrate design. A) Substrate size. B) Substrate manufactured in PDMS.

The digital image correlation method (DIC, isi-sys GmbH) was adopted for characterizing experimentally the mechanical behavior of the substrate under uniaxial stretch.

For the preliminary biological tests, after autoclave sterilization, the flexible substrates (n=6 for each cell type) were functionalized with collagen I (Sigma Aldrich) and seeded with human primary PDLSCs harvested from healthy subjects, in accordance with ethical principles (protocol n. 0107683, 03/10/2022) or with ASCs cell line (ASC52-telo hTERT, ATCC), used as reference cell type. After 4 h of static culture, required for enabling cell adhesion, the cell-seeded substrates (n=3 for each cell type) were clamped in the bioreactor culture chamber (Fig. 2) and were exposed to cyclic uniaxial stretch (8% pre-strain combined with cycles of additional 7% strain for 90 s, at 1 Hz, every 6 h [3]) for 3 days. As control group, cell-seeded substrates (n=3 for each cell type) were cultured statically for 3 days. At the end of day 3, the expression of osteogenic markers, i.e., alkaline phosphatase (ALP), osteocalcin (OCN), and runt-related transcription factor 2 (RUNX2) was assessed through real-time PCR.

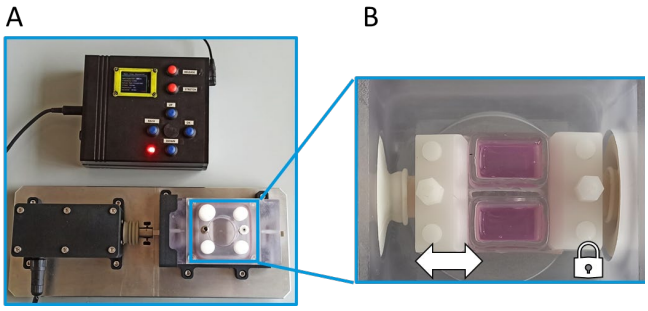

Fig. 2. Biomimetic investigation platform. A) Stretch bioreactor [10]. B) Flexible substrate clamped in the bioreactor culture chamber.

III. Results

FE analyses demonstrated that, when uniaxially stretched, the flexible substrate is characterized by an almost planar and uniform strain distribution at the well bottom (13.36 ± 0.25 %), in good agreement with the DIC results (14.33 ± 0.25%) (Fig. 3).

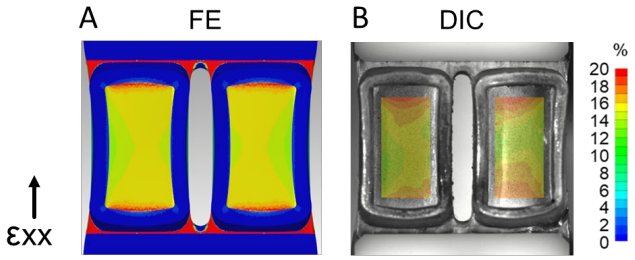

Fig. 3. Flexible substrate characterization. A) FE analysis. B) DIC analysis. Results are shown for the ϵ_{xx} strain.

Preliminary biological tests revealed that PDLSCs and ASCs respond differently to the applied uniaxial stretch culture protocol. In detail, stretched PDLSCs showed an increasing trend of ALP, OCN, and RUNX2 expression, with a significant double fold increase in OCN gene expression ($p<0.05$) in comparison to control, similarly to previously published works [12-14]. Contrarily, ASCs did not show significant differences in osteogenic marker expression between the stretched and the control groups ($p>0.05$) (Fig. 4).

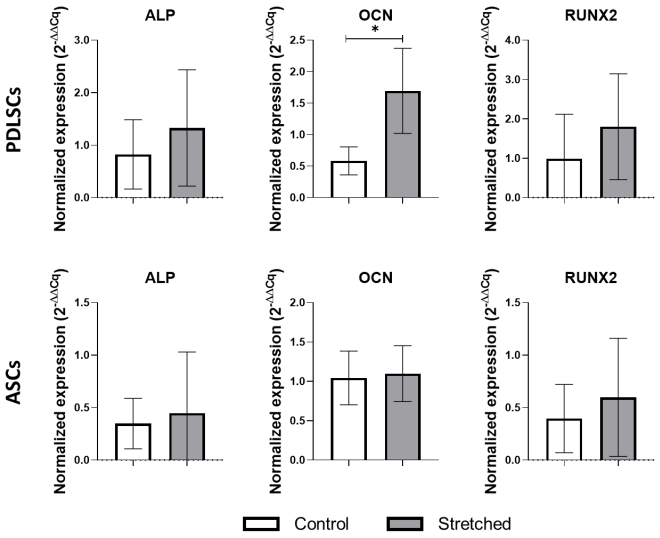

Fig. 4. Osteogenic markers expression of PDLSCs (top panel) and ASCs (bottom panel). Significative results for $p<0.05$.

IV. Conclusion

A biomimetic investigation platform for investigating the biological response of adherent cells to defined stretch protocols was developed and tested. In detail, the mechanical characterization of the flexible substrate through FE and DIC analyses allowed assessing that the platform exposes the adherent cells to highly controlled uniaxial stretch conditions, with uniform strain values over a wide area of each well bottom.

Preliminary biological tests, besides confirming the cytocompatibility of the flexible substrate, revealed that PDLSCs and ASCs respond differently to uniaxial stretch. In particular, cyclic stretching promoted osteogenic marker expression in PDLSCs, which seemed more responsive to the applied stretch stimulus than ASCs.

Combining the numerical and the experimental strain characterization with the cells biological response, this platform provides, for the first time, a powerful investigation tool for correlating the effective strain sensed by the cells and their response.

Further biological tests, imposing different stretch patterns for longer culture time and using different cell sources (healthy and pathological subjects), are ongoing with the final aim to understand in-depth the cause-effect relationships between mechanical stretch and specific cell behaviour. Moreover, such biomimetic platform, thanks to its versatility, will be used for investigating the effect of tensile and compressive stress on 3D constructs, in view of periodontal ligament engineering applications.

Such a biomimetic platform represents a powerful investigation tool for mechanotransduction studies on healthy and pathological cells and culture conditions and could lead to a significant advancement of knowledge for future tissue engineering applications.

Evaluation of the optimal pore size for 3D printed bone scaffolds in a perfusion bioreactor

E. Batoni[1], C. De Maria[1], and G. Vozzi[1]
[1] *Research Centre "E. Piaggio" and Dpt. of Information Engineering, University of Pisa, Pisa, Italy*

***Abstract*— In the bone tissue engineering field, the scaffold design has a great influence on cell behaviour in terms of metabolism, differentiation, and morphogenesis. Additive Manufacturing technologies can be used to fabricate scaffolds with controlled internal pore sizes, shapes, and distribution. Among the bioreactors used for culturing, perfusion bioreactor is preferred since the capability of providing efficient nutrient supply and waste removal, as well as mechanical stress which, if within a specific range, stimulates and enhances bone formation. For that purpose, experiments and computational models are needed to select the optimal scaffold design and culture conditions (e.g., flow rate and type) in order to achieve specific biological cell responses. This study aims at implementing a computational model to evaluate the influence of the scaffold pore sizes and strand orientation on the oxygen uptake and mechanical stress applied to cells cultured in a direct perfusion bioreactor. The model results will help to find the optimal pore size which will provide good oxygenation and enhance the osteogenic differentiation in bone scaffolds cultured in a perfusion bioreactor.**

***Keywords*— Bone tissue engineering, 3D-printed scaffold, perfusion bioreactor, computational modelling**

I. Introduction

Bone tissue engineering (BTE) is a multidisciplinary field aiming at developing biological substitutes for the repair and regeneration of bone tissue. This is based on three fundamental components, *i.e.*, cells, three-dimensional (3D) scaffold, and bioreactors [1].

Considering the influence of the scaffold on the cell behavior (*e.g.*, cell metabolism, differentiation, and morphogenesis), Additive Manufacturing (AM) technologies, such as Fused Deposition Modelling (FDM), can be useful to provide higher control over the scaffold design, as well as to optimize its internal morphology (*i.e.*, pore size, shape, and distribution) with high reproducibility and accuracy.

Among the dynamic culture systems for 3D scaffolds, the perfusion-based bioreactor is considered the most efficient as the medium is forced to flow through the scaffold architecture, thus, providing a more uniform and not diffusion-limited nutrient supply to the cells. Furthermore, the fluid movement through the pores provides mechanical stress to the cells improving their growth and guiding their differentiation toward a specific lineage. Studies demonstrated that fluid shear stress, within a specific range of intensities, enhances the activity of osteoblasts in bone formation and stimulates the expression of genes specific to the bone tissue [1,2].

Since the influence of the scaffold architecture on the biological cell response cultured in a perfusion bioreactor, the identification of the scaffold design is critical for BTE applications. For that purpose, computational models can be used to predict fluid dynamics and thus select the optimal design to achieve specific target properties. For instance, several studies implemented computational tools to optimize the scaffold design in terms of the transport of nutrients, the mechanical loads, as well as the scaffold degradation [3–5]. In addition, these represent a helpful tool to investigate the spatial and temporal distribution of the cellular responses to the difficulty to obtain real-time measurements in perfused scaffolds [1]. However, to the best of our knowledge, there is no study focused on optimizing the pore size and orientations of 3D printed scaffolds with cells seeded on the surface in a perfusion bioreactor.

The objective of the study was to implement a Finite Element Method (FEM) model to evaluate the optimal pore size of 3D-printed poly-L-lactic acid (PLLA)-based scaffolds seeded with cells in a direct perfusion bioreactor. Three different studies were implemented: (i) cylindrical scaffolds with different pore sizes and without lateral pores; (ii) cylindrical scaffolds with different pore sizes and lateral pores; and (iii) cylindrical scaffolds with different pore sizes, lateral pores, and different strand orientations. The model results will help to select the optimal scaffold porous design which provides good oxygenation and enhances the osteogenic differentiation of cells cultured in a direct perfusion bioreactor.

II. Materials and Methods

Cylindrical scaffolds (8 mm in diameter, and 6 mm in height) were designed in Autodesk® Fusion 360™ implementing a parametric function on the pore length and the presence of lateral pores. Three different studies were performed:

i. in the first study, three scaffolds without lateral pores were created differing in pore size (l [mm]), namely, 0.4 – 0.9 – 1.3mm, within the typical macropores range for BTE scaffolds (i.e., 0.1 to 1.2mm) (Fig. 1A) [2];
ii. in the second study, lateral pores were also created in each scaffold (Fig. 1B);
iii. in the third study, the orientation of the strands was varied for each scaffold, namely, 90° - 45° - 20°, in the XY plane, and featured with lateral pores (Fig. 1C).

Scaffolds are assumed to be fabricated through FDM by using PLLA-based filaments, thus, the deformations due to the medium flow are neglected and the scaffolds are considered as rigid bodies, which is also applicable to a wide range of thermoplastic polymers.

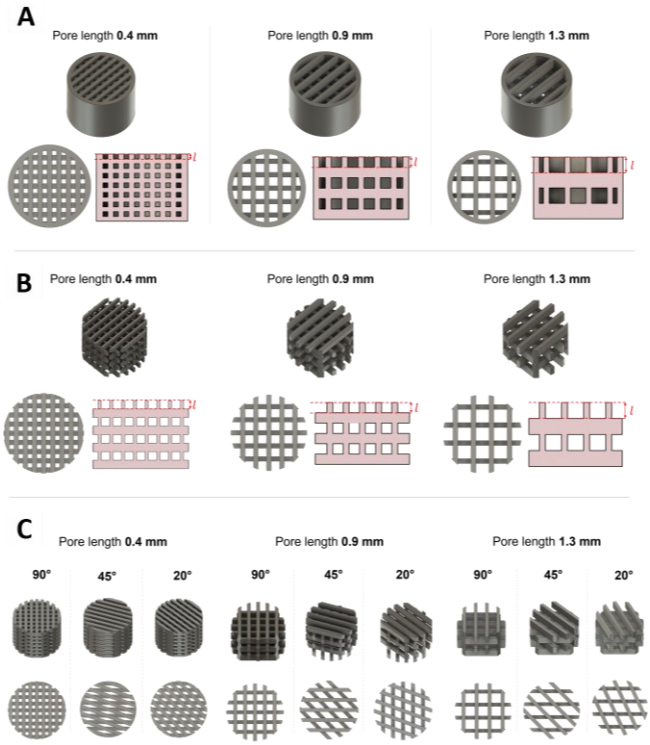

Fig. 1 Scaffold geometry. Scaffolds (A) without and with (B) lateral pores with different pore sizes (l [mm]), and (C) with lateral pores and strands oriented at different angles.

The FEM model was implemented in COMSOL Multiphysics® v6.0 using the "*Transport of Diluted Species*" and "*Laminar Flow*" modules. Like other studies [3-4], it was assumed that laminar flow conditions are verified for all porous scaffolds and flow rates. The geometry of the fluid domain, representing the culture medium, was obtained by the Boolean difference between the scaffold and the bioreactor geometry, taking as a model the perfusion-based bioreactor (8mm in diameter ($\varnothing_b$), and 24mm in length (L_b)) reported in the study of Coletti *et al.* [1] (Fig. 2). In detail, the culture medium is fed from the top channel of the bioreactor by a volumetric peristaltic pump, flows through the inlet section, perfuses through the scaffold pores, and then exits from the bottom channel through the outlet section. The channels dimensions are 2mm in diameter ($\varnothing_c$) and 3mm in length (L_c).

Regarding the boundary conditions of the "*Laminar Flow*" module, the flow rate was parametrically assigned to the inlet and a pressure of 0Pa was placed at the outlet. The medium fluid properties were assumed to be that of water.

In the "*Transport of Diluted Species*", an inflow concentration of 0.2 mol/m^3 was set on the inlet, whereas a surface reaction was placed on the scaffold surface where cells are seeded. A Michaelis-Menten kinetic was assumed for the oxygen consumption, given the following expression for the surface reaction (Eq. 1):

$$R = -\frac{OCR * \rho_s * c}{c + K_m} \quad (1)$$

where the oxygen consumption rate (OCR) was set equal to 2.75x10^{-17} mol/(s*cells), the superficial cellular density (ρ_s) to 3x10^9 cells, and the Michaelis-Menten constant (K_m) to 0.011 mol/m^3. The parameters were taken from the literature, considering the typical values for common scaffold and cell cultures given by experimental data [1].

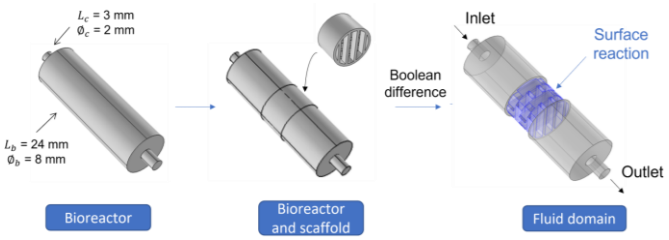

Fig. 2 FEM geometry and model setup. The geometry was obtained by the Boolean difference between the perfusion bioreactor (Coletti et *al.* [1]) and the scaffold, then, specific boundary conditions were placed on the inlet, outlet, and the seeded surface highlighted in blue.

A parametric sweep of the flow rate (0.01 – 0.2 – 0.5 ml/min) was also added in the first study (scaffolds without lateral pores) to evaluate the best condition in terms of oxygen supply and Wall Shear Stress (WSS) evaluated on the seeded surface. A stationary study was implemented to evaluate the cell viability and WSS effects after the transient.

III. Results and Discussions

For each study, the average and maximum WSS on the seeded surface were evaluated in all pore lengths and flow rates. According to the literature [6], the acceptable WSS range for osteogenic differentiation of cell lines in 3D perfusion bioreactors varies from 0.1 mPa to 15 mPa, whereas the critical oxygen concentration for cell vitality is equal to 0.04 mol/m^3. Thus, these values were taken as a threshold for finding the optimal scaffold pore size and flow rates. Considering the scaffolds without lateral pores, an inlet flow rate between 0.2 ml/min and 0.5 ml/min is preferred for all pore lengths both in terms of WSS and cell oxygenation (Fig. 3A/B).

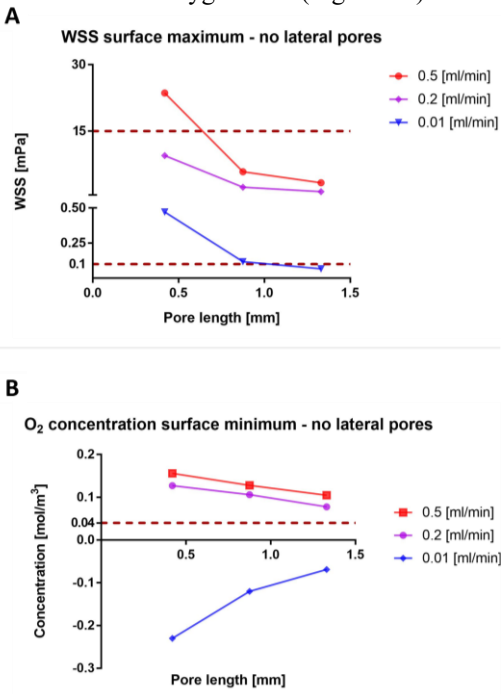

Fig. 3 (A) WSS and (B) oxygen concentration values in the scaffolds without lateral pores evaluated with three different flow rates, namely, 0.01 - 0.2 - 0.5 ml/min.

Comparing the WSS in the scaffold without and with lateral pores, no differences are shown for each of the flow rates (Fig. 4A/B). However, it results that a pore length greater than 0.4 mm (minimum size evaluated) is the optimal condition in

terms of WSS, being lower than the maximum acceptable value (i.e., 15 mPa) for osteogenic differentiation (Fig. 4A). On the other hand, cell oxygenation is improved in the lateral porous scaffolds (Fig. 4B).

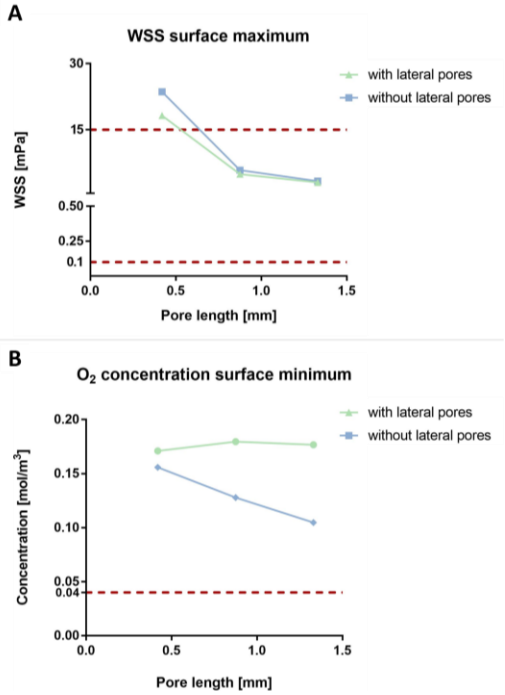

Fig. 4 (A) WSS and (B) oxygen concentration values in the scaffolds without and with lateral pores, with a flow rate of 0.5 ml/min.

Similarly, no differences were found in terms of WSS among the lateral porous scaffolds presenting different strand orientations (Fig. 5A). However, the 90°-oriented is the best condition to guarantee better oxygenation among the seeded cells (Fig. 5B).

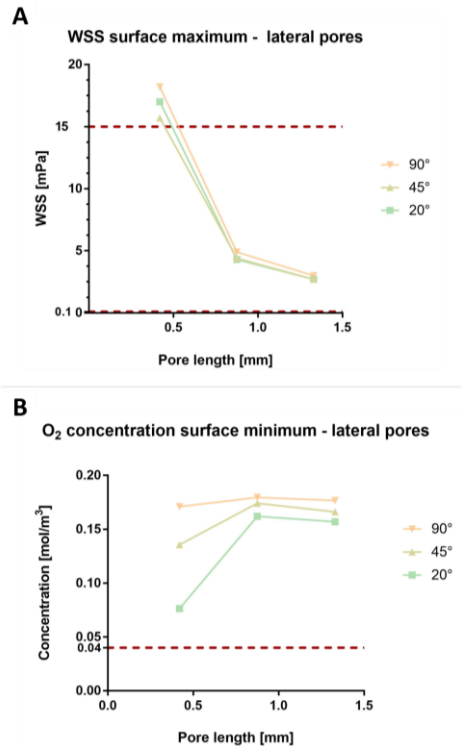

Fig. 5 (A) WSS and (B) oxygen concentration values in the scaffolds with lateral pores and different strands orientation evaluated with a flow rate of 0.5 ml/min.

It is important to highlight that model results are not applicable for scaffolds made in soft materials (e.g., hydrogels), which have low mechanical strength, and thus exhibit not negligible deformations even at low flow rates. In this case, the fluid flow and solid mechanics should be coupled to capture the fluid-solid interactions.

IV. Conclusion

For all pore sizes, the scaffold presenting lateral pores improved the oxygenation and showed acceptable WSS values for osteogenic differentiation. Although the strand orientation had little influence on the WSS, the 90° orientated scaffolds showed better oxygenation. Furthermore, among the scaffolds with lateral pores and 90° orientation, a pore length greater than 0.4 mm is recommended in terms of WSS acceptable values. Among the flow rates considered in this study, the 0.5 ml/min condition is preferable for oxygenation and WSS when pores are greater than 0.4 mm.

In the future, the selected optimal scaffold design will be used to evaluate the spatial-temporal variation with a transient study over the culture period (typically 7 days). In addition. the recirculation condition at the inlet and outlet of the bioreactor will be added to simulate a close system like a real experiment. Furthermore, the model will be integrated with different kinetic models to account for the cell growth and/or detachment/death, as well as the changes in the porosity due to the formation of extracellular matrix (ECM) and cellular activities, and scaffold degradation. Additionally, the model will be validated in vitro seeding cells on the PLLA-based scaffolds in a perfusion bioreactor.

***Abstract*—Robotic-based in situ bioprinting is a very promising technology to overcome the limitations of the traditional scaffold-based tissue engineering approach. One of the most used bioprinting technologies to deposit the biomaterial directly onto/into a damaged site of the patient is based on a pneumatic extrusion. During the printing phase, the robotic manipulator end-effector is subjected to continuous changes in speed and direction to follow complex anatomical surfaces. For this reason, in this work we describe the development of an extrusion control strategy to obtain a uniform biomaterial deposition during a robotic-based in situ bioprinting procedure. The proposed algorithm was tested onto IMAGObot, a 5-axes robotic platform optimized for in situ bioprinting applications.**

***Keywords*—robotic-based in situ bioprinting, pneumatic extrusion-based bioprinting, extrusion control strategy.**

I. Introduction

In recent years bioprinting technologies are attracting interest in the field of tissue engineering (TE) since they offer a promising solution to those diseases that damage a tissue/organ to such an extent that transplantation is necessary. These technologies allow precise placement of cells, biomaterials, and biomolecules in three-dimensional (3D) structures developed through a computer aided design (CAD) software [1-2].

Bioprinting approaches can be divided into two branches, *in vitro* and *in situ*, respectively. The first involves the development of a biocompatible scaffold (potentially built using cell-laden materials), colonized with cells, whose growth is promoted in a bioreactor. A surgical procedure can then be performed to transfer the scaffold into the patient's lesion. In contrast, *in situ* bioprinting consists of the direct deposition of the biomaterial on the intended anatomical location in the living body, using the body itself as a bioreactor. The *in situ* approach is promising because, given the direct printing into the defect, the risks of implant failure due to geometric mismatches is reduced, and the scaffold-tissue integration is promoted [1, 3].

Robotic-based *in situ* bioprinting is the most promising approach since it integrates the advantages of using a robotic manipulator for a precise biomaterial deposition. Once medical images are acquired, a digital model of the defect is obtained, and a printing trajectory is planned for the biomaterial printing onto the lesion. A list of commands, usually in a G-code format, is processed and provided to the robotic manipulator that executes the instructions and builds the desired structure. This approach provides multiple advantages such as: high printing accuracy, rapid biofabrication of complex multi-material scaffolds, minimization of human errors and compatibility with minimally invasive internal surgery tools [3].

One of the most common technologies for *in situ* bioprinting purposes is extrusion-based bioprinting [4-5]. Considering the robotic approach, a pneumatic actuation is preferred to reduce the load (*e.g.,* due to motor or other actuation systems) on the end-effector. Nevertheless, during the bioprinting step, an inhomogeneous biomaterial deposition can occur if a constant pressure is applied. Under/over extrusion problems arise when the extruder (used as end-effector of the robot kinematic chain) undergoes abrupt changes in velocity, when printing on uneven surfaces or during sudden changes in direction. Since most anatomical surfaces have such features, it is crucial to implement a strategy to improve the printing quality.

In this work, we present the implementation of a pressure control strategy to increase the accuracy of the bioink deposition with the robotic manipulator IMAGObot [6-8]. An algorithm was developed in Matlab to predict the end-effector speed and the optimal printing pressure and was integrated in the previously developed IMAGObot application.

II. Materials and Methods

A. IMAGObot robotic platform

IMAGObot (Fig. 1A) is a robotic biofabrication platform, developed from the 5 Degrees-of-Freedom (DoF) open source MOVEO robot from BCN3D [9], totally re-engineered both in hardware and software for *in situ* bioprinting applications [3]. The robotic manipulator has an electro-magnet as end-effector that enables quick and easy tool switching so that many instruments may be used for a single operation (e.g., touch probe, pneumatic extruder). In this work, the syringe-pump extrusion module based on a pneumatic actuation was used. IMAGObot is position-controlled using LinuxCNC, an open-source software that allows the interaction with the robot using a G-code, while the path planning is performed using the previously developed Matlab® R2020a application. The Linux CNC source code has also been released as open-source project on the GitHub platform [10] and is constantly updated.

B. Extrusion-control strategy

A preliminary analysis was conducted observing IMAGObot behaviour during simple trajectories, such as diagonal, vertical, and horizontal planar lines. The desired paths (Fig. 1B) were planned in Matlab and tested in the IMAGObot workspace at different z heights and with different points density. A Python code was written to collect end-effector speed and position (*i.e.*, joint angles for each point of the trajectory) data from LinuxCNC during printing

movements, every time that the robot reads a different G-code line. The collected data were then imported in Matlab, converting joint angles into Cartesian coordinates with a Direct Kinematic algorithm, and successively analysed to highlight any speed variation while traveling along horizontal and vertical lines according to the position in the robot workspace. From these data, two descriptive laws of motion along vertical and horizontal trajectories were derived. Combining all the data acquired from this analysis, a predictive algorithm was developed that, starting from the linear speed set by the user, and knowing the position and density of the trajectory in the IMAGObot workspace, computes multiplying coefficients to predict speed variations along the path. On the basis of the obtained speed data, the pressure value can be modulated for each portion of the trajectory to achieve a uniform biomaterial deposition.

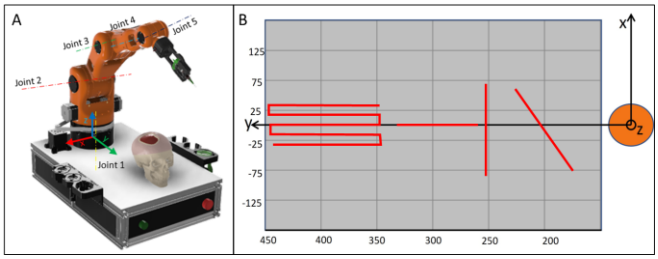

Fig. 1: A) Schematic of the IMAGObot platform: the robot workspace reference frame and the 5 joint axes are shown – B) Top view of the IMAGObot workspace. The robotic platform is here schematized with an orange circle, the reference axes are indicated with the black arrows, and the red lines indicate the trajectories tested for the preliminary analysis.

C. *Validation of the extrusion-control strategy*

The accuracy of the algorithm was tested by comparing the predicted (*i.e.*, obtained in Matlab) and real speed of the end-effector (*i.e.*, acquired from LinuxCNC), while executing both planar and non-planar serpentine trajectories.

Successively, to assess the printing quality provided by the algorithm, tests were performed depositing a 20% w/v Pluronic acid F127 (Sigma-Aldrich, Italy) biomaterial ink onto a planar surface: the same serpentine trajectory was printed without the pressure control algorithm (constant pressure value of 0.5 bar along all the pattern), and with the adaptive pressure values provided by the developed algorithm. The goal was to obtain a printed strand as uniform as possible, and a line width similar to the needle used for extrusion (0.82 mm internal diameter). The width value was obtained with the ImageJ® software averaging 28 values acquired on different cut lines along the trajectory (as shown in Fig. 7).

Finally, preliminary *in situ* bioprinting tests were performed by depositing the same biomaterial ink previously used onto two different non-planar surfaces.

III. Results and Discussion

A. *Extrusion-control strategy*

Preliminary tests were performed by executing simple trajectories to evaluate IMAGObot speed variations in its workspace and adjust pressure value accordingly. Results are shown in Fig. 2. Considering the diagonal paths (Fig. 2A), as can be seen from Fig. 2B the speed decreases if the end-effector is moving from the furthest to the closest point at the base of the robot while increases if travelled in the opposite way. The same behavior can be observed for vertical trajectories (Fig. 2C), where the speed decreases moving the end-effector towards the robot base but is not affected by x coordinate. Hence, moving away from the base of the robot, the contribution of joint 3 is added to that of joint 2 and consequently, the maximum speed attainable increases. Finally, considering horizontal paths, the speed decreases as y coordinate increases. In this case, this trend is due to the fact that joint 1 is the most involved in the movement and, given the robot configuration, would tend to perform a circumference (dotted line in Fig. 3, radius equal to the distance from the robot base).

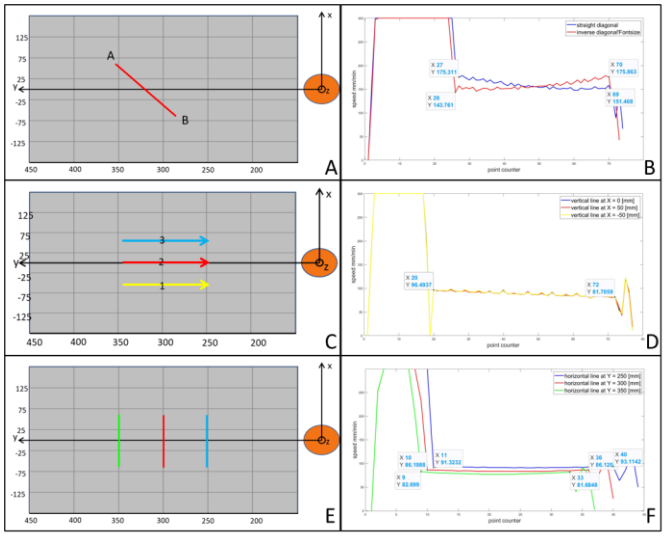

Fig. 2: A) Diagonal trajectory: two different tests were carried out moving the end-effector from A to B and *vice versa* – B) Speed trend for the two diagonal trajectories: going from A to B the speed decreases (blue plot), from B to A increases (red plot) – C) Vertical trajectories at different x coordinates – D) Speed trend along different vertical trajectories: varying the x coordinate the speed value does not change – E) Horizontal trajectories at different y coordinates – F) Speed trend along horizontal trajectories: the speed values increases as distance from the robot base (y coordinate).

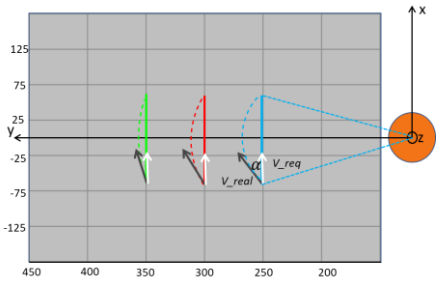

Fig. 3: Relationship between real and set speed for the end-effector movement along x axis is dependent on the distance from the robot base.

The contribution due to *z* height in the workspace can be neglected since it does not introduce a speed variation.

From the preliminary tests previously shown, two interpolation surfaces were obtained (Fig. 4) to relate all the considered parameters: distance between adjacent point s of the trajectory (x), set speed of the end-effector (y), distance from the robot base (z).

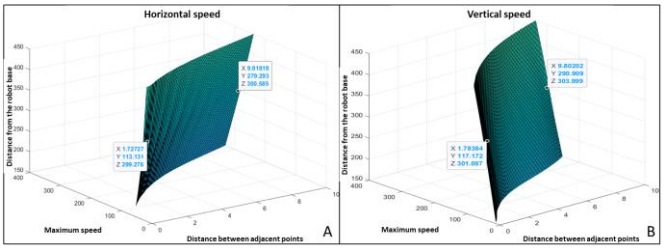

Fig. 4: Interpolation surface describing speed variation along x direction (A) and y direction (B).

The speed was thus found to be mainly influenced by two factors: the distance between the points of the trajectory, and the distance of these points from the robot base. Exploiting these data, the developed Matlab algorithm computes multiplying coefficients that starting from the set speed provides the predicted speed for each portion of the trajectory.

B. Validation of the extrusion-control strategy

Using the developed predictive algorithm, printing tests were performed on different substrates, both planar and non-planar (Fig. 5), and the predicted speed values for each point of the trajectory (Fig. 6A-C) were compared with the real speed acquired from LinuxCNC (Fig. 6B-D).

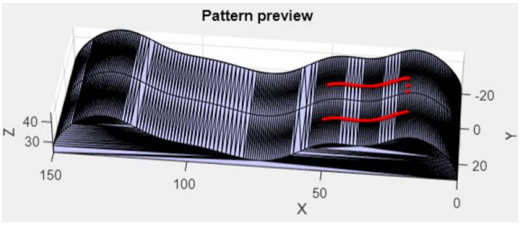

Fig. 5: Non-planar substrate tested for the validation of the extrusion-control strategy

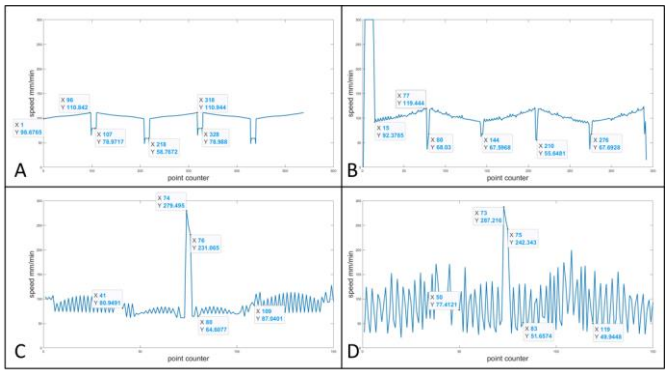

Fig. 6: Comparison between predicted (A-C) and measured (B-D) speed for a serpentine trajectory onto a planar (A-B) and non-planar (C-D) substrate.

Fig. 6A and 6B compare the speed of the end-effector during a planar serpentine trajectory. As shown in the outlined data, the computed speed value at the starting point is 7% higher than the real value, while in the ending point of the trajectory is 19% higher than the measured one. The change of direction is traveled at ~68 mm/min while the computed speed for this segment was ~78 mm/min (12% higher). The speed values were close enough to allow a notable improvement in the printing quality. Fig. 6C and 6D show the predicted vs measured speed of the end-effector while printing the non-planar serpentine trajectory. As can be seen, the speed profiles differ, but this is caused by the robotic arm vibration (due to low rigidity of the 3D printed manipulator), not predictable in the code. Nevertheless, the speed values match in most parts: the central spike was traveled at ~287mm/min, and the computed speed was ~279 mm/min, the following point is reached at a speed of ~242 mm/min when the computed speed was ~231 mm/min: also in this case the speed is thus predicted with an average accuracy >80%.

The improvement of printing quality was assessed by performing the same bioprinting test with and without the extrusion control strategy developed. The Fig. 7A shows the pattern printed with a constant pressure value of 0.5 bar along the entire pattern. The printed line width is not uniform, and several clots are visible when the pattern changes direction. The Fig. 7B shows the same trajectory being printed with adaptable pressure value (from 0.28 to 0.50 bar), according to the end-effector predicted speed.

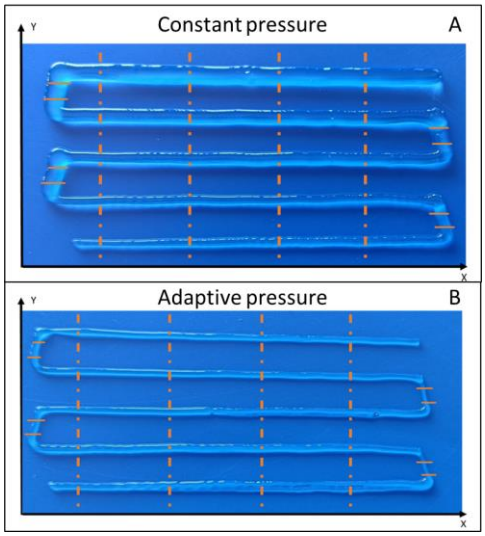

Fig. 7: Analysis of the printing quality: dashed orange lines represent the points where line width value was measured with the ImageJ® software. The obtained average value was compared between the printed pattern with a constant (A) and adaptive pressure (B).

A general improvement in printing quality is shown: the deposited filament is much uniform and there are no clots when the end-effector changes direction. The bar plot in Fig. 8 compares the average values of the printed line width highlighting how the obtained width with the extrusion control strategy is closest to the target needle internal diameter. The lower standard deviation also confirms a higher line width homogeneity.

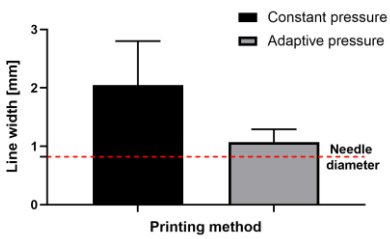

Fig. 8: Comparison between the line width obtained with and without the extrusion control strategy developed. Needle internal diameter was 0.82 mm.

Preliminary *in situ* bioprinting tests were then performed by printing a serpentine trajectory onto a non-planar surface using the developed algorithm (Fig. 9A-B). The printed line width is uniform and continuous. In the figure 9C the same trajectory was printed using a constant pressure value equal to the minimum computed by the algorithm (0.26 bar), while in the figure 9D the value is the maximum computed by the algorithm (0.5 bar). Both tests performed with constant pressure value showed printing inaccuracies, lack of material and biomaterial blobs, respectively.

A final printing test was conducted onto a surface with sudden changes in slope, with appreciable uniformity and continuity of the printed line width, as shown in Fig. 9E.

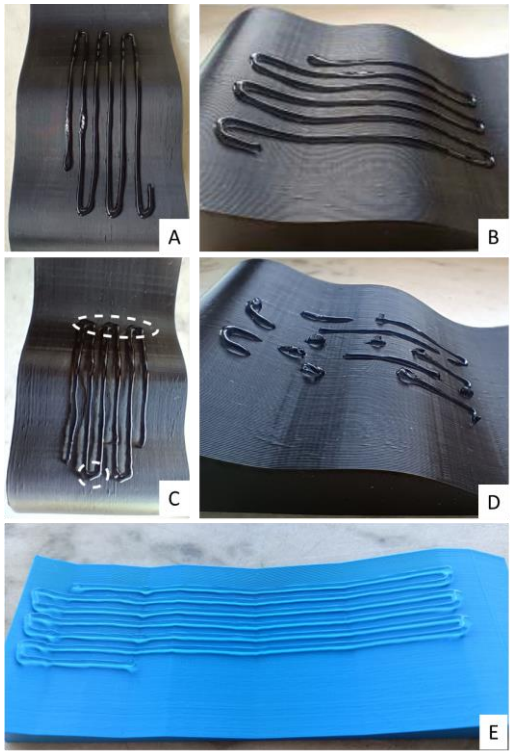

Fig. 9: Preliminary *in situ* bioprinting tests onto complex surfaces: A-B) Printed pattern with the adaptive pressure. - C-D) printing with a consatnt pressure equal to the maximum (C) and minimum D) pressure value obtained from the developed algorithm. Clots of material are visible in C, indicatd with white circles. In D a too low pressure causes a discontinous line.– E) Printing test onto a substrates with steep-slope changes using adaptive pressure

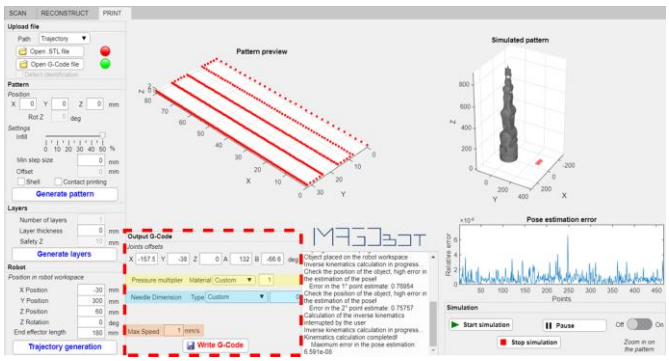

Fig. 10: IMAGObot Matlab application with the addition of the extrusion control strategy. The material and the needle diameter can be set from the user to adjust the obtained pressure value

The extrusion control algorithm was then implemented in the IMAGObot Matlab application using Matlab App Designer as shown in Fig. 10. Two dropdown menus were added to make the algorithm customizable based on the material and needle used.

IV. Conclusion

In this work we presented the development of an extrusion control strategy for pneumatic robotic-based *in situ* bioprinting. The implemented algorithm proved to be able to predict the printing speed for different trajectories according to the position in the robot workspace. Based on this outcome, the pressure value can be adjusted accordingly for each portion of the printed pattern. This approach was successfully tested onto different planar and non-planar substrates showing an improved printing quality when compared with a constant pressure along the entire path. The approach is very promising for robotic-based *in situ* bioprinting applications where complex surfaces are typical of anatomical defects. Furthermore, the pressure control algorithm was successfully integrated into the IMAGObot Matlab application allowing for higher customization as well as an easier interaction and usability by non-expert users. Future developments include refinement of the algorithm, with a finer control of the end-effector speed, as well as an expansion of the material library.

***Abstract*— This study evaluates degumming methods to obtain the best purity of silk sericin (SS) and the most suitable physicochemical features without affecting the yarn quality and the extractable sericin quantity. However, SS extracted by various methods results in SS exhibiting different physical and biological properties. The molecular weight of SS, which ranges from 10 to 400 kDa, is determined by the extraction and purification process. Higher molecular weight sericin peptides enable their use for many applications, including medical biomaterials, functional bio-membranes, and others. Lower molecular weight sericin peptides are mostly employed in cosmetic products. This study evaluates the molecular weight distribution of SS samples via sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) in addition with mass spectrometry. Also, the conformational properties of SS samples obtained by heat-under-pressure method were investigated by Fourier transform infrared (FTIR) and Circular dichroism (CD) spectroscopy.**

***Keywords*—silk sericin, degumming methods, physiochemical features, molecular weight.**

I. Introduction

Bombyx Mori sericin, a globular protein synthesized in the middle silk gland of B. Mori silkworm, has started to receive attention due to its unique properties desired in biomedical applications. A variety of discoveries on the structure, properties, biocompatibility, and processability have revealed the uniqueness of silk sericin (SS) and have opened new possibilities of applying SS as a major product in a wide variety of applications, including antibacterial, wound healing, antidiabetic, moisturizing, promotion of collagen synthesis, cryopreservation, replacement of serum for cell culture [1], [2].

SS has a larger content of hydrophilic amino acids than fibroin, another protein produced from silkworm that has undergone extensive research. Thus, it possesses more hydrophilicity and is more susceptible to chemical modification than fibroin. However, sericin's real biomedical value has not been completely investigated due to the difficulty in processing it into useable materials, unlike the already extensively studied silk fibroin [3]–[5].

Although SS has desirable composition, biocompatibility, and potential to be made into various biomaterials, the economic recovery of SS from the degumming process is still a challenge because the structure of SS varies depending on the ways through which it is obtained [6]. The dynamics of pH, temperature, chemicals and processing time will affect sericin's molecular and functional properties.

Different degumming methods can be used to extract SS. Using heat or heat under pressure has the advantage of producing no contaminants [1]. However, because the process takes too long, this approach is rarely used in the silk industry. Since they do not degrade fibroin and are very simple processes, soaps and detergents are currently used in practically all industrial removal techniques [7]. Since alkali, soaps, and detergents need to be removed prior to additional applications, these techniques make it very difficult to get high-quality SS for further investigations or applications.

This study aims to obtain SS from silk cocoons by degumming processes (heat-under-pressure method, alkali and acid-degradation and urea degradation) and evaluate them to get the best purity of SS and the most suitable physicochemical features. The molecular weight of recovered SS also affects its end-use; it has been reported that high molecular weight sericin (greater than 20 kDa) is suitable for making biomaterials and membranes, whereas low molecular weight sericin (less than 20 kDa) is suitable for cosmetics, skincare products and medications [1], [7].

The processability of the SS obtained is deeply related to its physio-chemical features; hence, SS extracts have to be evaluated in detail.

We started examining the molar mass distribution of SS obtained by different degumming methods by sodium dodecyl sulphate-polyacrylamide gel electrophoresis accompanied by mass spectrometry.

We did this to compare the molecular weight of SS products made using various degumming methods. This allows us to evaluate which degumming method suits the project's future objectives regarding the final target product.

SS secondary structure is characterized by FTIR (Fourier transform infrared) and CD (circular dichroism) spectroscopy.

II. Materials and Methods

A. Silkworm cocoons

Fresh B. Mori cocoons were kindly supplied by CREA (Council of Research in Agriculture and Analysis of Agricultural Economic, Padua, Italy), a germplasm bank responsible for the production of cocoons and collection by the

farmers who have been assisted with the traceability process by the CREA staff itself, together with cocoon sorting in different classes, cocoon cutting, pupae extraction, cocoon shell storage and preservation.

B. Extraction of silk sericin by heat-under-pressure (autoclaving) method

Applying a modified version of Aramwit et al.'s procedure [8], SS was extracted from the cocoons. 30 g of cocoons of B. Mori silkworms were placed in distilled water for autoclaving at 121°C, 15 lbs pressure for 20, 30 and 60 min (SS_{20MIN}, SS_{30MIN}, SS_{60MIN}), respectively. The aqueous solution obtained from autoclaving silk cocoons was centrifuged, followed by filtration to separate the silk fibroin and other solid residues. The filtrate was finally stored at −20 °C until further use.

C. Extraction of silk sericin by urea-degradation

SS from the cocoons was extracted using protocol reported by Aramwit et al. [9], cutting 6 g of freshly cocoon pieces, followed by soaking in 8 M urea (150 mL) and heating at 85 °C for 30 min. Afterwards, the SS solution was subjected to centrifugation (4000 rpm) and filtration to remove silk fibroin and other residues. The SS solution was then dialyzed (cellulose tube with MWCO of 6-8 kDa) for 48 h against distilled water with frequent changes. Dialyzed silk sericin solution was stored at −20 °C.

D. Extraction of silk sericin by acid and alkali-degradation

Acid and alkali-degraded SS was extracted from the cocoons using the modified protocol of Kurioka et al. [10]. Cocoons were cut into small pieces and soaked in 1.25% citric acid (for acid-degradation) or 0.5 M sodium carbonate (alkali-degradation) solution and boiled for 30 min. Post boiling, silk fibroin was removed, followed by filtration and centrifugation (4000 rpm). The obtained supernatant was dialyzed, and the pH of the final protein solution was measured to verify the removal of citric acid or sodium carbonate. Dialyzed protein solution was preserved at −20 °C.

E. Sample preparation and mass determination

SS solutions obtained using urea (200 and 400 µL), alkali (400 and 600 µL), and acid (400 and 600 µL) degumming methods were concentrated using a vacuum concentrator until 15 µL and used directly for further investigations.
SS solutions obtained using the heat-under-pressure method with different extraction times were processed using a spray drying machine (Shanghai Pilotech Instrument & Equipment Co., Ltd, YC-015) into SS powders.

To determine the molecular mass of SS, SDS-PAGE was performed.
Briefly, sample solutions obtained by urea, acid, and alkali degradation were prepared by adding an equal volume of Laemmli sample buffer to each protein solution. Each sample solution was then loaded on a gel.
Regarding the heat-under-pressure method, 2 mg of SS powder was solubilized in 1 mL of different buffers (Laemlli sample buffer 2X, Phosphate Buffer Saline (PBS) 2X, and IEF sample buffer) and loaded into a gel.
In each case, the gels obtained had smearing and lacked a distinct band pattern. The SS samples' precipitation through Chloroform Methanol Precipitation for 2D and AMICON ultrafiltration devices was performed to concentrate and purify them from contaminants, and the SDS-PAGE process was repeated. Nevertheless, the final SDS-PAGE results remained the same.
Therefore, having unsatisfactory results using a sericin powder, we switched to SS solution and presuming that insufficient protein concentration in our samples caused a predominantly smeared gels, a BCA protein kit was employed to detect the exact protein concentration in 30 µL of each of our samples obtained by 20, 30, and 60 min extraction time (SS_{20MIN}, SS_{30MIN}, SS_{60MIN}), respectively. After getting the exact protein concentrations in each sample Table 1, a protocol for further processing our sample was made to obtain more satisfactory results.

Sample	SS_{20MIN} (30 µL)	SS_{30MIN} (30 µL)	SS_{60MIN} (30 µL)
protein concentration	1.9 mg/mL	4 mg/mL	6 mg/mL

Table 1. Protein concentration in 30 µL of SS solutions obtained by 20, 30, and 60 min extraction time.

Subsequently, we mixed 50 mL sericin solution obtained with 60 min extraction time with a protease inhibitor tablet and prepared two aliquots containing 70 mg of protein.
The first aliquot was filtrated with filter paper, and the waste was recovered. Afterward, it was solubilized in Leammli-ß-mercaptoethanol at 99°C.
The filtrated solution was subjected to ProteoMiner™ technology using 200 µL of beads. Two obtained elutions (E11 and E12) were concentrated to 15 µL and mixed with 5 µL Leammli-ß-mercaptoethanol.
The second aliquot was subjected to ProteoMiner™ technology using 250 µL of beads. After 2 h of incubation, centrifugation at 4000 rpm for 10 min was done, and the supernatant was eliminated. The pellet was washed with water and centrifuged again, after which the elutions were performed. Both elutions (E21 and E22) obtained were concentrated until 15 µL and mixed with 5 µL Leammli-ß-mercaptoethanol.
The waste, elutions from the first aliquot, and elutions from the second one were loaded on a new gel, respectively.
Post-run, both gels were washed with distilled water and stained with Coomassie brilliant blue G-250.

Mass spectrometry analysis was done on solutions that contained all the denatured proteins extracted from SDS-PAGE gel, including urea samples (200 and 400 µl), elution 1 (E11) and elution 2 (E12) from the first aliquot and elution 1 (E21) and elution 2 (E22) from the second aliquot since those are the only ones with clear bands patterns in both gels.

A nano chromatography system (UltiMate 3000 RSLCnano System, Thermo Scientific) was coupled with a mass spectrometer (LTQ XL ion trap, Thermo Scientific). The MS data were analyzed by the Mascot search engine (Version 2.3.01), using the Proteome Discoverer software (v. 1.2.0 Thermo) and consulting specific UniProtKB/Swiss-Prot protein database.

F. Fourier transform infrared (FTIR) and Circular dichroism (CD) spectroscopy.

FTIR spectroscopy is used to analyse the maintenance of characteristic secondary structures. According to the literature, SS FTIR absorption spectra display the characteristic amide bands between wavenumbers 1700 cm^{-1} to 1600 cm^{-1} (Amide I), between wavenumbers 1600 cm^{-1} to 1520 cm^{-1} (Amide II) and between wavenumbers 1350 cm^{-1} to 1200 cm^{-1} (Amide III). Based on experimental FTIR studies on model peptides and proteins with known structure and theoretical analyses, it has been possible to correlate the peak position of the spectral components to a specific protein secondary structure [11], [12].
Assuming that the heat-under-pressure method is the most suitable procedure, we adopted it as the first one for this kind of analysis.
The SS powder was used for subsequent characterization.
Firstly, we preliminary tested the possibility of characterizing a small amount of SS sample by FTIR analysis, after which circular dichroism, a complementary spectroscopic approach, was employed to support the peak assignments to the protein secondary structures.

III. RESULTS AND DISCUSSION

A. SDS-PAGE

Fig. 1 shows the SDS-PAGE gel exhibiting the molecular weight distribution of SS after extracting from the cocoons using urea, acid and alkali degradation methods. SS extracted using urea-degradation exhibited a clear band pattern with molecular weight ranging from 15 to 160 kDa. Whereas SS extracted using alkali- and acid-degradation exhibited smear.

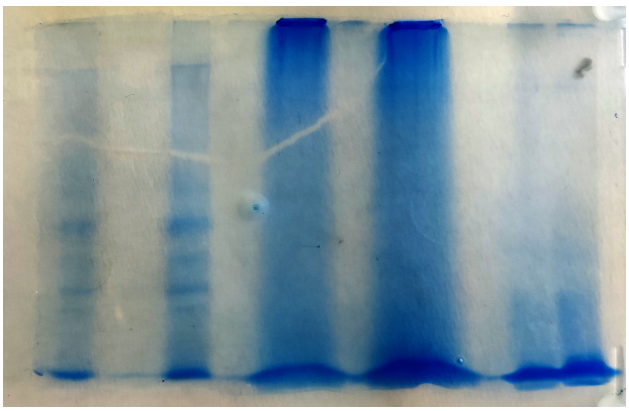

Fig. 1. The molecular weight distribution of SS solution extracted from cocoons using urea-degradation (200 and 400 µL), alkali-degradation (400 and 600 µL) and acid-degradation (400 and 600 µL) methods in SDS-PAGE.

SDS-PAGE of SS obtained by the heat-under-pressure degumming method, after which the sample solution was prepared using beads, is shown in Fig. 2. In the first row represented by the waste, we can see only the smear. In the two elutions obtained from the first aliquot, we can see some bands ranging from 15 to 100 kDa. Elutions obtained by the second aliquote show bands in the range of 30 to 50 kDa.

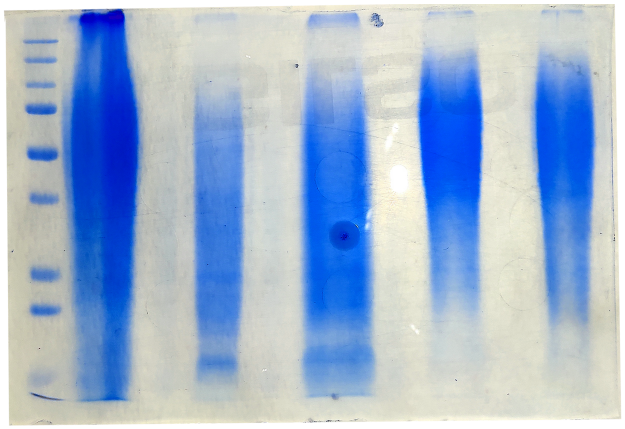

Fig. 2. The molecular weight distribution of SS solution extracted from cocoons using a heat-under-pressure method in SDS PAGE. SDS-PAGE gel showing bands of protein ladder, waste, elution 1 (E11) and elution 2 (E12) from the first aliquot, elution 1 (E21) and elution 2 (E22) from the second aliquot, respectively.

B. Mass spectrometry data

Mass spectrometry data with the highest MASCOT score of 14432 is represented in Fig. 3 and it is related to the second elution from the first aliquot (E12). The MASCOT score uses mass spectrometry data to identify proteins from peptide sequence databases. Furthermore, this number reflects the combined scores of all observed mass spectra that can be matched to amino acid sequences within the protein. Therefore, a higher score indicates a more confident match.

Fig. 3. Mass spectrometry data on elution 2 from the first aliquot (E12).

Since a mass spectrometry low-resolution instrument was used, we could not specify the amount of SS in our samples obtained by autoclaving. However, looking at the MS data in Fig. 3, we could conclude that our samples are enriched with SS protein having a high MASCOT score and many identified peptide sequences. Moreover, we detected fibroin-heavy chains in our samples in addition to the SS. However, when we compare their MASCOT scores in Table 2, we can notice a crucial difference, reaffirming that we have identified a significant portion of a SS protein's primary structure.

Silk sericin	14432
Fibroin heavy chain 1	1660
Fibroin heavy chain 2	1328

Table 2. MASCOT scores of SS and fibroin heavy chains.

Mass spectrometry data on urea samples will be provided in the nearest future due to technical problems we had with a mass spectrometer machine.

C. Fourier transform infrared (FTIR) and circular dichroism (CD) spectroscopy

In Fig. 4A, the IR spectrum is given. Absorption (blue line) and second derivative (green line) FTIR spectrum of SS powder was measured in attenuated total reflection (ATR). In particular, a small amount of the material was put directly in contact with the diamond ATR element and the spectrum was collected by a Varian 670-IR spectrometer [13]. The assignment of the main peaks is reported (Fig. 4A), which is in line with those reported in other IR analyses for SS [12].
The SS powder was resuspended in water and loaded in a custom-made sample cell. CD measurements were performed with the sample-cell close to the detector.
After averaging the spectra collected at different angles, the final spectrum was provided to avoid scattering and linear dichroism artefacts (Fig. 4B).
The hypothesis is that the envisioned extraction is suitable for an exhaustive study of SS.

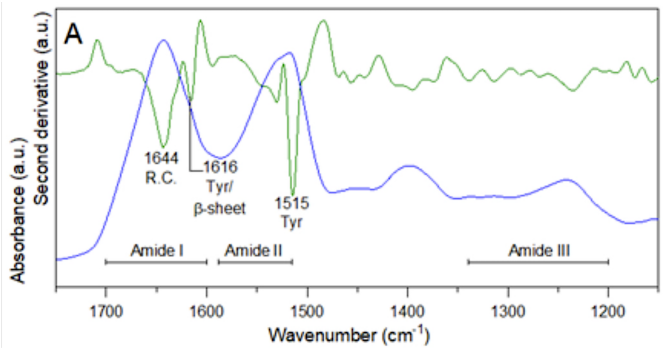

Fig. 4A. FTIR analyses on SS powder.

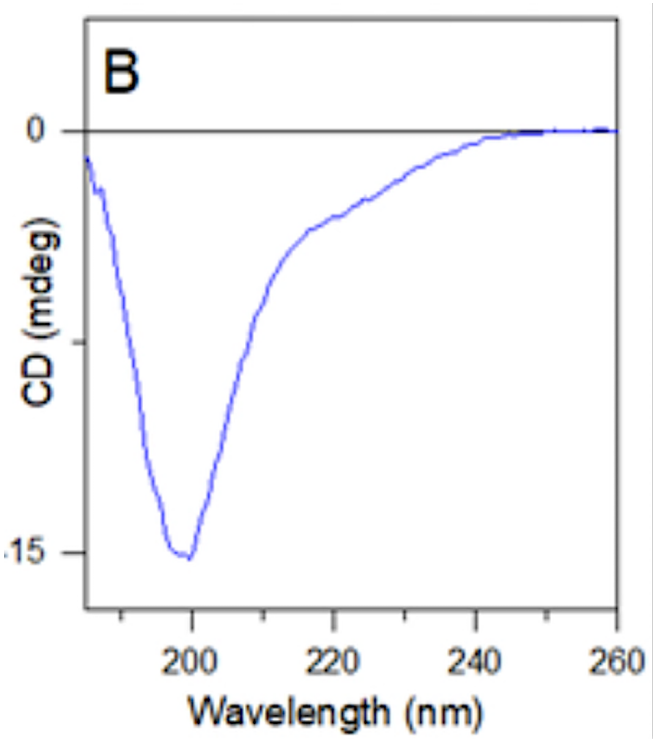

Fig. 4B. CD analyses on SS powder.

CONCLUSION

In the present study, the observed discrete clear bands and smear pattern in electrophoresis analysis (with each extraction procedure) demonstrated the breakage of SS into different-length peptides, which are of wide-ranging molecular weights.

The urea extraction method appears to be the most efficient way to obtain distinguishable bands with a broad range of molecular masses. This indicates that sericin degradation is less affected by the urea-based extraction method, allowing for sericin recovery with more precise molecular weights. However, this approach is time-consuming and expensive, and sericin extracted using urea is extremely hazardous to cells [8].

Given these drawbacks, heat-under-pressure is the most often utilized sericin extraction method. Sericin undergoes some deterioration with this procedure as well, particularly when high temperatures are utilized, or the solutions are administered for an extended period of time [14], but sericin still keeps its outstanding properties. However, the number of bands from the heat-under-pressure methods was less than those from SS extracted with urea, showing a lower range of molecular masses. Despite that, present findings propose using autoclave cocoon degumming on an industrial scale since the process is cost-effective and chemical-free, leaving no hazardous effect.

From the MS data regarding the autoclaving method samples, we could identify a high number of peptide sequences, which allowed us to recognize long sequences of the primary

structure of the entire protein. Moreover, SS FTIR results suggest that the chemical aspect of sericin was preserved during heat-under-pressure methods.

However, after obtaining MS data regarding urea samples, we would be able to proceed with a final comparison.

ACKNOWLEDGEMENT

This work was supported by SME (Leonardino Srl, www.leonardino.eu), which has the experience and full facilities in the degumming processes and electrospinning in Milan, Italy and CREA, in particular the moriculture and sericulture laboratory of the Agriculture and Environment Centre which is located in the Venetian Region, Padua, Italy.

***Abstract*— Electrochemotherapy (ECT) is a clinically used and effective treatment in the care of melanoma, and recently it was suggested as a promising tool for the treatment of other deep-seated solid tumors (*e.g.*, liver tumors).**

In general, ECT efficacy is evaluated *in vitro* on cell suspensions or in adhesion, and *in vivo* on animal models. Nevertheless, the first two mentioned approaches completely lack extracellular matrix (ECM) components, leading to unreliable results because they do not reflect the natural tissue architecture. To overcome this issue, several three-dimensional (3D) *in vitro* models, such as spheroids and hydrogel-based cultures, have been proposed to mimic the complex tumor microenvironment. In this frame, a new synthetic scaffold based on hyaluronic acid (HA) and self-assembling peptides (EAbuK) is proposed as an advantageous alternative.

HA-EAbuK scaffolds promote spheroids formation where cells experiment cell-cell interactions, but also improve cell-ECM interactions. Liver cancer (HepG2) cell lines were cultured on HA and HA-EAbuK scaffolds and preliminary bioassays were carried out to assess cell viability and spheroids formation. Then, cells were electroporated at different electric field amplitudes. 3D cultures on HA scaffolds and cells in adhesion (2D cultures), electroporated using culture medium or phosphate-based EP buffer, were taken as controls.

Our data showed that HepG2 cells cultured on HA-EAbuK scaffolds were already completely electroporated at 800 V/cm, whereas cells cultured on HA started to be electroporated at 1200 V/cm. In 2D cultures, HEPG2 cells were electroporated at 1000 V/cm and 1200 V/cm in EP buffer and in culture medium, respectively. Collectively, our preliminary results suggest that HepG2 cell cultures on HA-EAbuK hydrogels may represent a promising tool for *in vitro* evaluation of EP efficiency.

***Keywords*—Electroporation, hyaluronic acid, self-assembling peptide, liver tumor model**

I. Introduction

ELECTROCHEMOTHERAPY is a well-assessed therapy used for some skin-related tumors like melanoma or breast cancer recurrences after mastectomy [1]-[4]. In recent years it was evaluated in the treatment of some other types of tumors, such as liver, head and neck, colon carcinomas, and soft tissue sarcomas [5-6]. The electroporation (EP) efficiency of the cell membrane depends on cell size and density as well as on the conductivity and composition of the medium where cells are suspended during the EP. It is well known that in the tissue the cells experience cell-cell connection and are surrounded by the extra-cellular matrix (ECM) that is a component of the tumor microenvironment. Thus, several three-dimensional (3D) *in vitro* models have been used in EP experiments: the cell-cell interactions have been simulated using spheroids, whereas the cell-ECM interactions have been considered in cultures grown in hydrogels [7].

Herein, low molecular weight hyaluronic acid (HA) porous scaffolds were enriched with an ionic-complementary self-assembling peptide named EAbuK [9]-[12]. In aqueous solution, EAbuK forms β-sheet planes that pile up each other generating hydrogels [12]. Liver cancer (HepG2) cells were cultured on the above-mentioned scaffolds and were characterized by cell viability assessment and hematoxylin/eosin.

Eventually, cell cultures were electroporated varying the electric field amplitude in order to find the optimal EP condition. The use of these HA-EAbuK scaffolds can be considered as an optimization of *in vitro* EP tests, which would hopefully cause a drastic reduction in the need for animal tests, giving rise to a significant cut of the costs and time of pre-clinical studies, not to mention the great ethical impact of reducing the death of animals involved in cancer research.

II. Materials and Methods

A. Matrix preparation

The main stages of preparation of the matrices were: (i) Solid-phase peptide synthesis of self-assembling peptide EAbuK, followed by peptide purification by reverse phase high performance liquid chromatography (RP-HPLC), and characterization by MALDI-TOF mass spectrometry [9]; (ii) preparation of the hyaluronic acid:self-assembling peptide solution (95:5 % w/w) in H_2O Milli-Q (0.8% w/v of HA); (iii) freezing at -178 °C and freeze-drying; (iv) crosslinking with 60 mM EDC in 95% EtOH for 24 hours; (v) eventually matrices were washed 6 times with EtOH and 6 times with Milli-Q water, all washes were carried out sonicating for 2 min and without sonicating for an additional 1 min; (vi) freezing at -178 °C and freeze-drying [10].

B. Cell culture

The HepG2 cells were grown with DMEM containing 10% fetal bovine serum, 1% L-glutamine, and 1% antibiotic/antimycotic solution (Sigma-Aldrich) at 37°C in a humified atmosphere with 5% CO_2. Cells (1.8×10^5) were seeded on scaffolds previously put in different wells of a 24-well cell suspension culture plate. Cultures were daily observed with a phase contrast microscope (Nikon T-s). At 3 and 7 days from seeding, cell viability was assessed by using the PrestoBlue™ Cell Viability Reagent (Thermo Fisher

Scientific) according to the manufacturer's instruction, and culture morphology by hematoxylin/eosin staining.

C. *Electroporation of cell suspension – EP curve*

A suspension of 2.5×10^6 cells/mL (HepG2) was prepared. This HepG2 suspension was inserted in a chamber slide multi-well (245µL/well) and an EP sequence of 8 voltage pulses 100 µs long at 5 kHz, different amplitude, was applied. Eventually, cells were seeded in a 96-well plate to evaluate viability at 24 h after EP through Presto Blue assay. The experiments were repeated both in cell medium and in EP buffer (EPB,10 mM K_2HPO_4/KH_2PO_4, 1 mM $MgCl_2$, and 250 mM sucrose, pH 7.4) [13]-[15].

Cell suspension was put in a second chamber slide (245µL/well), and Propidium Iodide (PI) (15µL from 1mg/mL, Sigma Aldrich) was added, then EP sequence was applied and the PI fluorescence was recorded using a Victor plate reader (excitation 555 nm, emission 610 nm). The procedure was repeated for different voltage amplitudes.

D. *3D culture Electroporation procedure*

After 24h or 3 days of cell culture within the HA-EAbuK matrix, the culture medium was added with PI water solution (15µL from 1mg/mL, Sigma Aldrich). PI was added to mark EP cells since it penetrates the cell membrane when electroporated. EP sequence (8 voltage pulses 100 µs long at 5 kHz) at different voltage amplitude was applied to each sample. Then, Hoechst 33342 (5µL from 1mg/mL solution, Thermo Fisher Scientific) was added to mark all cell nuclei.

Image acquisition was assessed using a Fluorescence microscope (LEICA DMI4000) (Bright field, Hoechst 33342: exciting 360 nm, emission 470 nm, and PI: exciting 515-540 nm, emission 590 nm). Image analysis was performed using ImageJ software.

III. Results

A. *Cell viability*

At 3 days from the seeding, no significant differences in cell viability were detected between cultures grown in HA/EAbuK matrices and tissue culture-grade plastic (TCP), whereas at 5 days MFI was significantly lower in all HA-based cultures vs TCP (Fig. 1).

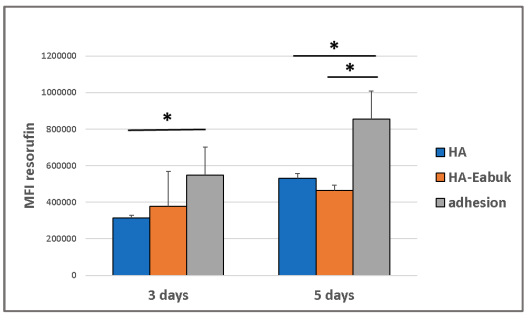

Fig. 1: Cell cultures on HA-based hydrogels. Cell viability at 3 and 5 days from seeding. MFI: mean fluorescence intensity. The control "adhesion" represents cells seeded on TCP. * p < 0.05, Student's t-test.

HepG2 cells organized themselves to form clusters inside both hydrogels and, at various degrees, spheroids were visible on their surface (Fig. 2)

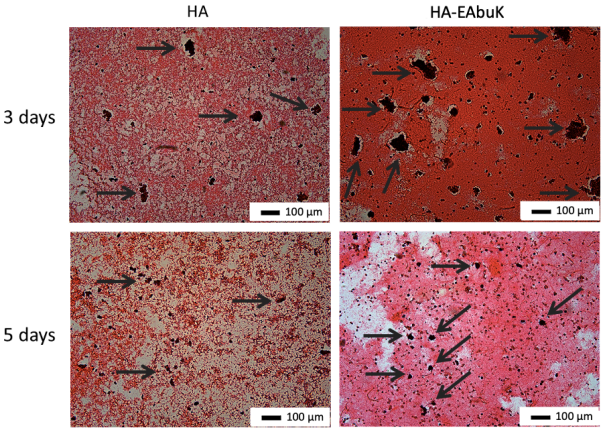

Fig. 2: Hematoxylin/eosin staining of cell cultures on HA-based Hydrogels. Arrows indicate the spheroids (scale bar=100 µm).

B. *Electroporation*

EP was carried out on cells in suspension, and cultures grown on TCP and HA-based hydrogels by applying increasing electric fields. Cell membrane permeabilization and cell viability were verified through PI staining immediately after EP and at 24 h from the treatment, respectively (fig. 3-4). In cell suspensions, PI uptake significantly increased starting from 1000 V/cm. Moreover, at 1200 V/cm it was higher in cultures where EP was carried out by using culture medium than that detected with EP buffer (Fig. 3).

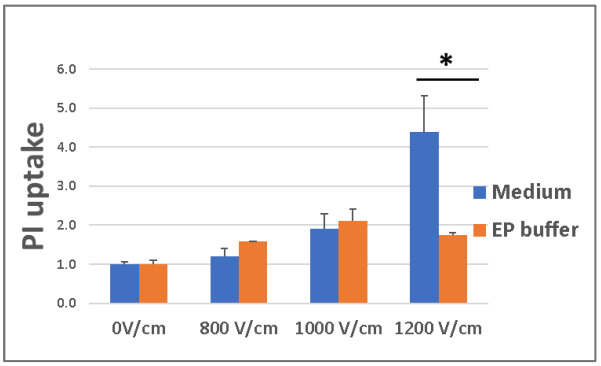

Fig. 3: Effects of EP on cell suspension. PI uptake immediately after EP. *=p<0.05, Student's t-test.

Significant decreases in cell viability were found only with culture medium at 1000 and 1200 V/cm (Fig. 4).

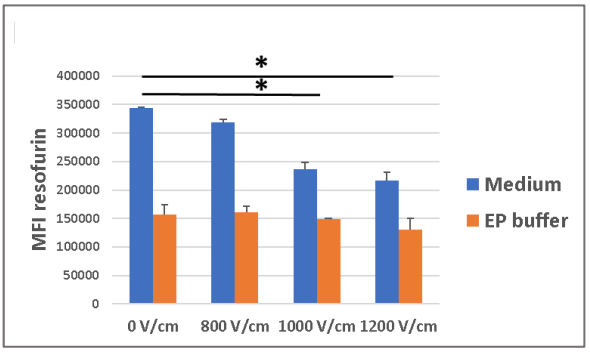

Fig. 4: Effects of EP on cell suspension. Cell viability at 24 h from EP. *=p<0.05, Student's t-test.

In HepG2 cultures grown on TCP, PI uptake was well visible starting from 1000 V/cm (Fig. 5). However, cell permeabilization was higher in cultures where EP was carried out by using EP buffer rather than culture medium.

No variations in cell viability were detected at all electric fields in medium cell suspension.

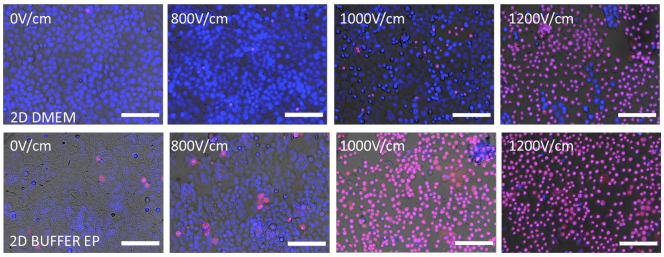

Fig. 5: Effects of EP on adherent cell cultures. Representative micrographs of cultures stained with PI (red) and Hoechst (blue) immediately after EP (bars: 100 µm).

HepG2 cultures on HA-based hydrogels appeared more sensitive to EP than those in suspension and adhesion (Fig. 6). Indeed, PI uptake was detected starting from 800 V/cm.

Moreover, cell permeabilization was higher in HA-EAbuK cultures than in HA ones.

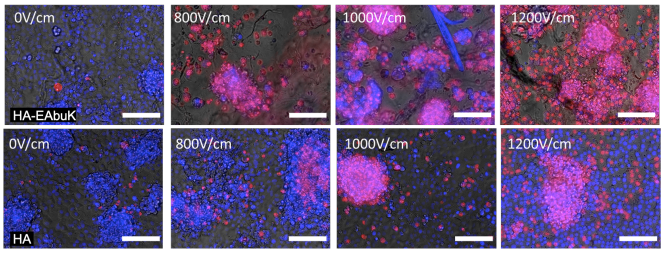

Fig. 6: Effects of EP on cultures grown on HA-based hydrogels. Representative micrographs of cultures stained with PI (red) and Hoechst (blue) immediately after EP (bars: 100 µm).

On the other hand, in HA and HA-EAbuK cultures cell viability significantly decreased starting from 800 V/cm and 1000 V/cm, respectively (Fig. 7).

Moreover, at all electric fields, MFI values were significantly lower in HA cultures than those detected in HA-EAbuK ones.

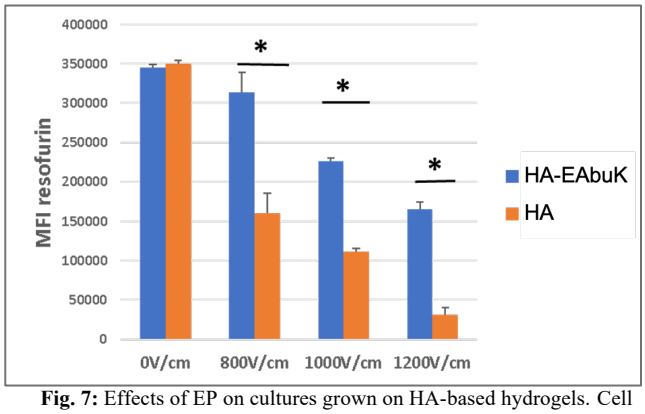

Fig. 7: Effects of EP on cultures grown on HA-based hydrogels. Cell viability at 24 h from EP, *=p<0.05, Student's t-test.

IV. Conclusion

HA-based hydrogels are widely used to obtain 3D cell cultures useful for anti-cancer studies, since HA, a major component of the extracellular matrix, allows migration, proliferation, and invasiveness of malignant cells [16]. In particular, hepatocytes, the main cell type of the liver, need extracellular matrix to maintain their morphology and biological functions. So far, several HA-based *in vitro* matrices have been developed to provide a cell friendly microenvironment and, ultimately, valuable liver models for drug screening and disease study [17]-[19]. Nevertheless, their application for EP studies has not been deeply investigated.

Herein, the effects of EP on HA-EAbuK-based hepatocyte cultures were evaluated, starting from our previous study [20] where HA-based hydrogels allowed ECM production by breast cancer cells.

Our data showed that HepG2 cells cultured on HA-EAbuK scaffolds were already completely electroporated at 800 V/cm, whereas cells cultured on HA started to be electroporated at 1200 V/cm. In 2D cultures, HEPG2 cells were electroporated at 1000 V/cm and 1200 V/cm in EP buffer and in culture medium, respectively. Collectively, our preliminary results suggest that HepG2 cell cultures on HA-EAbuK hydrogels may represent a promising tool for *in vitro* evaluation of EP efficiency. Further experiments will be performed to verify whether HepG2 cells could produce ECM molecules.

***Abstract*—Modelling hydrogel mechanical behaviour is fundamental for supporting the design of physiologically relevant scaffolds capable of guiding and maintaining cell phenotype and behaviour. In the literature, several approaches to describe the mechanics of soft structures has been proposed; however, they exploit complex algorithms with high computational times or do not include any experimental validation. Here, we propose a multiscale computational model based on the coupling of molecular diffusion and material mechanics. The model describes the viscoelastic properties of a hydrogel as a function of the liquid phase composition. Specifically, we combine mass transport equations and mesh size to describe the time dependent mechanical behaviour of agarose hydrogels. The simulations are coherent with the experimental characterisation of the hydrogels, confirming the predictive power of the model and its versatility. Further studies will be implemented to adapt the model to different materials and to couple material properties with cell mechanotransduction. This multiscale computational tool will be essential for targeted material design for regenerative medicine application and for the definition of advanced in-vitro models.**

***Keywords* — in silico models, viscoelastic properties, engineered hydrogels, agarose.**

I. Introduction

Predicting hydrogel mechanical behaviour is essential for defining precise mechanical stimuli to control and guide cell behaviour [1]. Hydrogel viscoelastic behaviour is strongly related to the interaction of liquid molecules with the solid network. Although different mathematical models have been proposed to simulate chemical and transport phenomena in gels (e.g. reaction, diffusion, and hindered convection), most of them lack the correlation with gel viscoelastic properties (e.g., relaxation time, τ_{rel}) or do not provide experimental validation [2], [3].

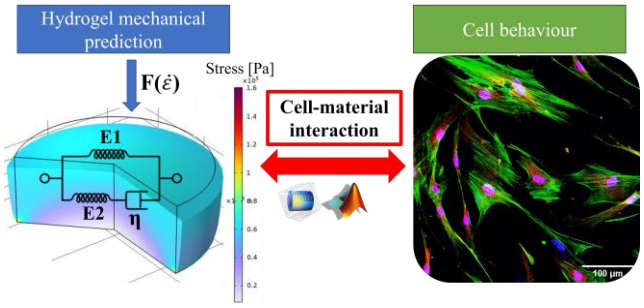

Fig. 1. Graphical description of the work ultimate goal.

For these reasons, we propose a versatile computational model to predict the viscoelastic behaviour of agarose hydrogels in the presence of tunable liquid phases. As reported in the literature, modulating the hydrogel liquid phase without altering the elastic network affects hydrogel mechanical behaviour. We investigated how the viscoelastic properties of agarose are affected by the presence of soluble polysaccharides in the liquid phase. In particular, we studied: dextran which is known to react mainly with water molecules thus augmenting the gel's liquid-like behaviour [4] and hyaluronic acid, which also binds to polymeric network, affecting both elastic and the viscous properties [5].

To correlate the hydrogel diffusive and mechanical properties, we considered the average gel mesh size ξ_{avg}, a fundamental structural parameter for the description of hydrogel architectures, which is related with the maximum size of molecules that can move through the polymeric network. This parameter is shown to be fundamental for the prediction of soft materials mechanical properties [6].

II. Materials and Methods

A. Modelling agarose hydrogel mechanics

Agarose hydrogels were modelled as a homogeneous porous system, while the viscous phase (i.e., dextran or hyaluronic acid (HA)) was considered as a spherical agglomerate linked to the water molecules. In the case of dextran, the hypothesis was that it can only bind water molecules in the liquid phase [4], while hyaluronic acid molecules can bind both water molecules and agarose fibres [5]. Therefore, the lumped parameter schematization considered for describing the mechanical behaviour of the agarose hydrogel in the presence of dextran was the Maxwell Standard Linear Solid model (SLS) (fig. 2A), while in presence of hyaluronic acid, the SLS model was adapted including a spring E_1 in parallel to E_0 (fig. 2B) to represent the hyaluronic acid effect on the elastic properties. In both the configurations, a dashpot η_2 in parallel with η_1 was included to represent the effect of dextran/hyaluronic acid on the viscous properties.

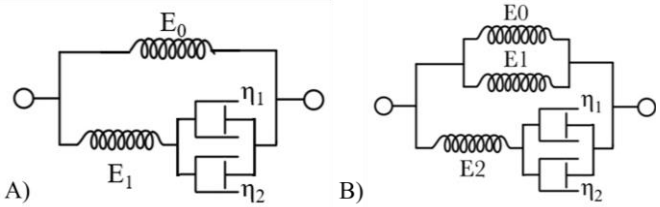

Fig. 2. A) SLS lumped parameter schematization in Maxwell configuration considered for the agarose-dextran hydrogel, and B) adapted SLS model in case of hyaluronic acid – agarose hydrogels.

The model, implemented on Matlab R2022a, consisted in solving the reaction-diffusion equation (eq. 1) that regulates the movement of the hydrogel liquid phase during a uniaxial compression test to derive the values of the lumped parameters, and thus the values of the viscoelastic descriptors,

i.e., the instantaneous (E_{inst}) and equilibrium (E_{eq}) elastic modulus, and the characteristic relaxation time (τ) (tab. I). E_{inst} refers to the initial elastic response, which is given by the sum of all the springs in the lumped model since the viscous components are shorted out and do not deform while sustaining the load. E_{eq} refers instead to the static response after the viscoelastic dynamics have occurred, as the viscous components are on open circuit, so they cannot sustain any load or stress. A lower relaxation time τ denotes a more viscous-like behaviour, i.e., when $\tau \to 0$ the material is ideally viscous and vice versa when $\tau \to \infty$ we have an ideally elastic material [1].

$$\frac{\partial c}{\partial t} = D_{app} \cdot \nabla^2 c - c \cdot \nabla v - v \cdot \nabla c - k_r c_{vm} \qquad (1)$$

TABLE I: LUMPED PARAMETERS COMBINATION FOR OBTAINING THE VISCOELASTIC DESCRIPTORS.

	Dextran - agarose hydrogel (Fig.3A)	*Hyaluronic acid - agarose hydrogel (Fig.3B)*
Equilibrium Elastic Modulus (E_{eq})	E0	E0+E1
Instantaneous Elastic Modulus (E_{inst})	E0+E1	E0+E1+E2
Characteristic Relaxation Time (τ)	η_1/E1	(η1+ η2)/E2

An apparent liquid phase diffusion coefficient D_{app} (eq. 2) was introduced using Brinkmann's theory of hindered diffusion in porous media, which adapts the Einstein-Stokes diffusion coefficient D_0 (eq. 3) through the coefficient β (eq. 4) that considers the obstacle imposed by the porous matrix using the permeability κ of the molecules. The latter was estimated through the Carman-Kozeny equation [3].
The coefficient δ (eq. 5) introduced the correlation between the diffusive and the mechanical properties of the agarose hydrogel, by considering the average mesh size (ξ_{avg}), i.e., the most important descriptor of the hydrogel porous structure defined as the distance between two adjacent cross-links (fig. 3). More specifically, Flory's theory of rubber elasticity and the Amsden obstructing-scaling model [6] were implemented to correlate ξ_{avg}, D_{app}, and the elastic modulus ($E(t)$) (eq. 5 - 6).

$$D_{app} = \beta \cdot \delta \cdot D_0 \qquad (2)$$

$$D_0 = \frac{k_b T}{6\pi\eta R_H} \qquad (3)$$

$$\beta = \left\{1 + \left(\frac{{R_H}^2}{\kappa}\right)^{\frac{1}{2}} + \frac{1}{3}\left(\frac{{R_H}^2}{\kappa}\right)\right\}^{-1} \qquad (4)$$

$$\delta = e^{-\frac{\pi}{4}\left(\frac{R_f + R_h}{R_f + 0.5\cdot\xi_{avg}(t)}\right)^2} \qquad (5)$$

$$\xi_{avg}(t) = \left(\frac{18 k_B T}{\pi E(t)}\right)^{\frac{1}{3}} \qquad (6)$$

The reaction between water and dextran or hyaluronic acid molecules was expressed using a first order equation as a function of the free polysaccharide concentration (c_{vm}); the binding rate k_r was estimated by a 0D Finite Element Model (FEM) implemented on Comsol Multiphysics 6, using the Chemical reaction module, and optimizing the simulation on the experimental viscosity data, acquired as described in section II.B.

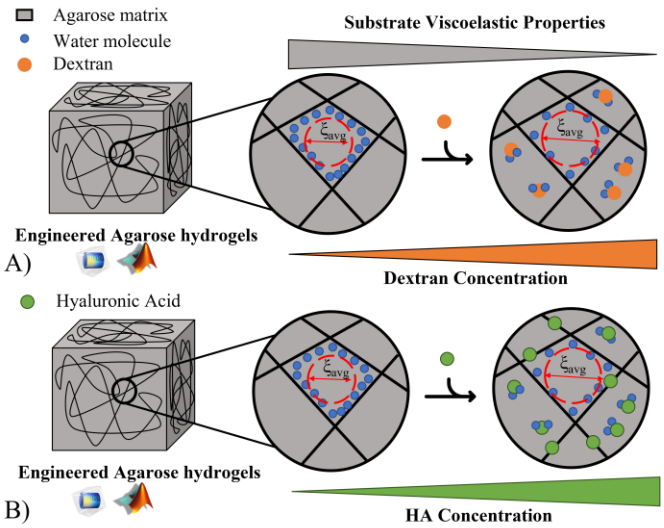

Fig. 3. Schematic picture representing the interaction of dextran (A) and hyaluronic acid (B) molecules with the polymer network and its effects on the hydrogel mesh size and therefore on its and diffusive and mechanical properties.

Finally, the hydrodynamic radius R_H of dextran and hyaluronic acid molecules (tab. II) was extrapolated from a 2D-axialsymmetric time-dependent FEM simulation of the molecule release from the agarose hydrogel, performed on Comsol Multiphysics 6. The physic module implemented was the Transport of Diluted species in porous media. The computational results were optimised on the experimental evaluation of Fluorescein isothiocyanate-Dextran-Conjugate (FITC-dextran, 500 kDa, Sigma-Aldrich, 1:100) and Fluorescein isothiocyanate-Hyaluronic acid-Conjugate (FITC-HA, 500 kDa, Sigma-Aldrich, 1:100) release from dextran/HA (50mg/mL) - agarose (5 mg/mL) hydrogels, after 1, 4 and 24 hours.

TABLE II: MODEL PARAMETERS

Parameter	*Symbol*	*Unit*	*Value*
Agarose hydrogel porosity	ε	-	0.57
Agarose fibre radius	R_f	m	$1.90\cdot10^{-9}$
Dextran diffusion coefficient (Stokes)	$D_{0\text{-}dex}$	m^2/s	$1.18\cdot10^{-12}$
Dextran hydrodynamic radius	Rh_{dex}	m	$2.20\cdot10^{-8}$
Hyaluronic acid diffusion coefficient (Stokes)	$D_{0\text{-}HA}$	m^2/s	$2.27\cdot10^{-12}$
Hyaluronic acid hydrodynamic radius	Rh_{HA}	m	$7.00\cdot10^{-8}$

B. Dextran/HA – agarose hydrogel fabrication and characterisation

Dextran and hyaluronic acid solutions were prepared dissolving the powders in different concentrations (tab. III) in deionised water on a magnetic stirrer. Agarose hydrogels were prepared by dissolving 5 mg/mL of agarose powder in the previous solutions on a magnetic stirrer, casted in a custom-made PDMS mold (cylindrical well dimensions: 13 mm diameter, 8 mm height) and crosslinked at 4°C for 30 minutes. The dynamic viscosity μ of the dextran/hyaluronic acid solutions was measured using a dynamic viscometer (DV-II+, Brookfield, Germany) as a function of the cooling

temperature; the LV1 spindle was chosen considering the range of viscosity values ($3 \cdot 10^0$ - $6 \cdot 10^5$ cP).

TABLE III: MATERIALS USED FOR HYDROGEL FABRICATION

Material	*Quantity [mg/mL]*
Agarose (A9539, Sigma Aldrich)	5
Dextran (D1037, Sigma Aldrich)	20, 30, 40
Hyaluronic acid (FH71634, Biosynth)	5, 7.5, 10

The hydrogel viscoelastic parameters were tested by means of the epsilon-dot method [7]. Briefly, unconfined bulk compression tests at different constant strain rates $\dot{\varepsilon}$ (0.0005, 0.001, 0.005, 0.01 s^{-1}) were performed using the Zwick/Roell ProLine Z005 uniaxial testing device (Germany). Each sample was tested partially submerged in the respective aqueous phases, to maintain the hydration. The time-force curves were collected and globally fitted to the Maxwell Standard Linear Solid model (SLS) (eq. 7, fig. 2A) in case of dextran and to the adapted SLS model (aSLS) (eq. 8, fig. 2B) in case of hyaluronic acid, to obtain the values of the lumped parameters, and thus E_{inst}, E_{eq} and τ.

$$\sigma_{SLS}(t) = \dot{\varepsilon}\left[E_0 \mathrm{t} + (\eta_1 + \eta_2)\left(1 - e^{-\frac{E_1}{\eta_1+\eta_2}t}\right)\right] \quad (7)$$

$$\sigma_{aSLS}(t) = \dot{\varepsilon}\left[(E_0 + E_1)\mathrm{t} + (\eta_1 + \eta_2)\left(1 - e^{-\frac{E_1}{\eta_1+\eta_2}t}\right)\right] \quad (8)$$

Moreover, the apparent elastic modulus (E_{app}) was estimated from the slope of the stress-strain curves in the linear viscoelastic region. 1-way ANOVA and t-tests were performed using OriginPro to determine respectively the significance of the results ($\alpha = 0.05$) and the fitting of the curve ($R^2 = 0.98$).

C. Numerical solving method and model validation

The reaction-diffusion equation was solved using Matlab 2022a by implementing discretization through the method of lines (MoL). Transport equations are commonly solved using MoL [8]. Briefly, the spatial domain was discretised and thus the partial differential equations (PDEs) were replaced with a vector system of ordinary differential equations (ODEs) and the solved using Matlab's ODE45. The conditions are reported in tab. IV.

TABLE IV: BOUNDARY CONDITIONS FOR SOLVING THE REACTION-DIFFUSION EQUATIONS ON MATLAB WITH MOL.

Parameter	*Symbol*	*Unit*	*Value*
Initial position	xi	m	0
Final position	xf	m	$1 \cdot 10^{-3}$
Geometric step	dx	m	$1 \cdot 10^{-5}$
Temporal step	dt	s	$1 \cdot 10^{-2}$
Upper concentration boundary	cU	mol/m^3	0
Lower concentration boundary	cL	mol/m^3	$C0_{dex} - C0_{HA}$

The mechanical compression test was simulated on Simulink (Matlab 2022a) proving a graphical tool for the prediction of the stress-time curves for both dextran (fig. 4a) and hyaluronic acid – agarose hydrogels (fig. 4b). The simulation results were compared to the experimental ones to optimise and validate the computational model, following the least squares method.

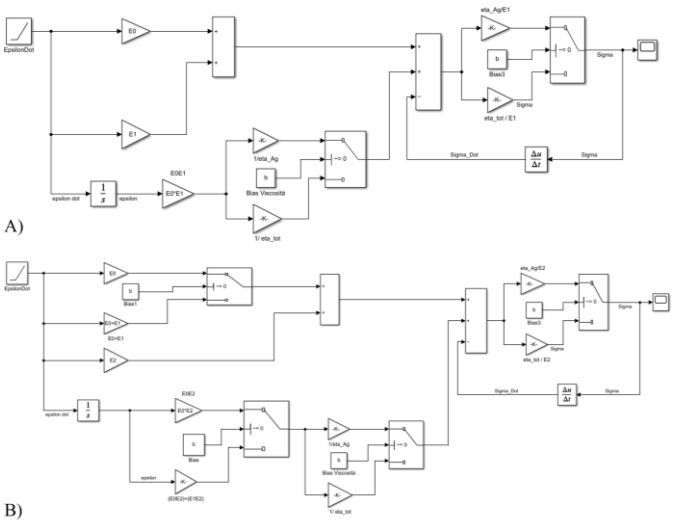

Fig. 4. Block diagram architecture of SLS (A) and adapted SLS Maxwell model (B) for simulating the mechanical behaviour, respectively, of dextran and HA-agarose hydrogel during a compression test according to the epsilon dot method.

III. RESULTS AND DISCUSSION

The simulation of dextran diffusion and the parameter optimisation on experimental results provided a hydrodynamic radius of $2.2 \cdot 10^{-8}$ m for dextran (fig. 5D) and of $7.0 \cdot 10^{-8}$ m for hyaluronic acid in water.

The liquid phase diffusion time (fig. 5A) predicted by the computational model showed that resistance to flow decreases as dextran concentration increases. This trend was also confirmed by the relaxation time. Moreover, the comparison with experimental data confirmed the capability of the model to predict the mechanical behaviour of agarose hydrogel in the presence of different molecule concentrations in the liquid phase (fig. 5B). It is reasonable to associate this behaviour to the modulation of the mesh size. Indeed, the dextran concentration increase results in a reduction of the amount of water molecules linked to the polymer, as demonstrated by the mesh size increase (fig. 5C), which promotes the liquid phase flow through hydrogel pores. In particular, the more the relaxation time decreases, the more the flow resistance decreases as the mesh size increases.

The mechanical characterization confirmed the capability of dextran to modulate the viscous properties of agarose hydrogels [4]. Indeed, as the dextran concentration increased, the instantaneous elastic modulus and the characteristic relaxation time decreased, as predicted by the computational model (fig. 6). Despite the increase in dextran concentration and hence liquid phase viscosity, τ_{rel} decrease (i.e., shifting toward a more liquid-like behaviour) is related to the reduction of liquid phase diffusion time and to the mesh size increase.

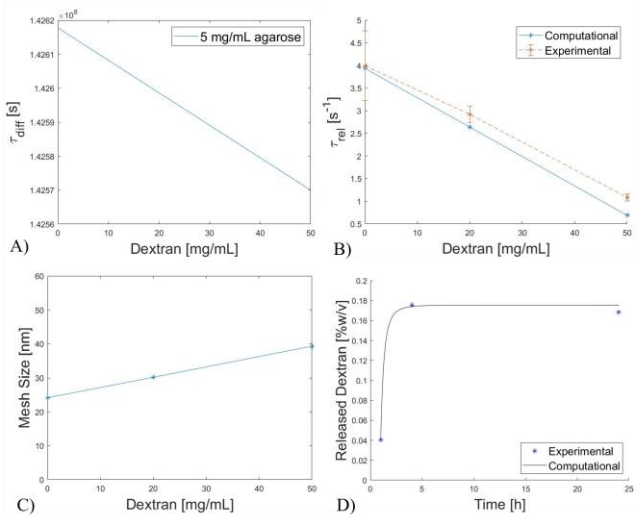

Fig. 5. A) Liquid phase diffusion time, B) relaxation time (p value > 0.05) and C) average mesh size of dextran-agarose hydrogel as a function of the dextran concentration. D) Dextran release profile compared to the experimental measures, in case of 50 mg/mL dextran - 5 mg/mL agarose hydrogels.

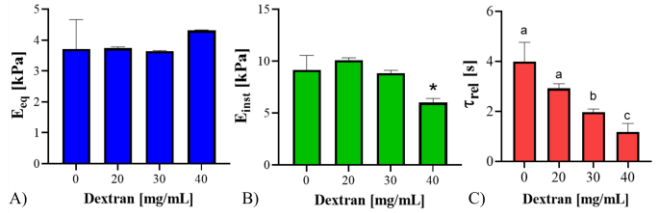

Fig. 6. A) Equilibrium (E_{eq}) and B) instantaneous (E_{inst}) elastic moduli and C) characteristic relaxation time (τ) as a function of different dextran concentrations for 5 mg/mL agarose hydrogels. Different letters indicate statistical significance (*= $p < 0.05$).

Mechanical analyses are ongoing to validate the model in the case of hyaluronic acid. However, preliminary tests on the apparent elastic modulus (E_{app}), suggested that the predicted values are comparable with the experimental ones. Moreover, the E_{app} increase with increasing HA concentration is coherent with previous results reported in the literature [5] (fig. 7).

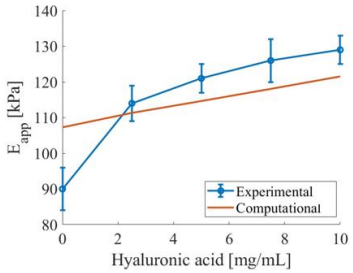

Fig. 7. Comparison between computational and experimental [5] trend of apparent elastic modulus of HA-agarose hydrogels as a function of HA concentration.

IV. Conclusion

The computational framework presented in this work resulted effective in predicting gel transport properties (mesh size and liquid phase diffusion time) and their effect on the resulting viscoelastic features. Indeed, the model can describe the interaction of molecules in the liquid phase with the solid network, and it can be used to predict bulk viscoelastic behaviour of hydrogels.

The model was validated on agarose gels with dextran in the liquid phases, showing its influence in weakening the bonds between water and agarose, with a consequent decrease of the steric hindrance and a faster flow. Therefore, although liquid phase viscosity increases with increasing dextran concentration, it contributes to reduce the resistance to flow preventing the formation of water-agarose bonds [4].

Preliminary simulations also suggested that the model can be used with different viscoelastic modulators, such as hyaluronic acid, which is a physiological component of extracellular matrix, thus its use will improve the physiological relevance of the hydrogels [5]. In this case, the model was adapted to consider its effect on both the elastic and viscous component. Comparison between experimental and computational data are ongoing to confirm the preliminary results; computational simulations on the Simulink workflow will be performed to determine the stress-time curves of agarose hydrogels for their mechanical characterization.

In the future, the model will be adapted to other material combinations by coupling it with in silico models well established in the literature for describing the effect of the crosslinking process. Moreover, it will be coupled with in silico descriptions of cell behaviour in response to the mechanical stimuli, e.g., the molecular clutch model [1], to provide a useful tool for the design of hydrogels with well-defined mechanical properties that mimic the physiological/pathological extracellular matrix. In conclusion, the presented computational framework will be essential for regenerative medicine applications and for the definition of advanced in-vitro models.

***Abstract*—Humans are continuously exposed to a wide variety of chemicals. Animal and bi-dimensional (2D) *in vitro* models currently represent the gold standard for chemical toxicity assessment, although they do not adequately reproduce the real human scenario, thus resulting in poorly predictive results. Conversely, three-dimensional (3D) bioengineered *in vitro* models hold the potential to closely represent the human physio-pathological milieu, enabling a more reliable evaluation of chemical toxicity. Among human tissues/organs, the myocardium is a target organ for chemical- and drug-induced toxicity. In this work, a custom-made poly(ester urethane) was synthesized and used as raw material to fabricate a platform of multi-layered structures with different geometrical features through melt extrusion additive manufacturing. The designed matrices were also surface functionalized with proteins to improve their biomimesis of the native cardiac extracellular matrix. The physico-chemical properties of the constructs proved their suitability for the development of *in vitro* bioengineered cardiac tissue models, enabling the investigation of physio-pathological processes and cardiotoxicity testing.**

***Keywords*—poly(urethane)s, *in vitro* cardiac tissue models, additive manufacturing, surface functionalization.**

I. INTRODUCTION

Drug development, chemical toxicity assessment, and disease modeling heavily rely on the use of animal models and two-dimensional *in vitro* models [1]. However, these models exhibit several drawbacks that make their outcomes poorly predictive of the real human scenario. Two-dimensional models are extremely simple and do not allow to replicate the complexity of human tissue structure [2]. Conversely, animal models present high management costs and ethical issues. Furthermore, due to interspecies differences, animal models are unlikely to faithfully replicate the human physio-pathological behavior. The concordance between toxicity levels evaluated in humans and laboratory animals is around 71% when both rodent (mice and rats) and non-rodent (dogs and monkeys) models are used. This concordance is reduced to 43% using only rodents as animal models [3].

The consequences of these issues are diverse and heterogeneous. The selection effectiveness of preclinical trials is reduced: only 11.8% of drugs entering clinical trials reaches approval. In addition, there are considerable cases of approved drugs showing undesirable toxic effects. For instance, during the last decade eight non-cardiovascular drugs have been reported to induce ventricular arrhythmia and sudden death, and thus they have been withdrawn from the market [4]. Furthermore, the proper and reliable assessment of the toxicity of chemicals and chemical mixtures is another key target to achieve, with important health, social and economic repercussions. Until 2008, only 5,000 chemicals out of 100,000 present on the western market had been subjected to an approved analysis process due to the limitations of two-dimensional and animal models [3].

In this complex scenario, the development of reliable 3D bioengineered *in vitro* models is of central importance since they can be very useful tools for overcoming the limitations of previously adopted approaches [5] [6]. In particular, the design of reliable 3D *in vitro* models of the cardiac tissue in gaining increasing interest in the research community. On the PubMed database the number of publications related to "cardiac tissue models" is exponentially increasing over time, with around 4000 publications in 2022. This trend can be correlated to the very high social and economic impact of heart diseases, that are responsible for around 17.5 million deaths worldwide each year [7]. Secondly, the high complexity of the cardiac tissue and the very limited possibility of modelling it with two-dimensional or animal models clearly prove the urgent need for reliable 3D bioengineered *in vitro* models of the cardiac tissue in different physio-pathological conditions and at different degrees of ageing [8].

Based on these premises, in this work, an *ad-hoc* synthesized poly(ester urethane) (PU) was microfabricated into 3D porous constructs by melt extrusion additive manufacturing and superficially modified with vacuum plasma treatment followed by immobilization of an extracellular matrix (ECM) protein (e.g., fibronectin, laminin) using the carbodiimide chemistry. Complete physico-chemical characterization of the developed constructs was performed, demonstrating the suitability of the designed matrices for the establishment of bioengineered cardiac tissue models.

II. MATERIALS AND METHODS

The PU used in this work to fabricate the 3D structures was synthesized using poly(ε-caprolactone) diol (2000 Da) as macrodiol, 1,4-butanediisocyanate as diisocyanate and L-lysine ethyl ester as chain extender [9]. The synthesis was performed under inert atmosphere through a two-step procedure according to an already optimized protocol [9]. The physico-chemical properties of the synthesized material were studied using infrared (IR) spectroscopy, size exclusion chromatography (SEC), and tensile tests. Rheological (dynamic temperature ramp tests, frequency sweep tests) characterization, differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were also conducted to investigate the thermal and thermo-mechanical properties of the PU. A melt extrusion additive manufacturing (AM) system was employed to realize three-dimensional multi-layered structures with different patterns (e.g., square and rhomboid grid). A vacuum plasma treatment in the presence of acrylic acid vapor was then employed to superficially modify the

structures and expose carboxyl groups subsequently used to covalently decorate the surface of the scaffolds with ECM proteins (laminin, LN, fibronectin, FN) through the carbodiimide chemistry [13] [14]. Optical microscopy was employed to analyze the morphology of the structures. IR spectroscopy, X-ray photoelectron spectroscopy (XPS), contact angle measurements and colorimetric assays (e.g., toluidine blue assay, bicinchoninic acid assay) were used to characterize the surface chemistry of the scaffolds.

III. RESULTS

The synthesis procedure of the PU was successfully carried out. IR spectroscopy evidenced the appearance of the typical peaks of the newly formed urethane and urea bonds: at *ca.* 1630 cm^{-1} the stretching vibration of carbonyl groups, at 1535 cm^{-1} the concurrent C-N stretching and N-H bending vibrations, and at 3340 cm^{-1} N-H stretching vibration. SEC analyses revealed a number average molecular weight of around 70 kDa, with a polydispersity index of 1.4. The PU showed an elastic behavior (Young's Modulus around 10 MPa, strain at break of hundreds %) suitable for the engineering of *in vitro* models replicating the cardiac tissue. Rheological characterization coupled with DSC and TGA results demonstrated the suitability of the material for processing via melt extrusion additive manufacturing. Dynamic temperature ramp tests evidenced a transition from a rubbery towards a viscous behavior around 135 °C while DSC thermogram evidenced a complete melting of both soft and hard domains at *ca.* 140 °C. Frequency sweep tests evidenced a shear thinning behavior at these temperatures, which is useful for PU processing through melt extrusion AM. Furthermore, TGA highlighted that PU thermal degradation started at 230 °C, thus enabling polymer microfabrication within a wide range of temperature.

Multi-layered structures with different patterns were successfully fabricated (Fig. 1) with high resolution and good fidelity to the CAD models.

Fig. 1: Multi-layered structures with different patterns fabricated by melt extrusion additive manufacturing.

The scaffold fibers had a diameter of about 500 μm, Plasma surface modification and subsequent surface binding of LN or FN was validated with contact angle measurements (decrease in static contact angle from around 90° to 60°), spectroscopic analyses and colorimetric assays. The bicinchoninic acid assay confirmed the presence of a protein coating of 10-15 μg/scaffold. Tests with human induced pluripotent stem cell-derived cardiomyocytes are currently in progress. Preliminary data have showed good cell viability accompanied by cell adhesion to the polymeric structures.

IV. DISCUSSION

The search for adequate biomaterials and processing techniques is a fundamental step towards the development of three-dimensional cardiac models. Biomaterials not only perform a passive function of structural support for the cellular counterpart of the model, but directly influence cellular development with their chemical and mechanical properties [8]. Biomaterials can be of synthetic or natural origin. The main synthetic polymers studied in the cardiac tissue engineering field are poly(lactic acid), poly(glycolic acid), poly(lactic-co-glycolic acid) (PLGA), and poly(ε-caprolactone) (PCL). Particularly interesting polymers of natural origin are, for example, collagen, gelatin, fibronectin, alginate, fibrin, chitosan and hyaluronic acid [10]. Synthetic materials are cheap, easily processed and tunable in terms of mechanical and chemical properties, but they do not exhibit the biochemical features of the native ECM. Natural materials more faithfully reproduce the biochemical properties of the extracellular matrix, but they show high production costs, poor physico-chemical stability, inadequate mechanical properties, limited processability, and higher batch-to-batch variability. To integrate the characteristics and overcome the limits of both categories of materials, numerous bioartificial systems and functionalization procedures have been studied in the literature [11]. The manufacturing techniques of polymer scaffolds are numerous. The conventionally used techniques are difficult to control and do not allow to obtain structures with controlled properties. Examples of these techniques are induced phase separation, emulsion freeze-drying, particle leaching and solvent casting [10] [12]. In order to produce structures with more precise geometries, spinning and additive manufacturing techniques can be used. In particular, additive manufacturing allows the fabrication of complex three-dimensional structures with controlled geometry [7]. The main AM techniques are inkjet, laser and extrusion-assisted bioprinting and melt extrusion AM. These technologies present different advantages and disadvantages. Inkjet-based bioprinting allows to reach very high resolution (< 100 μm) and to combine different biomaterials. The main disadvantage is the low structural and mechanical stability of the constructs. Laser-assisted bioprinting is a nozzle-free technique enabling high cell viability. However, this system is very expensive and the size of the fabricated structures is small for clinical applications. Lastly, extrusion-assisted bioprinting is a versatile technology that could be used with a wide range of different biomaterials. It is also economic, but the resolution that can be achieved is quite low (> 100 μm) [7]. One of the

most important drawbacks of bioprinting relies in the limited mechanical properties of the printed structures, that should also exhibit proper features (e.g., gas/molecule exchange) allowing cell encapsulation within the filaments. Furthermore, the printing of large-size structures is very complicated [13].
The melt extrusion AM technique is based on the use of thermoplastic polymeric materials. These materials exhibit a wide variety of mechanical and chemical characteristics, which can be combined to control the characteristics of the printed structures. The printing process is extremely fast, economical and highly repeatable [14]. The main limitations are the impossibility of printing cells due to the high temperature and the thermoplastic nature of the printed materials, and low resolution. However, the thermoplastic polymeric structures could be used as support to realize large-size constructs and to overcome the stability deficiency of biomaterial inks and bioinks [15]. The cells can then be grown on the printed structures or inserted using bioinks placed inside the constructs [16] [15]. For instance, a elastomer composed of poly-[glycerol sebacate] and poly-[ε-caprolactone] was printed with melt extrusion AM technique to realize scaffolds for cardiac application. The scaffolds had Young's modulus very similar to native myocardium (≈1 MPa) and the size of the fibres was about 300 µm. *In vitro* tests with rat cardiomyocytes, H9c2, showed good cell viability after 72 h, while *in vivo* tests confirmed a positive impact of the scaffold on cardiac tissues [17]. In another study, a complex and large structure (62.4 mm × 62.4 mm × 21.3 mm) was realized using polyvinyl alcohol and a melt extrusion AM system. The structure was filled with a hydrogel containing rat cardiomyocytes, H9c2, and umbilical vein endothelial cells. The survival rate of the cells was about 90% after 14 d of cell culture.

Within this context and with the aim to further advance the current state of the art, in this work we designed 3D structures based on a custom-made PU as potential frameworks for 3D cardiac tissue model establishment. A polyurethane consisting of a thermoplastic polyester and an amino acid-derived chain extender was used to combine the processability characteristics of synthetic polymers with the bioactive features of natural materials. Furthermore, it presented suitable mechanical characteristics for the fabrication of porous constructs with Young's modulus matching the requirements for cardiac tissue engineering applications [10]. The melt extrusion AM technique was then used to fabricate PU-based porous structures, relying on its high reproducibility, simplicity and low costs. The fiber size was consistent with typical values of the melt extrusion AM technology. To improve the resolution of the fibers it is possible to modify the printing process parameters. Surface modification resulted in a functional protein coat for cellular tests. The study of the mechanical properties of the printed structures and tests with human induced pluripotent stem cell-derived cardiomyocytes are currently underway. The synthesized PU and the used AM process have manifested excellent characteristics for the realization of large sized cellularized constructs.

V. Conclusion

The customized polyurethane showed excellent mechanical characteristics, good processability through melt extrusion additive manufacturing technique and suitability for surface functionalization with proteins. The developed matrices could pave the way towards the design of *in vitro* bioengineered cardiac tissue replicas. Interestingly, the chemical and technological versatility of polyurethane biomaterials, additive manufacturing techniques and surface functionalization procedures could be exploited to finely tune the physico-chemical properties of the fabricated structs, enabling cardiac tissue modelling in different physio-pathological conditions and at different degrees of ageing. In the end, this would significantly advance our knowledge of the mechanisms underpinning ageing and pathology onset and progression, while providing reliable tools for cardiotoxicity testing.

***Abstract*—Freeform Reversible Embedding of Suspended Hydrogels (FRESH) printing technique is arising as a novel strategy to obtain a 3D channel network in 3D *in vitro* models, aiming to recapitulate human vascularization and tissues properties. In our work, we coupled a novel combination of Pluronic F127 (fugitive ink) and GelMA (supportive bath) to obtain and characterize vascularized hydrogel-based 3D models. By optimizing the FRESH printing of Pluronic into pre-crosslinked GelMA bath, we aimed to realize 3D *in vitro* models with an internal hollow channel which dimensions resulted comparable with human vasculature. Moreover, we obtained models whose physical, mechanical and biological features resembled properties of pathological breast cancer conditions.**

***Keywords*—FRESH printing, adipose tissue, vascularization, extracellular matrix.**

I. Introduction

HYDROGEL-BASED models recently gained attention to recapitulate *in vitro* physical, mechanical and biological properties of tissue extracellular matrix (ECM). Two-dimensional (2D) cell cultures were traditionally employed in drug discovery and validation process, and for investigating cell behaviour and tissue physiology. Anyway, 2D cell cultures cannot perfectly recapitulate *in vivo* conditions, exhibiting non physiological cell growth kinetics and attachment [1]. Hence, three-dimensional (3D) cell cultures arose as an ideal solution to better mimic cell-cell and cell-ECM interactions, offering cells a 3D space where they are able to adhere, grow, proliferate, and interact each other in a 3D microenvironment. Moreover, 3D-based models are under study to reproduce tumour microenvironment (TME) by mimicking hypoxic and nutrient deprivation conditions, which typically appear in cancer progression [1]. Pathological models claimed to better understand disease development and offered versatile platforms to test new drugs and treatments. 3D-based models are produced using hydrogels, bulk scaffolds, decellularized tissues, to realize an ideal 3D environment for cell cultures. Among all the possible biomaterials, natural hydrogels were largely investigated for 3D models, due to their high porosity, hydrated nature, excellent biocompatibility, biochemical and biophysical tunability [1].

Nevertheless, lack of vascularization in 3D models represents nowadays the main limitation in the obtainment of suitable constructs for tissues mimicking. Among all the applied strategies to overcome latter drawback, Freeform Reversible Embedding of Suspended Hydrogels (FRESH) printing technique is arising as a novel technique to directly print a vasculature network in a supportive bath [2]. For this purpose, the selected supportive material should exploit an ideal viscosity to allow nozzle movement and subsequent printing in the bath, ensuring the maintenance of the printed structure integrity at the same time. The supportive bath was traditionally realized in gelatin or Carbopol [2], both sacrificial materials which dissolved once the 3D structure has been printed into the hydrogel. Alternatively, a fugitive ink could be printed in a permanent supportive bath [3], as we performed in our work. Herein, we optimized a FRESH printing approach for the printing of a sacrificial material in a permanent supportive bath, aiming to obtain a hollow internal channel resembling human vasculature into the permanent hydrogel (i.e., scaffold). Indeed, FRESH approach has never been reported for 3D *in vitro* models vascularization, while a permanent supportive bath which exploited favourable rheological properties for FRESH printing and resembled human tissues features has never been described in literature. For this purpose, we selected Pluronic F127 as sacrificial material to print a channel network, while methacrylated gelatin (GelMA) acted as permanent bath mimicking adipose tissue (AT) properties. FRESH printing approach was optimized by investigating rheological properties of sacrificial ink and supportive bath, which was pre-crosslinked at different exposure times to increase its viscosity allowing accurate extrusion of Pluronic. Once the FRESH printing of the channel network was optimized, the 3D model was characterized in physical, mechanical and biological terms, by assessing preadipocytes growth, proliferation and differentiation into mature adipocytes in the model. Moreover, endothelial cells were perfused into the obtained channel network.

II. Materials and Methods

A. Supportive GelMA bath and Pluronic F127 fugitive ink

GelMA was synthetized by following a procedure described elsewhere [4]. Briefly, gelatin (Gel) type A was fully dissolved in Dulbecco's Phosphate Buffered Saline (DPBS) at 50 °C (10% w/V), and methacrylation was carried out by dropwise addition of methacrylic anhydride (MA). The polymeric mixture was then dialyzed and freeze-dried. Degree of methacrylation (DoF) was evaluated by H-NMR spectroscopy (Bruker ARX 400 Instrument). Obtained GelMA was employed as permanent supportive bath; hence, GelMA hydrogels were obtained by dissolution in DPBS (10% w/V), addition of 2-hydroxy-4'-(2-hydroxyethoxy)-2-methylpropiophenone, Irgacure 2959 (0.05% v/V), and subsequent pre-crosslinking with UV light (TissueStart UV light, $\lambda = 405$ nm) exposure for 60, 90, 120 and 150 s. Different exposure times were investigated to increase GelMA viscosity which should be comparable to the ink one. Pluronic F127 was

fully dissolved in distilled water at 4 °C (23% w//V), and fugitive ink was obtained.

B. Rheological characterization

Rheological properties of the selected materials were investigated by using a rotational rheometer (Anton Paar GmbH, Austria), equipped with parallel plates and cone-plate (25 mm) geometry, respectively for GelMA and Pluronic F127. Strain (0.01-100%), temperature (4-50 °C) and shear rate (0.1-1000 s^{-1}) sweep tests were performed on both materials, to assess their transition temperature and viscosity. Moreover, thixotropy tests were carried out on GelMA hydrogels (0.1 s^{-1} for 120 s, 100 s^{-1} for 100 s, 0.1 s^{-1} for 300 s). Rotational properties of GelMA were modelled Herschel-Bulkley model (Eq. (1)) [5]:

$$\sigma = \sigma_y + K\dot{\gamma}^n \quad (1)$$

where σ = total stress, σ_y = yield stress, $\dot{\gamma}$ = shear rate, K and n are fitting parameters.

C. Pluronic F127 printing parameters optimization

Channel network template was designed (SolidWorks 2020) and printed (TissueStart, TissueLab, CH) in planar platform. The template geometry was a serpentine model, characterized by 6 sides (L,l), where L = 8.50 mm, l = 1.70 mm, α (L,l) = 90°. Different printing parameters were investigated to assess printing accuracy: extrusion multiplier (EM) = 0.4-0.8, velocity = 8-12 mm s^{-1}, flow = 300%. Then, printing parameters were investigated in the GelMA supportive bath for embedded 3D printing optimization: EM = 1-6, velocity = 3-8 mm s^{-1}, flow = 300-800%. All the printing tests were performed at 25 °C.

D. 3D in vitro models characterization

Channel network template was printed in the supportive bath which was pre-crosslinked as previously described. Then, GelMA/Pluronic samples were photocrosslinked by UV rays exposure (OSRAM Ultra Vitalux, 150 s). Obtained structures were immersed in deionized water (24 h, 37 °C) allowing Pluronic leaching and obtaining an opened internal channel. GelMA structures with channels (GelMA_ch) were characterized and compared to bulk GelMA samples (GelMA).

Channel morphology was analyzed with an optical stereomicroscope (Leica) by acquiring images before and after manually perfusion of the samples (n = 3). Then, models stability in physiological-like environment (distilled water, 37 °C) was evaluated considering the percentage weight variation ($\Delta W\%$) up to 4 weeks (GelMA_ch vs GelMA), by applying formula reported in Eq. (2):

$$\Delta W\% = \frac{w_t - w_0}{w_0} * 100 \quad (2)$$

where w_t = weight at the scheduled time point, w_0 = weight prior to water immersion.

Compressive mechanical properties were evaluated by testing hydrated samples (n = 3) with a Dynamic Mechanical Analyzer (DMA Q800, TA Instruments) at 37 °C. Briefly, a load phase was carried out by applying a strain ramp down to -30% strain at 2.5% min^{-1} rate, followed by an unload phase at 5% min^{-1} rate up to 1% strain.

E. In vitro biological tests

Cytocompatibility tests were performed by encapsulating 3T3-L1 preadipocytes (1×10^6 cells mL^{-1}) in GelMA solution prior to UV pre-crosslinking and Pluronic FRESH printing. AlamarBlue assay was performed up to 14 days to evaluate cells metabolic activity in terms of Relative Fluorescence Unit (RFU) (n = 3), as in Eq. (3):

$$RFU = f_{sample} - f_{control} \quad (3)$$

where f_{sample} = cell-laden sample fluorescence, $f_{control}$ = control sample fluorescence.

Live/Dead staining (1 µM calcein-AM, 10 µM propidium iodide) was carried out to qualitatively observe cells distribution in the cell-laden hydrogel (GelMA_ch vs GelMA). Moreover, model suitability as a 3D *in vitro* model of AT was assessed by testing the encapsulated preadipocytes ability in differentiating into mature adipocytes. For this purpose, cell-laden samples (n = 3, GelMA_ch vs GelMA) were prepared and cultured for 24 h (37 °C, 5% CO_2) in complete growth medium (Dulbecco's Modified Eagle Medium, DMEM, added with 10% bovine foetal serum, 1% penicillin-streptomycin P/S, 1 mM sodium pyruvate PyR, 10 mM 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid HEPES, 4 mM L-glutamine Glut). Then, growth medium was replaced by differentiating medium (growth medium added with 0.5 mM 3-isobutyl-1-methylxanthine IBMX, 1.0 µM dexamethasone, 2.0 µM rosiglitazone, 10 µg mL^{-1} insulin) and, after 48 h of incubation, the medium was substituted by maintenance medium (growth medium added with 10 µg mL^{-1} insulin). Metabolic functionality was qualitatively evaluated by NileRed staining (1 mg mL^{-1} NileRed stock solution), which stained intracellular lipidic droplets accumulated into mature adipocytes. Finally, preadipocytes and endothelial cells (EA.hy 926) were co-cultured up to 7 days, by embedding 3T3-L1 into GelMA and by injecting EA.hy 926 into the hollow channel. After 7 days of co-culture, cell growth of co-cultured cells was evaluated by Live/Dead staining.

III. Results and Discussion

A. GelMA and Pluronic F127 preparation

GelMA methacrylation was successfully verified by H NMR spectra acquisition. Briefly, samples of Gel and GelMA, dissolved in deuterium oxide (2% w/V), were analyzed by spectroscopy and obtained spectra were processed with Mestrenova software. DoF was calculated as the percentage of the amino groups (i.e., lysine, hydroxylysine) which resulted properly modified in synthetized GelMA macromers [6] and resulted approximately equal to 40.42%.

B. Rheological properties

Pluronic F127 exhibited a gel-like behaviour (G' > G'') at shear strain lower than 1%, while its gelation temperature was detected at 23 °C. For this finding, the printing temperature was set at 25 °C, above Pluronic 3D sol-gel transition. GelMA rheological behaviour was investigated towards thixotropy tests, as supportive bath should promote nozzle movement during the printing and restore its initial morphology after the printing process. This test claimed to establish the speed recovery of the supportive bath material after exposure to shear

rate [7]. As regard, GelMA should exploit an elastic behaviour in rest condition, and act as a liquid-like material when a sufficient shear rate (i.e., yield stress) is applied. GelMA recovered approximately 60% of its initial viscosity, exploiting a recovery time of 38.70 s. Although its recovery time resulted higher than values reported in literature for supportive bath in agarose (0.89 s) or Carbopol (1.42 s) [7], its ability in maintaining the morphology of the internal printed structure was enforced by post-printing photocrosslinking.

Additionally, we evaluated the viscosity kinetic of both materials once exposed to shear rate ramp (Fig. (1)). Both materials should contemporarily exhibit a comparable viscosity to accommodate nozzle movement and print a more precise internal 3D structure [8]. Different exposure times for GelMA pre-crosslinking were tested, and 120 s was selected as the most suitable exposure time to ensure a comparable viscosity between ink (i.e., during the printing) and bath (i.e., static conditions). Yield stress value of the supportive bath (σ_y = 0.29 Pa) perfectly fell in the range reported in literature for FRESH printing approach (0.16-8.80 Pa) [8].

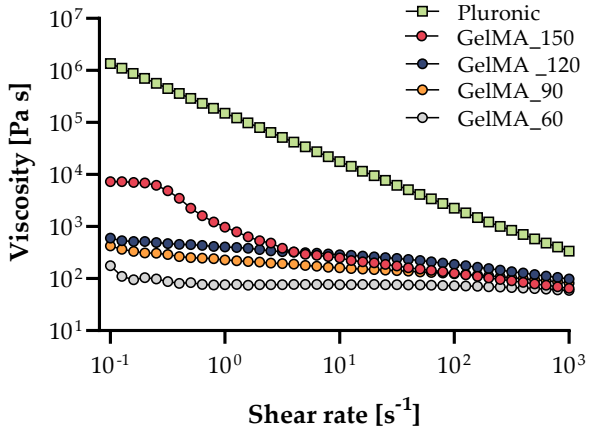

Fig. 1: viscosity curves of Pluronic F127 (square) and pre-crosslinked GelMA for 60 (gray), 90 (orange), 120 (blue), 150 (red) s. 120 s was chosen as the best exposure time since GelMA resulted in comparable viscosity in rest conditions to the one of Pluronic at high shear rates.

C. *FRESH printing parameters definition*

Optimal printing parameters for FRESH printing of Pluronic F127 were selected by starting from printing a serpentine geometry: v = 10 mm s^{-1}, EM = 0.6, flow = 300%. Printing of Pluronic F127 in the GelMA supportive bath required higher EM and flow, compared to Pluronic alone. Contrarily, printing speed should be decreased, to enhance printing process success. For this purpose, optimized parameters for FRESH printing were reported in Table I.

TABLE I: OPTIMIZED PARAMETERS FOR FRESH PRINTING OF PLURONIC

Printing parameters	*Value*	*Unit of measurement*
Printing speed	6	mm s^{-1}
Extrusion multiplier	4	-
Flow	400	%
Needle gauge	25	G
Extruder temperature	25	°C

D. *3D in vitro model properties*

Once Pluronic F127 was printed towards FRESH printing in GelMA supportive bath, images of the obtained internal channel were acquired by optical stereomicroscope. As regard, cross-section of the sample showed the successful obtainment of the channel, which diameter ranged (400-900 µm) in values reported in literature for vascular-like structures FRESH printed with Pluronic F127 [3]. Moreover, 3D printed channel diameter resulted comparable with human arteries diameters (0.1-10 mm). Latter finding enlightened the consistency of our work, aiming to mimic a microenvironment as close as possible with physiological one. Preliminary perfusion tests strengthened the feasibility of the model, as dye solution, which was manually injected, gradually flew towards the obtained channel (Fig. (2)).

Fig. 2: perfusion tests performed on vascularized 3D models by manually injecting colouring solution (scale bar: 5 mm)

Stability of 3D *in vitro* vascularized models was investigated by weight loss kinetic evaluation. GelMA_ch structures lost 45% of their initial weight due to the release of uncrosslinked gelatin chains and the dissolution of the Pluronic F127 ink.

Mechanical compressive tests were performed on 3D models to assess their suitability in fully recapitulate AT properties (Table II).

TABLE II: MECHANICAL COMPRESSIVE PARAMETERS (AVERAGE VALUE ± STANDARD DEVIATION)

Printing parameters	*GelMA_ch*	*GelMA*
Elastic modulus (kPa)	8.57 ± 2.01	10.45 ± 0.79
Stiffness (kPa)	33.94 ± 4.94	32.73 ± 8.95
Maximum stress (kPa)	6.31 ± 1.48	5.90 ± 1.71
Residual strain (%)	4.90 ± 0.20	5.50 ± 2.30
Hysteresis area (J dm^{-3})	0.13 ± 0.03	0.13 ± 0.02

Statistical differences between obtained values were not found ($p > 0.05$), enlightening how the FRESH printing process did not affect the mechanical features of the GelMA_ch. Moreover, 3D *in vitro* models exploited an elastic modulus comparable to the range reported in literature for AT in pathological conditions [9], depending on the progression state of the cancer disease. As regard, insurgence of benignant fibroadenoma express an elastic modulus equal to 6.41 kPa, while elastic modulus of low grade invasive ductal carcinoma (IDC) and ductal carcinoma *in situ* (DCS) resulted equal to 10.40 and 16.38 kPa, respectively, as reported in Fig. (3). Both latter conditions are referred to breast cancer, which determined an increase in AT stiffness [9]. This finding resulted highly interesting for our work, as the supportive bath should accommodate nozzle movement during the printing by restoring its initial conformation and should recapitulate

mechanical properties of physiological/pathological AT.

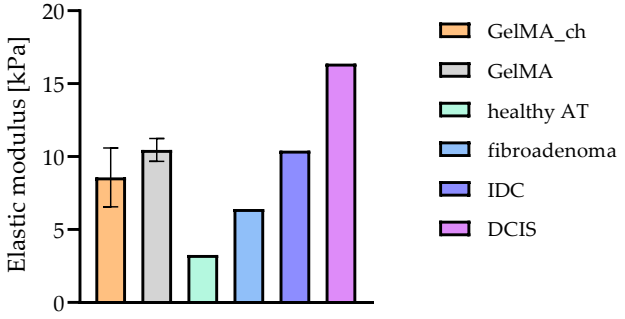

Fig. 3: Comparison between elastic modulus (kPa) of GelMA_ch and GelMA samples with healthy AT, fibroadenoma and early stages breast cancer conditions (i.e., IDC, DCIS) [9]

E. In vitro biological properties

Metabolic activity of encapsulated preadipocytes increased ($p < 0.05$) from day 1 up to day 14 of cell culture, enlightening how 3D *in vitro* models recreated a favourable microenvironment for cells proliferation. In particular, RFU values resulted higher ($p < 0.05$) for GelMA_ch than GelMA bulk samples at day 1 and 14, showing the effectiveness of the obtained internal hollow channel in promoting nutrients, oxygen and metabolites diffusion from the external to the internal environment of the sample. Live/Dead staining allowed to qualitatively evaluate the cells distribution into the samples, strengthening the importance of the internal hollow channel also in influencing cells proliferation. As regard, preadipocytes resulted highly active and closer to the internal hollow channel walls, where a possible higher exchange of gas and nutrients can be present (Fig. (4)). Contrarily, bulk GelMA samples resulted more homogeneously colonized in the whole scaffold volume than GelMA_ch hydrogels.

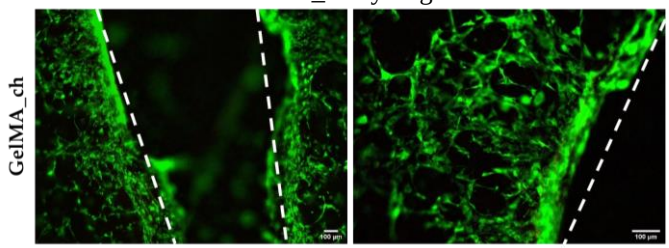

Fig. 4: Live/Dead staining of encapsulated 3T3-L1 in GelMA_ch samples (scale bar: 100 µm)

Moreover, suitability of GelMA_ch samples in recapitulating AT features was successfully verified by investigating the ability of encapsulated preadipocytes in differentiating into mature adipocytes. For this purpose, preadipocytes were cultured in proper conditions for the differentiation. After 14 days of culture, differentiated and undifferentiated samples were stained by NileRed staining, to qualitatively enlighten the accumulation of intracellular lipidic droplets into mature adipocytes. A higher amount of lipidic droplets qualitatively accumulated into cultured cells in GelMA_ch, and this finding claimed how developed vascularized 3D models worked as a versatile *in vitro* platform for preadipocytes which remained metabolically active in exploiting all their physiological functions.

Once GelMA supportive bath was investigated in preadipocytes proliferation and differentiation, a co-culture with EA.hy926 endothelial cells was tested. After 7 days of co-culture, Live/Dead staining qualitatively showed that endothelial cells resulted active and well attached to the walls of the internal hollow channel, showing a more elongated morphology ($p < 0.05$) during time. Cell morphology was analyzed by ImageJ software, comparing the endothelial cells diameter between day 1 and day 7 of co-culture, enlightening how endothelial cells assumed a typical flat morphology due to the attachment to RGD motifs of GelMA polymeric chains.

IV. Conclusion

3D *in vitro* models were realized aiming to recapitulate the AT ECM. For this purpose, we successfully optimized the FRESH printing technique by carefully characterizing in terms of rheological properties both the fugitive ink of Pluronic F127 and the supportive bath of GelMA. Findings from the characterization enlightened how the developed 3D models resulted suitable for mimicking AT ECM, as preadipocytes 3T3-L1 proliferated and differentiated once cultured in GelMA, while endothelial cells tended to colonize the internal walls of the hollow channel. Future perspectives could be directed in better investigating AT pathologies, since our model showed mechanical properties close to IDC and DCIS.

***Abstract*—A proper oxygenation and nutrients substances supply such as glucose are crucial in 3D *in-vitro* models. In most cases, hydrogel-based scaffolds are employed as culture systems. 3D bioprinting allows uniform cell distribution and to create complex structures in high reproducible manner. However, the diffusion of molecules be difficult in the innermost areas of the scaffolds and the presence of gradients could impact on cell proliferation. Hence, the mathematical modelling of the transport of oxygen and other nutrients as well as their consumption by the expanding cell culture withing the scaffold, can be useful to optimize the tissue construct properties, for generating more predictive and robust outcomes.**

***Keywords*—Mathematical modelling, Homogenization, Tissue engineering, Hydrogels**

I. Introduction

Three-dimensional (3D) in-vitro models are fundamental tools in tissue engineering and drug discovery. Differently from two-dimensional (2D) systems, where cells grow in an unnatural spatial environment, characterized by a uniform exposure to culture medium and gas supply, in 3D cultures, cells have different access to nutrients, in a way strictly dependent on the size of the *in-vitro* model [1].

In general, cells close to the medium are exposed to high levels of oxygen, while those further away perceive lower levels. Additionally, their behavior is drastically affected by the chemical/topological/biomechanical conditioning provided by the artificial 3D extracellular matrix [2]. In particular, cancer cells exposure to hypoxic conditions activates, through the hypoxia-inducible factor (HIF-1α) expression, several target genes related to angiogenesis, extracellular matrix remodeling and metabolic adaptation (Warburg effect) and finally metastatic progression. All these internal variations make chemotherapeutic agents inefficient and fail on hypoxic cells [3], [4]. For these reasons, there is a growing need to develop research tools capable of reproducing the complexity of a tumor microenvironment (TME), including physiologically relevant oxygen conditions, to better understand drug resistance, ensuring an in-vivo like cell response, and eventually allowing one to test novel, more effective therapies.

To this purpose, 3D bioprinting is a particularly promising technique because it allows to produce hydrogels characterized by a high spatial control of the tissue model, also encapsulating different cell types, thus more accurately mimicking the complexity of the TME [5]. Furthermore, 3D bioprinting offers the possibility of tuning the physical and mechanical properties of biomaterials through a specific crosslinking method [6] or by modulating parameters such as printing speed, pressure and temperature during the printing process [7], [8].

As previously discussed, the diffusion of oxygen and nutrients such as glucose plays a key role in 3D culture. However, this can be difficult in the innermost parts of the hydrogel, due to various factors such as the large size of the structure. Therefore, it is of great importance to model at a mathematical level the diffusion of gases, nutrients and their consumption by proliferating cells inside the scaffold, with the fundamental aim of avoiding anoxic conditions. In case of healthy cells, it is fundamental to maintain the oxygen level above a critical value, the hypoxic threshold. For tumor cells, it is interesting to study cell behavior both in oxygenated and hypoxic conditions.

In this perspective a synergic approach based on computational modelling and experimental validation can be useful to optimize the tissue construct properties, for generating more predictive and robust outcomes. Several mathematical models have been developed using continuum and discrete approaches to capture the dynamics of cell proliferation. Considering the oxygen as the main nutrient, Obradovic *et al*. [9] showed the development of spatial tissue cell density heterogeneities in scaffolds, modelling oxygen consumption with Michaelis-Menten kinetics. The study conducted by Lewis *et al*. [10] about the interaction between oxygen and cell distributions in static cultures proved that the lack of perfusion produces high proliferative regions near the border of the construct, where the oxygen level is higher. Shakeel *et al*. [11] developed a continuous mathematical model of cell proliferation and nutrient transport in a perfused bioreactor, considering the time variation in scaffold porosity induced by cell culture evolution and the effect of shear stress on nutrient consumption and cell proliferation. This last model can be easily adapted for a static culture by excluding perfusion advection terms. Recently, Mendoza-Juez *et al*. [12] described the growth and phenotype switching of two populations of oxidative and glycolytic tumor cells. Despite the predictions of this mathematical model being in good agreement with different cancer cell lines, the spatial variability of nutrients has not been considered, limiting the validity of the study to two-dimensional culture systems.

The present study aims at investigating the spatial and temporal variability of oxygen and glucose within an alginate-based hydrogel, finding the critical thickness which guarantees an oxygen level above the hypoxic threshold for the entire height of the scaffold and for the entire duration of a cell culture. To this purpose an *in-silico* model was implemented in COMSOL Multiphysics. The most innovative part of our

study concerns a mathematical procedure called homogenization, allowing to macroscopically analyze the behavior of a hydrogel with a heterogeneous and porous microstructure. Therefore, firstly, homogenization theory [13] was applied to estimate the diffusion coefficient of the two nutrients within a porous and heterogeneous scaffold. Then, a time-dependent study was performed to predict oxygen transport/consumption and time evolution of cell density and the nutrients concentrations.

II. MATERIALS AND METHODS

A. Application of homogenization theory

Considering the extrusion bioprinting technique, a scaffold with a cross-fiber microstructure was chosen. The transport of nutrients within the construct takes place both inside the polymeric material and in the culture medium that not only surrounds the hydrogel but also fills the hydrogel pores.

To conduct simpler computational analysis, homogenization theory was applied, following the approach by Mei *et al.* [13], based on the use of multiples scale asymptotic expansions. This mathematical method allows one to replace a heterogeneous material with a homogeneous fictitious material whose overall characteristics are macroscopically equivalent to those of the original material. A representative volume element (RVE) Ω composed of two different materials is considered, where Ω_a e Ω_b are respectively the volumes occupied by the hydrogel and the culture medium. For generality, each component material is nonhomogeneous and anisotropic.

Solution of an appropriate set of PDEs on the RVE subject to periodic boundary conditions leads to the determination of the components of the diffusivity tensor $\boldsymbol{D}_{\alpha,}$ which described the diffusion properties of the homogenized material. This implies that with this approach it is possible to reproduce the transport properties of materials that are not isotropic, as they might contain fibers that have a preferential direction. It is important to note that the effective diffusivity is not simply the volume average of the diffusivities of the two materials.

In the case of interest, a bioprinted fibrous scaffold has been considered. For the application of the homogenization theory, the Weak Form PDE module in COMSOL Multiphysics was employed. The problem was solved on a parallelepipedal RVE, which represents the culture medium unit cell, including two crossed layered cylinders, which represent the hydrogel fibers.

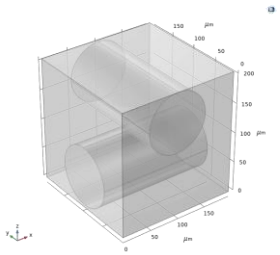

Fig. 1: Representative volume element (RVE) of the alginate fibrous scaffold with a porosity of 60%

The fibers diameter was set to 100 µm, in agreement with the minimum nozzle diameter of the available bioprinter, while it was chosen to vary the porosity in the range 30-90%. The height of the parallelepiped is slightly more than twice the diameter, while the base side is obtained through a simple calculation, as a function of the porosity.

Starting from literature data, the oxygen and the glucose homogenized diffusion coefficients through the alginate scaffold were obtained [14] – [17].

B. Nutrient transport and cell growth modelling

Subsequently, the evolution of a static cell culture inside the hydrogel previously described has been studied through development and implementation in COMSOL of a continuous mathematical model of transport/consumption of oxygen and glucose and cell proliferation. The whole static culture system consists in the culture medium domain Ω_m and the hydrogel one Ω_h. The scaffold, having a radius of 2.5 mm, is put in a 24 multi-well plate and covered by 250 µl of culture medium. An axisymmetric geometry allows to simplify the calculations. In the actual model, the following assumptions have been made:

- the deformation of the scaffold due to its biodegradation and due to the deposition of the extracellular matrix by the cells is neglected
- oxygen at the top surface of the medium is constant and it is the only element on which cell growth depends, since the efficiency of aerobic energy production is higher than the anaerobic glycolysis, despite the upregulated consumption of glucose [18]
- the nutrient consumption is linear in the nutrient concentration and cell density
- the doubling time of the cells is about of 5 days at least in the external and more oxygenated part of the construct

In static culture, nutrients surround the scaffold and don't flow. Therefore, in the culture medium domain nutrients are transported by diffusion, as described in Eq (2) and (3). D_{sm} and D_{gm} are the diffusive coefficient of oxygen and glucose in the culture medium.

$$\frac{ds}{dt} = -\nabla \cdot (-D_{sm}\nabla s) \qquad (2)$$

$$\frac{dg}{dt} = -\nabla \cdot (-D_{gm}\nabla g) \qquad (3)$$

In the hydrogel domain, also nutrients consumption and cell growth take place. D_{sh} and D_{gh} represent the homogenized diffusive coefficient previously obtained. α_s and α_g are multiplicative coefficients related to the single breast cancer cell oxygen consumption rate and glucose consumption rate [19], [20]. The dynamics of cancer cells density n [1/m^3] is given by a term which represented the effect of random movements and a logistic proliferation term, as shown in Eq. (6). The parameter β is related to the growth rate of the cell population, while D_n is the coefficient of diffusion of the cells [11].

$$\frac{ds}{dt} = -\nabla \cdot (-D_{sh}\nabla s) - \alpha_s sn \qquad (4)$$

$$\frac{dg}{dt} = -\nabla \cdot (-D_{gm}\nabla g) - \alpha_g g n \quad (5)$$

$$\frac{dn}{dt} = -\nabla \cdot (-D_n \nabla n) + \beta(s - s_{min})n\left(1 - \frac{n}{n_{max}}\right) \quad (6)$$

It has been hypothesized that the cells cannot migrate out of the hydrogel, thus a condition of zero-flux at the scaffold boundary has been fixed, while as regards the nutrients a continuity condition has been applied at the interface between the two domains.

In this first model, a normoxic cancer cell culture has been studied for 6 days. To this purpose, a hypoxic threshold s_{min} of 0.04 mM has been established, under which the cell culture exhibits a metabolic alteration. Moreover, the initial cell density was set to 10^{13} cell/m^3, while a maximum cell density of $2\text{x}10^{14}$ cell/m^3 has been estimated. The initial concentration of oxygen and glucose within the hydrogel and the medium were set to 0.2 mM and 25 mM. It is important to highlight the complete change of culture medium was simulated at day 3, refreshing the initial condition of glucose.

III. Results

A diffusivity matrix was obtained and the elements on the diagonal were considered (D_{11}, D_{22}, D_{33}), which respectively represent the diffusive coefficients in the *x*, *y* and *z* directions. The results achieved from the application of the homogenization theory show that, as porosity increases, the coefficient of the homogenized material assumes values close to that of the culture medium. On the contrary, by decreasing the porosity, the coefficient is reasonably more like that of hydrogel. Moreover, D_{11} and D_{22} are identical, owing to the symmetry of the microcell, while D_{33} is slightly lower, indicating a more limited diffusion along the vertical axis. In Fig. 2 oxygen diffusivity through the homogenized structure is shown.

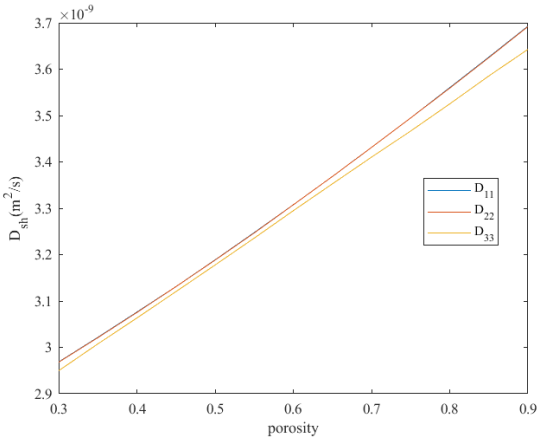

Fig. 2: Oxygen homogenized diffusive coefficient in alginate fibers vs hydrogel microstructure porosity

Results related to nutrients concentration and cell density during a 6 days *in-vitro* culture have been calculated using the values of the diffusion tensor computed with the homogenization approach. As shown in Fig. 3, within the hydrogel, an oxygen gradient is produced. According to the implemented *in-silico* model, the maximum height required to ensure a normoxic microenvironment for breast cancer cells is 350 µm. In particular, according to this model, the minimum level of oxygen above hypoxia is reached in the bottom core of the scaffold in a relatively short time, of the order of ten minutes (data not shown) and maintained for all the days of *in-vitro* culture (Fig. 4). It is also possible to note a great difference of oxygen tension between the outer zone of the hydrogel and the internal one. More specifically, in the bottom core, an oxygen reduction of the 80% is observed.

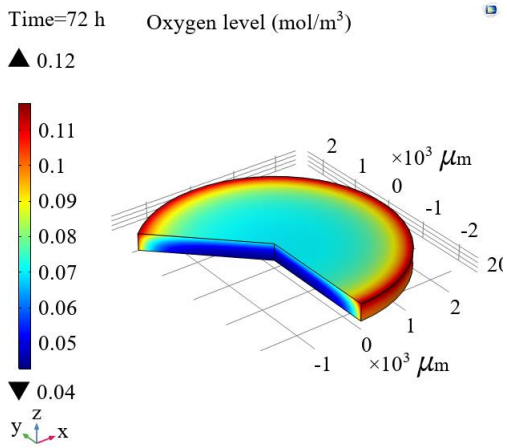

Fig. 3: Oxygen concentration in the homogenized scaffold at day 3

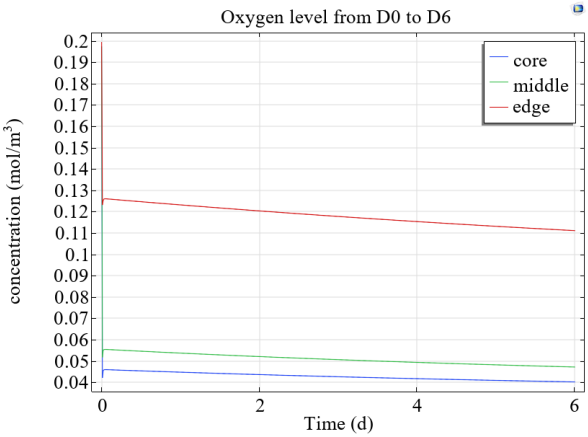

Fig.4: Oxygen profile during in vitro culture

This discrepancy is also observable in the cell growth profile, where there is a greater proliferation in the top outer edge of the hydrogel. This is because it has been hypothesized that cell growth depends only on oxygen, even though cells also consume glucose. As shown in Fig. 5, the cell density duplicates at day 5. Therefore, a more oxygenated zone leads to a more proliferative cell behavior.

In contrast, glucose does not exhibit a great gradient in the different zones of the scaffold. In fact, Figure 6 displays three almost overlapping trends. The refresh of culture medium is simulated at day 3, immediately after reaching a level of just over 80%, compared to the initial condition. Starting again from a concentration of 25 mM, at day 6 a lower glucose level is reached than at day 3, due to a greater number of cells present in the hydrogel.

However, the concentration of the different nutrients should

be experimentally monitored with sensors and/or chemical kits to validate the mathematical model.

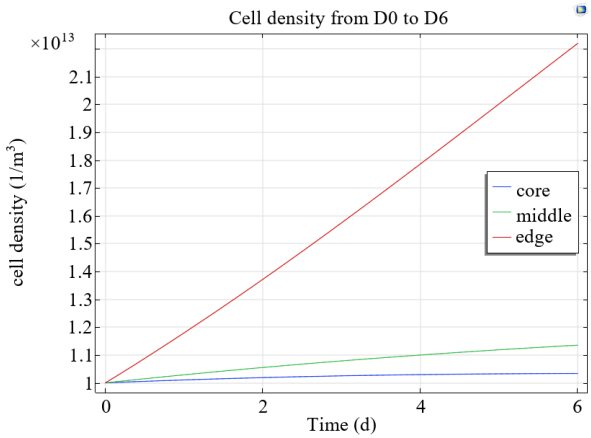

Fig. 5: Cell growth profile during in vitro culture

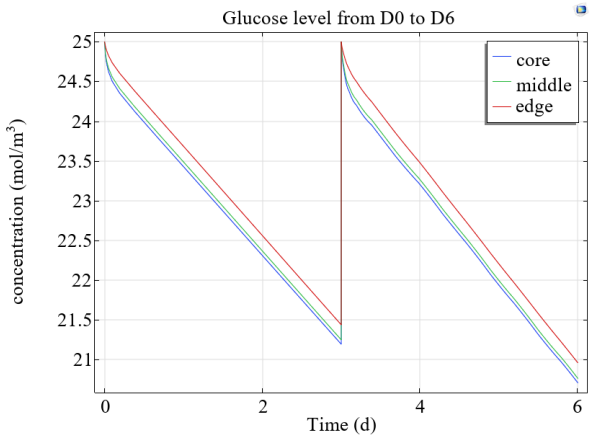

Fig. 6: Glucose profile during in vitro culture

IV. CONCLUSION AND PERSPECTIVE

In this study a mathematical model for nutrient transport and cell growth in a homogenized fibrous hydrogel was discussed. The homogenization represents a powerful tool to simplify heterogeneous structures such as bioprinted fibrous scaffolds. To study oxygen tension and glucose concentration within an alginate hydrogel a normoxic breast cancer cell culture was considered. From the mathematical model, that couples nutrients and cells, we established the maximum height of a porous hydrogel scaffold. This approach contributes to optimize a 3D printed hydrogel by providing information about how to ensure the correct amount of oxygen and glucose throughout the construct during a static culture. However, the model is subject to some limitations. In particular, the main challenges of future studies will have to concern the definition of a law that accurately describes the consumption of nutrients by cells, defining a relationship between oxygen and glucose, considering the Warburg and, thus, the incorporation of both normoxic (oxidative) and hypoxic (glycolytic) cancer cells. Moreover, deposition of extracellular matrix by cells or hydrogel degradation, which mechanically and chemically influences the microenvironment of the cells, could be considered.

***Abstract*—Mechanobiology of vascular cells plays an important role in vascular remodelling and stenosis formation. Mechanical stresses acting on vascular wall may derive from mechanical vibrations. This preliminary study aims to investigate the effects of vibrations on endothelial cells (ECs) exploiting an experimental setup capable of expose cells to mechanical vibrations obtained by a 50 Hz sound-generated pressure wave. To validate the efficacy of the system, a preliminary cell viability evaluation was performed on ECs exposed for 48 hours to vibrations. A mean displacement of 71 μm was measured and sound recording showed consistency between sound and culture dish vibrations during the time course. Phase-contrast analysis of the stimulated and unstimulated cell cultures showed that sound-induced vibrations caused changes in ECs typical cobblestone shape and determined their detachment from the substrate, with a number of death cells higher than the static control. Alamar Blue assay highlighted a significant reduction in the metabolic activity of live cells after the mechanical stimulation, as compared to the static culture.**

***Keywords*— endothelial cells, sound, vibration, frequency.**

I. Introduction

Despite huge research efforts, cardiovascular diseases remain the primary cause of mortality and morbidity worldwide [1]. The understanding of the fundamental processes responsible for vascular remodelling, crucial in vascular pathology such as stenotic vascular disease [2], is still limited. The main cause of stenosis is the development of neointimal hyperplasia (NH), a fibrotic-muscular thickening of the vascular wall due to the migration of smooth muscle tissue cells into the intimal layer of the vessel [3].

Beyond flow disturbance, the mechanobiology of the vessel plays a key role in vascular remodelling and stenosis formation [4]. Indeed, a large body of evidence [5]–[7] showed that turbulent hemodynamics largely influence endothelial cells (ECs) functions *in vitro*.

Cells are capable of sensing and adapting to their mechanical environment through dynamic processes involving multiple signalling pathways. This property is crucial because mechanical stimuli are critical regulators of homeostatic processes, physiological conditions and are involved in the development of diseases [8], [9].

The effect of mechanical stresses on vessels remodelling was recently investigated through numerical simulations, revealing that "turbulent-like" blood flows might induce vascular wall vibrations [10]. However, the biological effects of high frequency dynamic mechanical stresses on cellular functions remain still unclear.

Therefore, this preliminary study aims to investigate the effects of vibrations on ECs. To achieve this goal we developed an experimental setup capable of providing cells with mechanical vibrations and related mechanical stresses by means of a pressure wave generated by reproducing a sound at a known frequency. Thus, a preliminary cell viability evaluation was performed to investigate the effect of vibration on ECs.

II. Methods

A. Study design

An aluminium support structure was built and embedded with an instrument for sounds generation. Cell culture was mounted and positioned in order to make it receive vibrations. Human umbilical vein endothelial cells (HUVECs) were seeded and cultured in two 150 mm cell culture dishes, one of them subjected to low frequency vibration and the other used as static control for 48 hours, a time interval previously shown to induce changes in ECs by shear stress [7]. The sounds emitted by the speaker and the vibrations of the cells subjected to low frequencies were recorded at the start of the experiment, after 24 and 48 hours. At the end of the experiment a viability assay was performed both on the cells subjected to vibrations and on static control ones.

B. Experimental setup

To expose a cell culture dish to vibrations, a support structure was built with aluminium profiles and corner fittings. At 10 cm from the base, a perforated aluminium plate was fixed in which the speaker was soldered. At 4 cm from this, a second aluminium plate, with a hole of the same size as the cell culture dish, was placed. The use of screws allowed securing the cell dish making it integral with the speaker. In this way the lower part of the dish, where the cells were located, was affected only by the vibration from the sound wave. To generate the sound induced vibrations, the speaker was connected with a two-channel digital power amplifier (Kinter 500W MA-700) capable of receiving as input a sound recording in .wav file format. The frequency of the sound was 50 Hz, continuously applied for 48 hours. The choice of the sound frequency of 50 Hz was selected in order to simulate the vibrations of the wall of an arteriovenous fistula under turbulent-like flow conditions, that was estimated by a preliminary fluid-structure interaction simulation (FSI). During the 48-hour experiment, the structure was placed in a 37 °C, 5% CO_2 incubator, while the amplifier and electronic

components remained isolated from the humid environment.

On the other hand, the control cells weren't subjected to vibrations and were kept for the same duration of the experiment in an incubator, acoustically isolated from the other one, under the same conditions of the cells subjected to vibrations.

C. Cell culture

HUVECs were isolated from umbilical cords collected by a local hospital (Azienda Ospedaliera, Bergamo EST). Before tissue harvesting, informed consent by the donor was obtained. Cells were isolated by collagenase digestion, as described in our previous publication [7], cultured on gelatin-precoated culture dishes [7] and propagated in M199 medium supplemented with 10% newborn calf serum (Gibco™), 10% human serum (directly separated in our laboratory from human plasma), 1% (v/v) 200 mM L-glutamine (Gibco™), 1% antibiotics (100 U/mL Penicillin-Streptomycin, Gibco™), 1% amphotericin B solution (Sigma-Aldrich), 0.1% heparin (5000 U.I./mL, Teva Italia S.r.l.), and 25 µg/mL endothelial cell growth supplement (Sigma-Aldrich). HUVECs were maintained at the temperature of 37 °C and 5% CO_2 of humidified environment and used between passages 3 and 5. The medium was changed every 3-4 days. When the cells reached 80-90% confluency, they were plated on two gelatin-precoated 150 mm cell culture dishes at a density of 1 x 10^6 cells per dish and incubated for 4 days. At day 4, when the cells reached about 80% confluency, the experiment was started.

D. Sound and vibrations tests

Sound recordings were performed with an in-house device consisting of an Adafruit Pulse Density Modulation (PDM) microphone and an Arduino Nano 33 BLE board. Adafruit PDM Microphone Breakout is an audio sensor, mounting on board a Micro Electrical Mechanical System (MEMS) omnidirectional digital microphone (MP34DT01-M produced by ST electronics). The Arduino Nano 33 BLE board bias the microphone and allows data collection. The system is also equipped with an ad-hoc designed circuit to trigger the start and the end of sound recordings. Data were stored real time on a .txt file using Coolterm (version 1.9.1.964), a simple serial port terminal application that is customized to exchange data with hardware connected to serial ports. Sound recordings were analyzed in time and frequency using MATLAB R2022a (9.12.0).

The vibrations of cell culture dishes were detected using the accelerometer (LSM9DS1) mounted on the Arduino platform. Acceleration data were collected with Coolterm and analyzed in MATLAB. Specifically, acceleration data were evaluated in time and frequency domain: information of cell culture dish velocity and displacement during time were obtained by the integration, respectively one and two times, of the acceleration data following appropriate high-pass filtering steps to avoid the drift effect due to integration of the accelerometer offset [11].

Preliminary sound tests were performed before starting the experiment and the noise emitted by the incubator was also recorded to check the possible effect on cell vibration.

At the beginning of the experiment, after 24 and 48 hours the sound emitted by the speaker were recorded by the PDM Microphone. The sound was recorded just below the bottom of the cell dish to test what cells were receiving.

Similarly, the acceleration of the dish was recorded with the Arduino-based accelerometer at 0, 24 and 48 hours from the experiment start. Vibrations were detected on the bottom of the dish carefully securing the device to the cell culture dish so that its movements were joint to the accelerometer ones.

E. Cell morphology and viability evaluation

The morphology of vibrations-exposed and static control cells was investigated at the end of the experiment by taking phase-contrast microscopy images, ascertaining the homogeneity within the dishes as well. Then, cell counting was performed to evaluate the effect of vibrations on HUVECs, quantifying the number of detached cells in the two conditions.

To determine the viability of HUVECs, Alamar Blue assay was performed on the samples. After the experiment, 10% v/v Alamar Blue solution (Sigma-Aldrich) was added to the cells and was further incubated for 1.5 hours at 37 °C and 5% CO_2 environment. The solution containing the reduced form of the compound was then transferred into a 96-wells plate, and the fluorescence of each sample was measured with a microplate reader (Tecan Infinite 200 PRO) at the excitation and emission wavelength of 570 nm and 600 nm respectively. The percentage of cell viability was calculated by comparing the fluorescence of the culture subjected to sound-induced vibrations to the fluorescence of the static culture, considered as 100% of cells metabolic activity.

III. Results

A. Experimental setup

In Figure 1a shows the experimental setup, while the device used for sounds and vibrations recording was reported in Figure 1b.

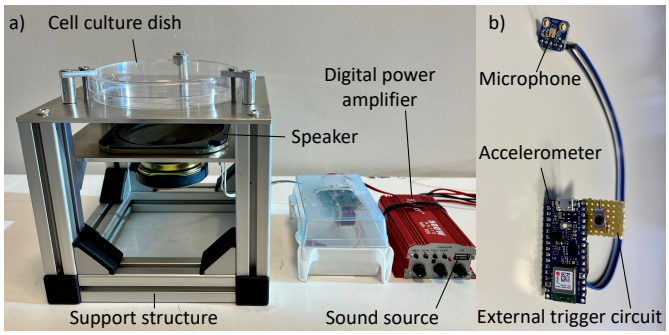

Figure 1: a) experimental setup. b) Arduino-based device for sound and vibration measures.

B. Sound and vibrations tests

Before the beginning of the experiment, the noise of the incubator was recorded. A main frequency of 90 Hz was detected, with a significantly lower amplitude (2 orders of magnitude) with respect to the sound imposed to generate the ECs vibration.

The sound emitted by the speaker and received by cell culture dish were acquired with the PDM Microphone. Figure 2 shows a representative example of the acoustic

recordings at the experiment beginning. In addition to the main frequency at 50 Hz there are also its odd harmonics of lower amplitude and other very low amplitude peaks spread over the entire frequency spectrum.

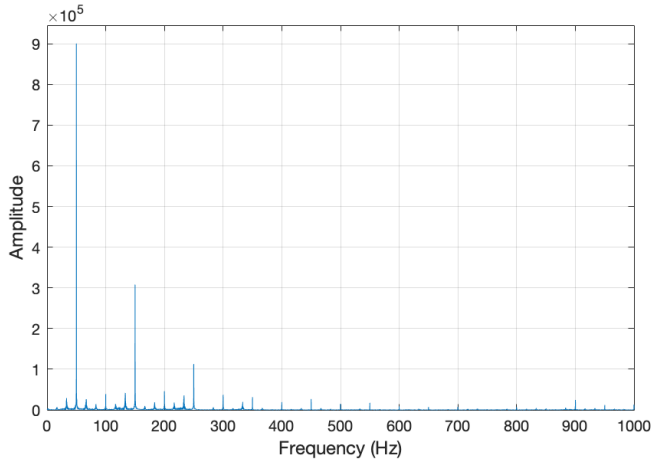

Figure 2: 50 Hz sound emitted by the speaker.

The acceleration was recorded with the Arduino-based accelerometer integral with the cell culture dish. Acceleration, velocity and displacement of the plates were relevant only in the direction perpendicular to the dish. Assumed a normal distribution of velocity and displacement, mean velocity obtained from acceleration data was 0.04 m/s (4σ) and the associated $2\sigma = 71$ μm indicates the amount of movement of the cell culture dish given by vibrations. The Fourier transform of the acceleration data showed a frequency consistent with that detected in sound. In Figure 3 is reported a representative example on the HUVECs displacement due to sound induced vibrations.

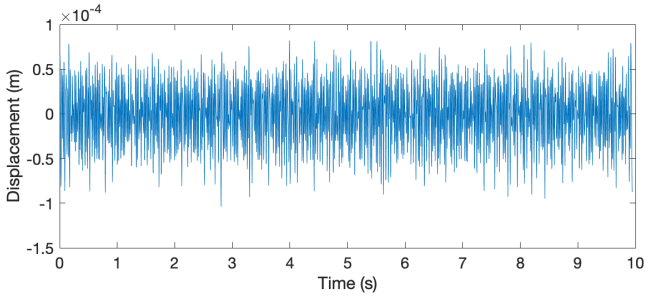

Figure 3: Vibration induced displacement of the cell culture dish.

C. Cell morphology and viability evaluation

As shown in Figure 4, HUVECs morphology was affected by vibrations exposure. Indeed, the cell culture stimulated for 48 hours by the sound-generated vibrations presents cells with irregular edges and some empty spaces between them, which were the result of HUVECs detachment (black arrows in Figure 4). On the contrary, the culture maintained in static condition during the time course consisted in a monolayer of cells with the typical randomly oriented cobblestone shape. Morphology of vibrations-exposed and control cells were homogenous within their cell culture dishes.

Cell counting confirmed the result of the morphologic analysis. The total cells number per dish, which was the same at the beginning of the experiment, was significantly lower in cells exposed to vibrations as compared to control cell (3.7 and 4.7 million cells, respectively). This indicates that the mechanical stimulation led to detachment of approximately 24% of total HUVECs which accumulated in culture medium, compared to about 4.5% detachment in control cells.

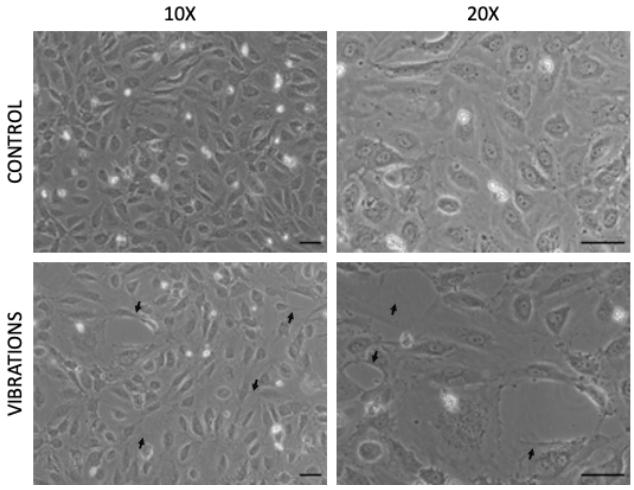

Figure 4: Effect of vibrations exposure on HUVECs morphology. Black arrows indicate the detachment-induced empty spaces in the cell monolayer. Left: magnification 10X and scale bars 50 μm; right: magnification 20X and scale bars 50 μm.

Alamar Blue assay was performed on HUVECs at the end of the 48 hours experiment both on stimulated and unstimulated cells. The results are reported in Figure 5, as metabolic activity normalized to the number of live cells. A decrease in cell viability was observed for HUVECs exposed to the mechanical stimulus compared to control ones. In details, the metabolic activity of stimulated cells resulted more than 50% lower than that measured in the static culture, suggesting that 48 hours exposure to mechanical vibrations importantly affected cell functions.

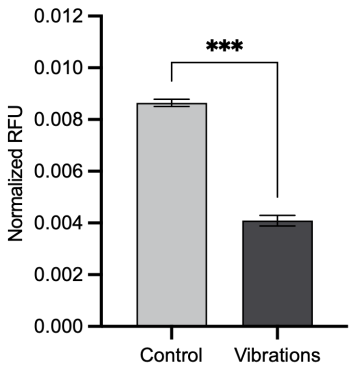

Figure 5: Alamar Blue assay to determine cell viability of HUVECs exposed to 48 hours vibrations and maintained in static conditions. Data are normalized to the number of live cells and are represented as mean ± SD (****p* < 0.001*, using student paired t test, n = 1).

IV. Discussion

In this preliminary study we developed and tested an experimental procedure to investigate the effects of mechanical vibrations on ECs in vitro. The development of an experimental setup capable of providing HUVECs with sound-induced mechanical vibrations is a results per se.

The choice to look at vibrations effects at 50 Hz is consistent with what reported by Bittle [12] about blood flow vortex frequencies in post-stenotic location. While Bittle examined

the effects of vibrations on vascular smooth muscle cells, we for the first time studied ECs, that play an important role in vascular remodelling and stenosis formation [6], [7].

The 90 Hz low amplitude noise of the incubator didn't importantly affect the cells since it was overpowered by the sound emitted by the speaker. The main frequency of the latter was at 50 Hz, and the presence of its odd harmonics suggests the imposition of a square wave, while the white noise spread along the entire spectrum is negligible compared to the amplitude of the main frequency. The multiple recordings in time of the 50 Hz sound and cell culture dish vibration demonstrate the consistency of the experiment during the entire duration of the experiment. Furthermore, the fact that the measurements were taken under the cell dish confirms that those data actually represent the vibration sensed by ECs adherent to the bottom of the culture dish and are not due to interference effects within the incubator. The Fourier transform of the data obtained with the accelerometer shows the same frequencies as the sound imposed on the cells, confirming that the recording device was integral with the structure. This is also shown by the fact that the vibrations occur only in the direction perpendicular to the cell dish, and that the imposition of a sound at a certain frequency causes a vibration consistent with it. From the acceleration data, an average displacement of the cell culture dish of about 70 μm was measured. This result is in line with the displacement values of vascular vibrations, based on preliminary data of a CFD simulation [10].

Phase-contrast analysis of the stimulated and unstimulated cell cultures shows that sound-induced vibrations affected HUVECs morphology, causing changes in their typical cobblestone shape and determining their detachment from the substrate, which led to the formation of empty spaces in cell monolayer. This evidence was confirmed by the number of death cells found in the culture medium of vibrations-exposed HUVECs, about 20% higher than the static control cell monolayer.

Preliminary viability evaluation by Alamar Blue assay strongly supported previously results, highlighting a significant reduction in the metabolic activity of the residual live cells after the mechanical stimulation, compared with that of the static culture.

A large body of evidence proofs that the dynamics of wall shear stress largely influence ECs functions *in vitro,* which play a crucial role in NH development [5]–[7]. Furthermore, recent FSI results revealed that turbulent-like blood flows cause the vessel-wall to vibrate, but no data about the effect of mechanical vibrations on ECs are available in literature. Thus, this is the first feasibility study exploring this linking. Overall, the results of our preliminary work confirm that mechanical vibrations affect ECs *in vitro*.

The current study is a preliminary investigation, and the experiment must be further investigated to ensure its reproducibility and statistical significance. As a future development, the effect of vibrations on ECs functions may be investigated by more specific cell function tests, such as LDH, ROS production and Caspase-3 activation assays. Furthermore, it would be interesting to identify a displacement threshold over which cells show detachment or reduced viability, and relate it to turbulent-like flow. Another future development may be the investigation of the effects of vibrations on ECs after different time of exposure.

V. Conclusion

Our study provides a simple but reliable system to explore the effects of vibrations on ECs function. The preliminary results underline a lowering of cell viability when cells are stimulated by a 50 Hz frequency for 48 hours. Our framework showed a great potential for the investigation of vascular remodelling and the related cell dysfunctions that are responsible for vascular diseases.

***Abstract*—In recent years, non-viral vectors have gained some public acceptance and come to the forefront of advanced therapies. Unfortunately, the use of non-viral vectors is still plagued by low efficiency due to their scarce ability to overcome cellular barriers. Herein, we used mechanical cell stimulation as a tool to boost polymer-based nanoparticles effectiveness.**

***Keywords*—transfection, mechanical stimulation, non-viral gene delivery, polyethyleneimine.**

I. Introduction

The rise of nucleic acids (NAs)-based therapeutics has emerged as a breakthrough in molecular medicine and set the stage for the development of advanced therapeutics and preventatives[1,2]. Broadly speaking, the introduction of NAs into target cells is achieved by either physical means or vector-mediated delivery systems. Physical methods, such as electroporation, sonoporation, and optoporation, enable the delivery of the genetic cargo intracellularly through the use membrane-disruptive stimuli[3]. Despite being very effective in accomplishing the delivery task, such methods are often associated with extensive cell damage as a consequence of cell membrane disruptions[4]. On the other hand, vector-based delivery systems rely on the use of carriers able to pack the NA cargo into (nano)particles, making it easier to overcome the cell membrane barrier. Viral vectors, i.e., an engineered version of highly evolved viruses that naturally gain access to cells, currently dominate the clinical trial landscape[5]. Nevertheless, some issues in terms of safety and manufacturing have fuelled the development of non-viral alternatives. Non-viral gene delivery vectors are categorized as cationic lipids (such as the key components of COVID-19 Pfizer/BioNTech's and Moderna's mRNA vaccines)[6] and polymers[2,7]. These molecules spontaneously self-assemble with NAs into nano/micro-sized particles called lipoplexes and polyplexes, respectively, ultimately protecting the NA payload from the harsh extracellular environment[8]. Unfortunately, the efficiency of such delivery systems is greatly hampered by several extra- and intra-cellular barriers that stand in the way toward a successful intracellular delivery of genes. In this context, although a tremendous effort has been made to optimize the vector chemistry[9], there is still a long way to go. In this work, we focus on a way to enhance the transfection efficiency (TE) of commonly used non-viral vectors by triggering cell responses through mechanical stimuli. Of note, cells are constantly subjected to a combination of chemical and mechanical cues, which orchestrate any cell process, such as motion, proliferation, and phenotypic switching events[10]. In line with this, the interaction between the cell membrane and the underlying cytoskeleton regulates the endocytic and trafficking processes[12]. In this light, we herein propose an innovative *in vitro* cell transfection strategy relying on the combination of polymer-mediated transfection (hereafter referred to as polyfection) and a short-lived mechanical stimulation in terms of micro-to-nanovibrations applied to cells to temporarily control their behaviour[11]. Overall, this resulted in a boost of polyplexes TE.

II. Materials and Methods

A. Vibrational loading device

The vibrational loading device (**Figure 1a**) comprises i) a sine wave signal generator (Lascells, Market Drayton, UK), able to modulate the wave frequencies from 0.1 Hz to 10 kHz and characterized by a peak-to-peak wave amplitude from 0 to 24 V. This is connected to ii) a mechanical wave driver (Arbor Scientific, Ann Arbor, MI, USA), equipped with a motion arm consisting of iii) a driveshaft moving in vertical (z-axis) direction and iv) a built-in-home cell culture plate housing on the top of it. The shaft displacement along the z-axis was assessed as a function of the wave frequency (f_{in}) by using a *homemade* accelerometer sensor.

B. Evaluation of vibrational loading on cell viability and proliferation

Mycoplasma-free adherent L929 (murine fibroblasts from subcutaneous connective tissue, CCL-1; American Type Culture Collection (ATCC®), Manassas, VA, USA) cells were routinely cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10 % (v/v) fetal bovine serum (FBS), 1 mM sodium pyruvate, 10 mM HEPES, 100 U/mL penicillin, 0.1 mg/mL streptomycin and 2 mM glutamine (hereinafter referred to as complete DMEM, cDMEM) at 37°C in a humidified atmosphere under constant supply of 5% (v/v) CO_2 (hereafter referred to as standard culture conditions). L929 cells were seeded in 96-well plates at a density of 2×10^4 cell/cm^2 and maintained in standard culture conditions for 24 hrs. Afterward, cells were stimulated for 5 min at different vibration frequencies (f_{in} = 10 Hz, 50 Hz, 100 Hz, 500 Hz, and 1,000 Hz) and maintained in standard culture conditions. Twenty-four hrs after the discontinuation of the stimulation, cell viability was evaluated using AlamarBlue® assay according to the manufacturer's instructions. Briefly, the medium was removed from each well and replaced with 100 µL/well of 1× resazurin dye solution in cDMEM. Next, plates were incubated in standard culture conditions for 2 hrs, then the fluorescence was read with a Synergy H1 reader (BioTek, Winooski, VT, USA) (λ_{ex} = 540 nm; λ_{em} = 595 nm). The viability of unstimulated cells (CTRL) was assigned to 100 %

and the viability of stimulated ones was determined as follows:

$$\text{Viability [\%]} = \frac{F_{stimulated\ cells}}{F_{CTRL}} \times 100$$

where F is the recorded fluorescence.

To assess the effect of vibrational loading on cell proliferation, the viability assay was repeated 48 hrs from the discontinuation of the stimulation as described above, then the cell doubling time was calculated as follows:

$$\text{Doubling time [hrs]} = log_2(\frac{F_{t48}}{F_{t24}})$$

Where F is the recorded fluorescence 48 hrs (F_{T48}) and 24 hrs (F_{T24}) from the discontinuation of stimulation.

C. Evaluation of vibrational loading on cell morphology

The effect of vibrational loading on cell morphology was assessed by means of Scanning Electron Microscopy (SEM). Briefly, L929 cells were seeded at a density of 2×10^4 cell/cm^2 on sterile glass coverslips (Ø = 15 mm) inserted into separate wells of 24-well plates, and kept in standard culture conditions for 24 hrs. Twenty-four hrs post-seeding, cells were stimulated for 5 min at different vibration frequencies (f_{in} = 10 Hz, 50 Hz, 100 Hz, 500 Hz, and 1,000 Hz), next prepared for SEM analysis right after the stimulation was discontinued or at different time periods post-stimulation (i.e., 5 min, 30 min, and 60 min). Unstimulated cells were used as controls. For SEM analysis, cells were fixed in 2 % (v/v) glutaraldehyde solution for 20 min, dehydrated with graded ethanol series, then samples were gold-sputtered, mounted onto stubs, and examined using an accelerating voltage of 10 kV. SEM images were acquired at ×1,500 and ×7,000 magnification.

D. Evaluation of vibrational loading on transfection efficiency

For transfection assays, the *gold standard* transfectant 25 kDa linear polyethyleneimine (*l*PEI) was used to prepare polyplexes. Briefly, polyplexes were prepared at r.t. by adding an aqueous solution of pDNA encoding the secreted *Gaussia* luciferase (pGLuc, 160 ng/cm^2) to *l*PEI solutions at a stoichiometric ratio of 1:10 (v/v) to give a final DNA concentration of 20 ng/µL and N/P 30, where N/P is defined as the number of amines (N) of *l*PEI used to complex the phosphate groups (P) of a given amount of pDNA. *l*PEI/pDNA polyplexes were incubated for 20 min at r.t.. Transfection assays were carried out either in standard (i.e., static, polyfection) conditions, that served as internal transfection control, or upon vibrational loading (vibropolyfection conditions).

For polyfection, cells were challenged with 100 µL/well of polyplexes-containing culture medium, then incubated under standard culture conditions for 24 hrs. For vibropolyfection, cells were next stimulated for 5 min at different stimulation frequencies (f_{in} = 100 Hz, 500 Hz and 1,000 Hz), then cultured in standard conditions for 24 hrs. The cytotoxicity was evaluated 24 hrs from transfection using the AlamarBlue® viability assay as described hereinabove. The viability of unstimulated, non-transfected cells (CTRL) was assigned to 100 % and the cytotoxicity was determined as follows:

$$\text{Cytotoxicity [\%]} = \left(1 - \frac{F_{transfected\ cells}}{F_{CTRL}}\right) \times 100$$

To evaluate the overall luciferase activity, 20 µL of cell supernatant were mixed with 50 µL of luciferase assay substrate and the luminescence signal (expressed as Relative Light Units, RLU) was measured by means of a Synergy H1 reader.

E. Evaluation of vibrational loading on polyplexes internalization

Plasmid uptake was quantified in transfected L929 cells via real-time polymerase chain reaction (qRT-PCR). Briefly, 24 hrs after *l*PEI/pGLuc polyplexes delivery either via classical polyfection or vibropolyfection (f_{in} = 1,000 hz), cells were washed with sterile PBS and total DNA from whole cells was extracted with SingleShot Cell Lysis kit. RT-PCR reactions were carried out in a CFX Connect Real-Time PCR Detection System (Bio-Rad Laboratories) using the SsoAdvancedTM Universal SYBR® Green Supermix (BioRad Laboratories) (hereafter referred to as the master mix) as recommended by the manufacturer. Absolute quantification of pGLuc in transfected cells was achieved by comparing the C_T values of test samples to a standard curve generated by 10-fold serial dilution of the pGLuc template. Data were expressed as a fold-increase in pDNA uptake in vibropolyfected cells with respect to the polyfected counterparts. Confocal microscopy analyses were carried out as well to shed light on the role of mechanical stimulation on polyplex uptake. Briefly, seeded L929 cells were challenged with fluorescently labelled *l*PEI/pDNA polyplexes following either polyfection or vibropolyfection protocol at 1,000 Hz. Four hrs from polyplexes delivery, cells were fixed in 4% (v/v) paraformaldehyde, permeabilized with 0.1% (v/v) Triton X-100, next F-actin and nuclei were stained with TRITC-Rhodamine Phalloidin and Hoechst dyes, respectively, to better localize polyplexes. Stained samples were subsequently mounted on glass slides and digital images were taken with a Nikon A1 Confocal Microscope.

F. Evaluation of polyplex uptake by endocytosis inhibition and protein expression

Transfection assays in the presence of endocytosis inhibitors were carried out to investigate the contribution of each endocytic route on the polyplex uptake by cells undergoing polyfection and vibropolyfection. Briefly, L929 cells were seeded as described before. Twenty-four hrs post-seeding, cells were pre-treated with subtoxic concentrations of either chlorpromazine (10 µg/mL) or filipin (5 µg/mL) to inhibit clathrin-mediated endocytosis (CME) and caveolin-mediated endocytosis (CvME), respectively. The medium was replaced and the cells either underwent vibrational loading at 1,000 Hz for 5 min or were rested. Cells were next challenged with *l*PEI-based polyplexes for 3.5 hrs, the medium was replaced, and cells were cultured in standard conditions for 20 hrs before assessing the cytotoxicity and the transfection efficiency. Transfected cells in the absence of inhibitors served as positive controls. Immunostaining of clathrin and caveolae was performed as well. Briefly, L929 cells were seeded, transfected and fixed as described before, then mouse anti-clathrin heavy chain and mouse anti-caveolin 1 primary antibodies were used to stain clathrin and caveolin, respectively. Immunostained samples were mounted on glass slides and digital images were taken with Nikon A1 Confocal Microscope.

G. Statistical analysis

Statistical analyses were carried out using Prism version 8 (GraphPad software, La Jolla, CA). All data collected from at least three independent experiments were initially analyzed using the D'Agostino & Pearson omnibus normality test. Unpaired t-test and one-way ANOVA (multiple comparisons) with posthoc Tukey test were used to compare two or more experimental groups, respectively. Significance was retained when $p < 0.05$. Data are expressed as mean ± standard deviation (SD, $n \geq 3$).

III. Results and Discussion

A. Assessment of the vibrational loading device

A vibrational-loading device was conceived to apply sinusoidal micro-to-nanoscale displacements to adherent cells in culture. The displacements caused by the input frequencies (f_{in}) set on the sine wave generator were characterized using an accelerometer. As shown in **Figure 1b**, the higher the sinusoidal wave frequencies applied, the smaller the displacement of the culture plate. Specifically, the device allowed controlling the generation of vibrational cues ranging from the millimeter (f_{in} = 10 Hz) to the nanometer (f_{in} = 1,000 Hz) scale, such that they can be used to control cells' behavior.

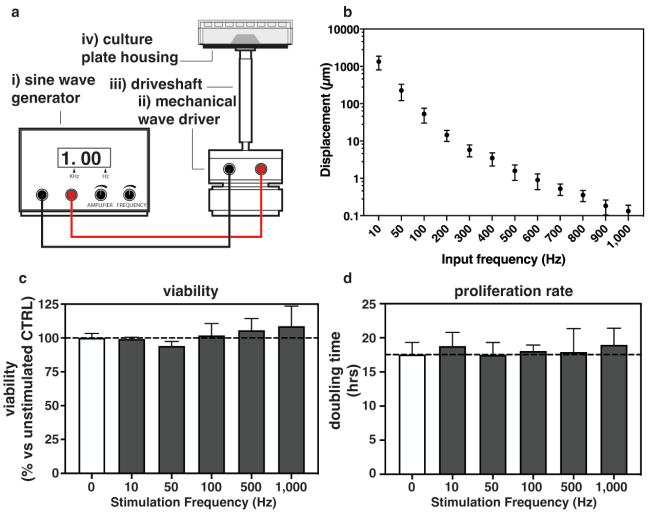

Figure 1. (**a**) Representation of the vibrational loading device. (**b**) Displacement values of the motion shaft as a function of the input frequency (f_{in}). (**c**) Viability and (**d**) doubling time of L929 cells that underwent vibrational loading for 5 min at different stimulation frequencies. Data are expressed as mean ± SD (n = 3).

B. Assessment of the cell response to vibrational loading

To assess the effects of the vibrational loading on the overall cell response, the viability and proliferation rate of adherent L929 cells were evaluated upon a 5 min-long vibrational loading. Interestingly, there were no changes in the cell viability as a function of the wave frequency applied (**Figure 1c**) nor alterations in the cell doubling time (**Figure 1d**).

To shed more light on the effect of vibrational loading on cell response, SEM analyses of stimulated cells were carried out. Because plasmalemma defines cell boundaries, it is the first barrier to the delivery of exogenous cargoes into the cell. In this case, a 5-min vibrational loading at $f_{in} \geq 100$ Hz did elicit gross cell morphological changes (**Figure 2a**). As opposed to unstimulated controls that appeared markedly smoother, stimulated cells at $f_{in} \geq 100$ Hz exhibited a rough surface, densely studded with membrane protrusions, which are blister-like outgrowths of the plasma membrane that may occur upon membrane detachment from the underlying cytoskeleton in diverse circumstances[12]. We also decided to monitor the cell membrane recovery after vibrational loading. As reported in **Figure 2b**, cells mostly reverted to normal morphology within about 1 hr, thus suggesting that mechano-induced membrane destabilization could be harnessed to enhance membrane trafficking and improve the delivery of NAs into cells.

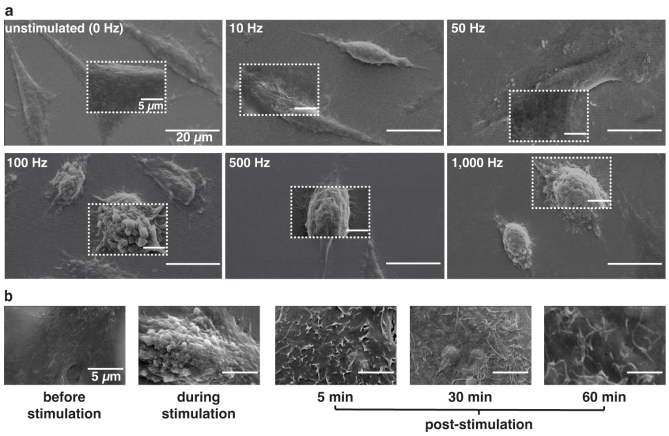

Figure 2. SEM images of L929 cells (**a**) undergoing vibrational loading at different input frequencies and (**b**) before, during and at 5, 30 and 60 min after discontinuation of the vibrational loading. Scale bar = 20 µm (a), 5 µm (insets in (a) and (b)).

C. Effectiveness of the vibropolyfection strategy

To explore whether the vibropolyfection strategy would improve transfection, we challenged vibrational loaded L929 cells with non-viral gene delivery particles consisting of the *gold standard* *l*PEI and pGLuc as described in the previous section. It is apparent from **Figure 3a** that the cytotoxicity induced by vibropolyfection was negligible, thus highlighting that the combination of vibrational loading and polyplexes delivery does not compromise cell viability.

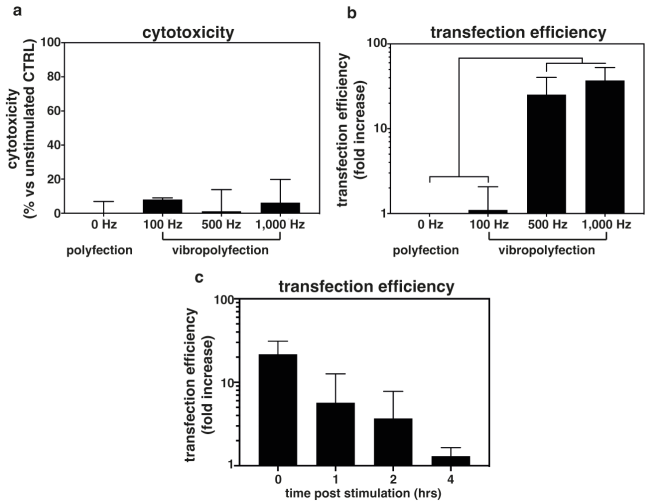

Figure 3. (**a**) Cytotoxicity and (**b**) TE, expressed in terms of fold increase with respect to polyfection, of /PEI/pDNA complexes delivered in the presence of 5-min vibration loading at different frequencies. (**c**) Fold increase in TE of /PEI/pDNA complexes on L929 cells transfected at different periods from stimulation. Data are expressed as mean ± SD (n≥3), *p<0.05.

Besides, the higher the f_{in} the higher the TE. Of note, cells stimulated at f_{in} = 1,000 Hz displayed a 37-fold increase in TE compared to polyfected cells (**Figure 3b**).

We observed that the positive effect of the vibrational loading on transfection steadily decreased over time, alongside membrane recovery, and was practically lost 4 hrs upon the discontinuation of the stimulation (**Figure 3c**). We can speculate that the cell membrane recovery that occurs in response to the mechano-induced plasmalemma blebbing and ruffling may favourably impact endocytosis[13], which ultimately improves transfection efficiency.

D. Vibrational loading positively affects polyplex uptake

To study the effect of vibrational loading on polyplex uptake, we quantified the amount of pDNA internalized during classical transfection *vs*. vibropolyfection by means of qRT-PCR. As depicted in **Figure 4a**, vibropolyfection induced a ≈ 8.5-fold increase in the amount of pDNA uptaken by cells. We thus assumed that the boost in TE found in vibropolyfected cells directly relates to an increase in polyplexes internalization, as also suggested by the greater amount of polyplexes (green dots) found in vibropolyfected cells assessed by confocal microscopy (**Figure 4b**).

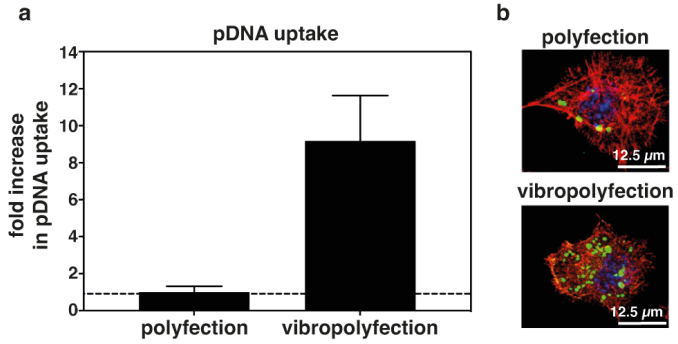

Figure 4. (**a**) Fold increase in pDNA uptake by polyfected *vs.* vibropolyfected cells as determined by qRT-PCR. Data are expressed as mean ± SD (n=3). (**b**) Confocal images of L929 transfected cells according to polyfection and vibropolyfection at 1,000 Hz. Cells were fixed 4 hrs from polyplex delivery. Polyplexes are in green, F-actin in red and nuclei in blue. Scale bar = 12.5 μm.

E. Vibrational loading triggers clathrin-mediated endocytosis

There is a general consensus that two distinct endocytic pathways (i.e., CME and CvME) may contribute to polyplex internalization[14]. To investigate the contribution of each endocytic pathway to the overall polyplex uptake in vibropolyfected cells, L929 cells were treated with either chlorpromazine or filipin, which are two inhibitors of CME and CvME, respectively, before undergoing polyfection and vibropolyfection. In polyfected, cells, TE was not affected by the inhibition of clathrin-mediated endocytosis (**Figure 5a**), whereas luciferase expression was dramatically reduced by caveolae inhibition, in accordance with literature data[15]. On the contrary, the separate inhibition of CME and CvME significantly impaired TE in vibropolyfected cells (**Figure 5a**), thus suggesting that vibrational loading triggers the activation of CME. Of note, CME was found to be upregulated in response to changes in cell membrane tension. To gain more insight into the role of CME and CvME on polyplex uptake, we also immunolabelled clathrin heavy chain and caveolin-1 proteins in polyfected and vibropolyfected cells. As shown in **Figure 5b**, vibropolyfected cells showed significantly higher clathrin levels than polyfected cells, in accordance with data reported in **Figure 5a**.

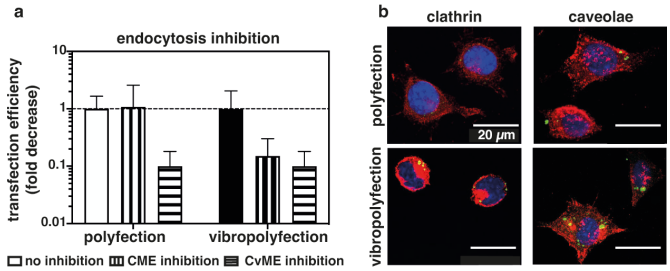

Figure 5. (**a**) Effect of CME and CvME inhibitors on polyfected and vibropolyfected cells. Data are expressed as fold decrease in TE in cells treated with inhibitors compared to cells transfected in the absence of inhibitors. Data are expressed as mean ± SD (n = 3), *p<0.05 vs cells transfected in the absence of inhibitor. (**b**) Confocal images of polyfected and vibropolyfected L929 cells. Clathrin heavy chain and caveolin-1 are stained in red, polyplexes in green and nuclei in blue. Scale bar = 20 μm.

IV. Conclusion

Herein, we developed a safe, user-friendly, and efficient *in vitro* transfection strategy based on the coupling of mechanical loading to commonly used polymeric particles. The study paves the way for using mechanical cell stimulation as a tool to improve the effectiveness of gene delivery vectors by modulating cell responses.

***Abstract*— In-vitro 3D models of human nasal mucosa cells can offer a deeper understanding of airway pathophysiology and drug discovery. In this work, a microfluidic chip was designed with an air-liquid interface (ALI) as a model to mimicry the *in vivo* environment of the respiratory mucosa. A biopolymeric scaffold was integrated to act as biocompatible ALI membrane. The platform was structured using a rapid prototyping technique. A computational fluid dynamic (CFD) analysis was conducted to evaluate the air-induced shear stress on the scaffold. CFD was employed to find the target flow rate to replicate desired mechanical characteristics within a specific region of the human nasal cavity. According to this data, peristaltic pumps for air and liquid flows, were programmed to replicate physiological flows and dynamic air-induced shear stresses shear stresses on the culture.**

***Keywords*— Air-Liquid-Interface; Organ-on-Chip; Laser ablation; Rapid prototyping; PLLA scaffold.**

I. Introduction

Long-term functional solutions for extensive airway diseases and damages a central focus of research in the fields of regenerative medicine and tissue engineering. Among the airway tissue of the human body, the nasal mucosa is the first site to be exposed to inhaled agents, such as pollutants, particles, allergen, or gases [1]. Three-dimensional (3D) cultures represent a significant advancement in the field of cellular biology and regenerative medicine, providing more realistic and physiologically relevant models for the study of cells and tissues. The 3D culture outgrowth model is based on the formation of self-organized three-dimensional structures derived from patient biopsy tissue, which grow and interact similarly to what is observed *in vivo*.

To create a nasal mucosa biological model, an air–liquid-interface (ALI) culture is needed so that the basal cells can differentiate in goblet and ciliated cells, allowing the movement of mucus and foreign particles that *in vivo* are pushed along the airways. The direct exposure of epithelial cells to air is the pivotal differentiation stimulus to obtain properly developed ciliated elements [2], [3]. Previous studies reported values from CFD simulations performed on computed tomography (CT)-based nasal cavity models investigating the velocities and shear forces applied to mucosal walls during quiescent breathing [4].

Organ-on-Chip (OoC) platforms play a key role in actively supporting the three-dimensional (3D) maturation of cells by replicating the proper biomechanical and biological conditions, such as providing adequate hydrodynamic stimuli and mass transport [5].

This study aimed to develop an air-liquid interface (ALI) microfluidic device for growth of human respiratory mucosa biopsies by means of a rapid prototyping fabrication technique. The device was manufactured by laser cutting and multilayer assembling of polymethylmethacrylate (PMMA) sheets. A biopolymeric scaffold made in Poly-L-Lactic Acid (PLLA) was also integrated into the platform and used as biocompatible ALI membrane [6].

In order to induce the physiological range of wall shear stresses on the outgrowth [4], fluid dynamic simulations were carried out to determine the appropriate air flow rate to be delivered. The flow delivery system of both the air and medium chambers was controlled by a microcontroller connected to peristaltic pumps. To investigate the effective dynamics of both air and medium flows in the OoC, the fluids of interest were characterized through the use of pressure sensors. The morphology of the scaffold was evaluated before and after their integration in the OoC platform.

Finally, preliminary cytocompatibility tests were performed on human nasal mucosa grown under dynamic conditions in the OoC.

II. Materials and Methods

A. Design and fabrication of the ALI microfluidic device

The ALI -OoC consisted of (1) channels for the transport of air and medium, and (2) a 0.32 cm^2 culture chamber.

The culture chamber was designed with two compartments separated by a biopolymeric membrane. The upper compartment was designed for the gaseous flow while the bottom compartment consisted of micro-channels for the medium flow.

The design of whole device was divided into 6 functional layers to be fabricated by means of laser cutting (Maitech, 40 W, Italy) of PMMA sheets (Clarex, Nitto Jushi Kogyo Co. Ltd., JP). The functional PMMA layers were then bonded together by means of multilayer assembling in hot press. Layers were aligned in a custom-made mold endowed with metallic pins. The PMMA layers and the scaffold were placed in the mold and was applied to their surfaces before bonding. The bonding was process was conducted at 70 °C and 100 bar for 3 min in a laboratory press [6].

B. Design and fabrication of the tubing connectors

The customized tubing connector was designed by means of a CAD software (Fusion 360©) and printed via stereolithographic 3D printer (FormLab, Form 2) by using a commercial resin (Clear V4, FormLab). The connector included pins for the easy alignment with the OoC platform and holes for the integration of commercial plastic ferrules and

PTFE tubing (OD 1/16", ID 1/32"). The sealing of the connector with the ALI-OoC was ensured via screws.

C. PLLA scaffold preparation

The biopolymeric scaffolds were prepared via Thermal induced phase separation TIPS technique. TIPS membranes were prepared by dissolving PLLA (4 wt%) in an 87/13 *w/w* dioxane-water mixture at 120 °C. The solution, kept above 60 °C to ensure homogeneity, was hot poured in a cylindrical high-density polyethylene (HDPE) mold. The mold filled with the polymer solution was first immersed for 10 min in a 0 °C bath and then moved to a –20 °C bath for 20 min in order to allow the complete freezing of the as-obtained structure. Successively, the foams were extracted from the mold and subjected to a washing step in distilled water. Finally, the foams were dried under vacuum for 24 h to ensure the complete removal of any solvent trace. The subsequently obtained membranes were then cut to obtain slices 0.5 mm thick. The scaffolds were furtherly cut via laser cutting and surface modified by means of air-plasma treatment before assembling in the OoC platform.

D. Morphological Analysis

The morphology of the PLLA scaffolds was evaluated by scanning electron microscopy, (SEM-FEI QUANTA 200F) before and after integration in the ALI platform. The samples were attached on an aluminium stub using adhesive carbon tape. Therefore, they were sputter coated with gold (Sputtering Scancoat Six, Edwards) for 60 s under argon atmosphere before imaging to avoid electrostatic discharge during the test.

E. Chip transparency

The transparency of the PMMA sheets 0.5 mm thick before and after bonding was tested by analysing the transmittance of the light through in the visible region using a UV-vis spectrophotometer (model UVPC 2401, Shimadzu Italia s.r.l., Milan, Italy).

F. Flow analysis

Fluid dynamic simulations were performed by using ANSYS Fluent © as software to determine the WSS in the culture chamber of the OoC platform. Those values were compared to previously reported data from CFD simulations performed on computed tomography (CT)-based nasal cavity models.

Culture chamber geometry was created in Fusion 360© and imported into ANSYS ICEM CFD© in which mesh geometry was generated with tetrahedral elements. The final culture chamber geometry mesh ranged from 300×10^3 to 400×10^3 hybrid finite elements.

The generated mesh was imported into ANSYS Fluent, and a steady state laminar flow was simulated at various inlet velocities whit a outlet pressure of 0 Pa. The fluid material properties was set as air, and the usual no-slip velocity condition was assumed.

The SIMPLEC algorithm was used to link pressure and velocity and convergence was obtained when the scaled residuals of continuity and momentum quantities were less than 10^{-5}. WSS values were obtained in the lower wall of the culture chamber that coincides to the upper surface of the scaffold.

LabSmith pressure sensor (LabSmith uPS-series pressure sensor, model: uPS1800-T116-10) was used to measure both medium and air pressure in the device as a function of time.

G. Outgrowths

Upon obtaining a respiratory mucosa biopsy sample (nasal mucosa from patients undergoing partial turbinectomy), the specimen is washed in PBS (supplemented with 100 µg/ml of streptomycin and 100 IU/ml of penicillin) to remove excess blood and mucus. The tissue is then transferred for the subsequent 24 hours to a Petri dish containing Dulbecco's Modified Eagle Medium with the addition of 10% fetal bovine serum and supplemented with 100 µg/ml of streptomycin and 100 IU/ml of penicillin. After 24 hours, necessary for assessing the presence of contaminants, the tissue was processed, creating fragments of approximately 0.5 mm^3. This tissue fragment includes the epithelial, the endothelial, and the connective cellular elements of the original tissue, as well as the progenitor cells required to ensure tissue turnover.

The OoC system was sterilized by flowing 70% ethanol for 5 minutes inside the channels and chambers, dried, washed with sterile Dulbecco's phosphate-buffered saline (DPBS) and irradiated with UV for 6 hours.

The biopsy was placed in the center of the upper surface of the scaffold and 13 µl of protein gel (Cultrex Basement Membrane Extract, BME) was added to the chamber and polymerized at 37 °C for ten minutes.

Both peristaltic pumps were connected to the microfluidic inlets of the device and to the reservoirs using 3D printed customized connectors. The entire platform was placed in a cell incubator and the pumps were turned on.

A constant flow of the culture medium (1.4 ml/s) was supplied for the replacement of the liquid medium. The dynamic flow rate of the aeriform medium was set according to the FANTASIA database of respiration belt data by means of a microcontroller. The outgrowth was maintained for up to 14 days and both microscopical evaluation and histological analysis (hematoxylin & eosin staining) were performed to visualize the tissue.

III. Results and Discussion

A. OoC Platform fabrication

The fabrication of the OoC for the nasal mucosa involved the laser ablation of six PMMA layers according to the design in Fig. 1A. The processing allowed obtaining patterns with maximum resolution of 200 µm. After assembling, the device appears transparent exception for the biopolymeric membrane, Fig. 1B. By flowing water containing a green dye, no leaking was observed thus convincing about the correct sealing of channels, chambers, and tubing connectors, Fig. 1C. The transparency of the device was measured by UV-Vis transmittance of 0.5 mm thick PMMA layers before and after bonding. Results (not shown) highlighted a transmittance greater than 91.7% for both samples in the entire visible

spectrum (400-700 nm). The transmittance of the bonded system is slightly lower than the single layer of PMMA, only for wavelengths lower than 400 nm. Therefore, this characterization allowed us to conclude that the transparency of the chosen materials is preserved even after the multilayer assembly process making them suitable for direct investigation of the culture by means of optical micrographs.

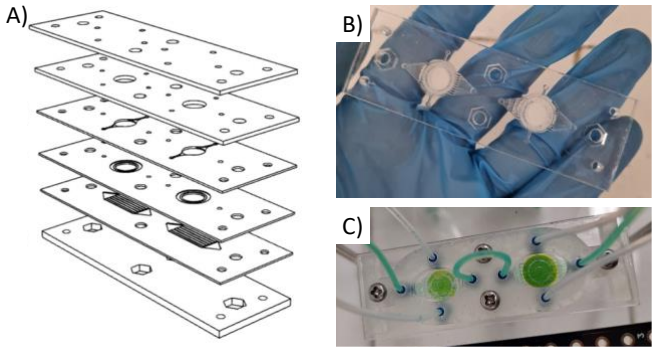

Fig. 1: A) Design of the six layers composing the whole OoC; B) Picture of the assembled OoC; C) Picture of the OoC filled with a green dye.

B. *Flow analysis*

In order to imitate the physiological breath, the air flow peristaltic pump has been programmed to manage a bidirectional flow following the trend of a single breath isolated from the Fantasia data.

According to the CFD analyses (Figure 2), the air flow at the peak of the inhalation was set at 0.2 ml/s to allow a gradient of the wall shear stresses (WSSs) in the range 0 - 0.3 Pa. This range of WSSs agree with the physiological values in healthy humans according to [4].

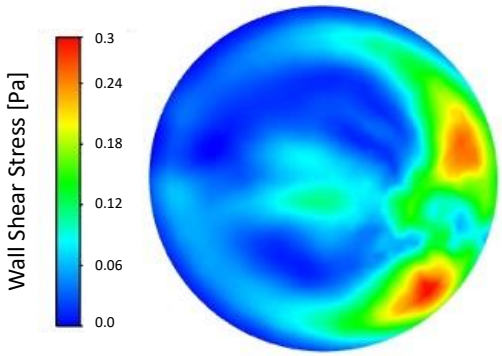

Fig. 2: Wall shear stress map evaluated on the top surface of the scaffold.

Figure 3 reports the pressure due to the air and medium flow inside the culture chambers measured at the inlets of the device. Interestingly, the air pressure curve is comparable to the physiological data obtained from the Fantasia database in terms of breath frequency and inhalation vs. exhalation amplitude ratio. These results convinced about the correct functioning of the programming code implemented in the microcontroller for the regulation of the flows. The pressure the fluid flow was evaluated at a constant flow rate equal to 1.4 ml/s, Fig. 2. It can be observed that the liquid pressure varies in a range of about -1 and -3 kPa, tanging an average value of -2 kPa. This result was desired since the liquid pump was plugged at the medium outlet in order to suck up the liquid phase thus avoiding the flooding of the upper culture chamber.

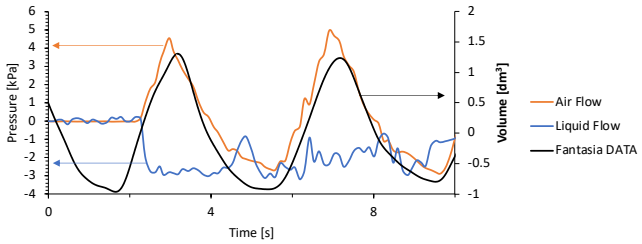

Fig. 3: Pressure of liquid and air flow in the OoC and breath volume obtained from FANTASIA belt data.

C. *Scaffold morphology*

Fig. 4 reports SEM images of the PLLA before (Fig. 4A) and after (Fig. 4B) their integration into the OoC platform. From the micrographs, it is possible to appreciate that the liquid-liquid phase separation process has correctly taken place since a porous structure with well-interconnected pores can be observed. The mean pore size is around 25 µm and the pore size distribution is quite homogenous. This pore size was chosen as adequate since allowed the diffusion of the liquid medium avoiding the permeation of the outgrowth cells inside the scaffold. The effect of thermal treatment needed for the integration of the scaffold in the OoC platform had no effect on the porous architecture of the scaffolds. This result convinced us about the efficacy of the chosen processing route for the integration of biopolymeric porous structures made in PLLA by means of TIPS.

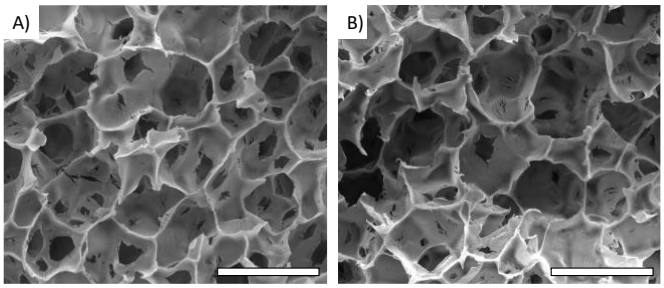

Fig. 4: SEM images of the PLLA scaffolds A) before and B) after integration in the OoC platform. Scale bars are 50 µm.

D. *Nasal mucosa viability*

The device allowed maintaining the air–liquid interface up to 2 weeks. After two weeks of culture, the cell populations start to outgrowth from the initial biopsy fragment to form a 3D structure. Histological results showed the presence of viable cells above the membrane, (Fig. 4). Furthermore, the outgrowth appears well-adherent on the PLLA membranes used as support for the culture.

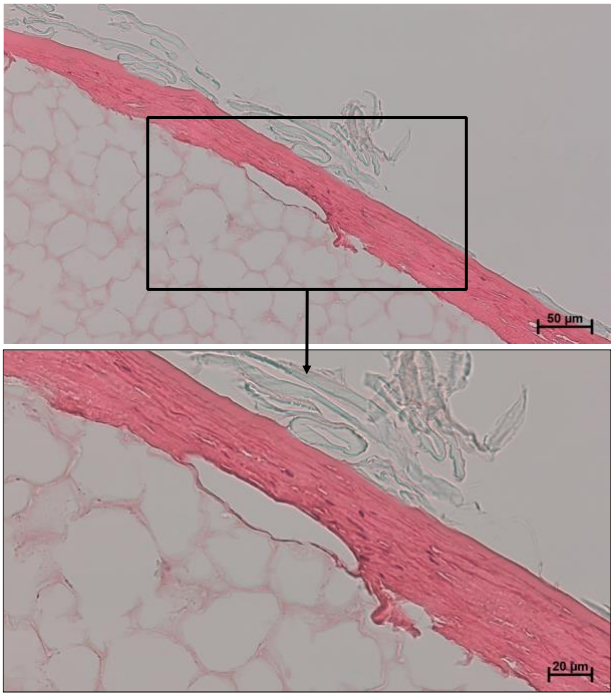

Fig. 5: Histological assay in hematoxylin and eosin of human nasal mucosa tissue after 14 days of culture in the OoC platform.

IV. Conclusion

This work demonstrated the feasibility of an ALI device for nasal mucosa outgrowth culture by means of a rapid prototyping technique. The processing route allowed integrating a biopolymeric scaffold to separate the air-liquid chambers and able to support the growth and differentiation of nasal mucosa cell population . The customized control of the air-pumps allowed for replicating physiological air flows and shear stresses on the culture. The device allowed maintaining the ALI condition for up to 2 weeks and to allow for the growth and differentiation of the outgrowth culture.

***Abstract*— Patients with Parkinson's disease are often afflicted by non-motor symptoms including fatigue. Alterations of multiple neurotransmitter systems, including dopamine and noradrenaline, have been hypothesized to play a role in the pathogenesis of fatigue. However, whether and how dysfunction in their underlying neurocircuitries contribute to fatigue remains elusive. Here, we used resting-state functional MRI data of 29 patients with Parkinson's disease to investigate associations between clinical ratings of fatigue and functional connectivity within dopamine and noradrenaline transporter-defined functional networks by applying a recently developed multimodal framework "Receptor-Enriched Analysis of functional Connectivity by Targets". We found a negative linear relation between fatigue and noradrenaline-enriched functional connectivity in regions of the sensorimotor and salience networks, and a positive linear trend between fatigue and dopamine-enriched functional connectivity in regions of the default mode network. These findings provide empirical support to the hypothesised dysfunctions in the brain's monoaminergic circuits in Parkinson's patients with fatigue.**

***Keywords*— Parkinson's disease, fatigue, resting state functional connectivity, neurotransmitter.**

I. INTRODUCTION

Fatigue is a frequent symptom in patients with Parkinson's disease (PD) and it affects about half of PD patients, reducing the quality of life and limiting their physical and cognitive performances [1]. To date the precise neurobiological mechanisms underlying fatigue in PD remain elusive, posing limitations to the identification of targeted treatments.

PD is associated with abnormal degeneration of nigrostriatal dopamine (DA) neurons combined with alterations of multiple neurotransmitter systems [2]. Previous studies have examined the role of DA in fatigue, showing that a disruption in the pathways between the striatum and the prefrontal cortex, which is regulated by DA, is linked to fatigue [3]. Moreover, functional and structural neuroimaging studies of PD have shown abnormalities in the frontal and striatal regions that are heavily innervated by DA neurons [3].

In addition to DA, another neurotransmitter, noradrenaline (NE), has also been hypothesized to play a role in the pathogenesis of fatigue. However, the link between NE and fatigue in PD has been explored only in one single study [4] so far, which has reported no significant correlations between fatigue severity and degeneration of the locus coeruleus, where NE is mainly synthesized.

To date, the brain mechanisms underlying fatigue in PD have been investigated mostly using functional magnetic resonance imaging (fMRI). Employing resting-state fMRI (rs-fMRI), two studies [5], [6] have shown that fatigue is correlated with decreased functional connectivity (FC) within the sensorimotor network in the supplementary motor area and increased FC in the prefrontal and posterior cingulate cortices within the default mode network. However, since BOLD fMRI lacks specificity to dissect the contribution of specific neurotransmitters to the signal changes observed in patients, identifying which neurotransmitters might hold greater value as potential targeted treatments has been challenging.

Recently, a new framework of analysis named "Receptor-Enriched Analysis of functional Connectivity by Targets" (REACT) [7] has been developed to enhance rs-fMRI with Positron Emission Tomography imaging data derived from publicly available receptor templates to investigate FC changes within networks informed by the spatial distribution of the density of specific molecular targets. Applying this new framework to rs-fMRI data of multiple sclerosis patients, a recent study [8] has found a negative linear association between cognitive fatigue and noradrenaline transporter (NET)-related FC in frontal regions.

In this study we applied REACT to rs-fMRI data of PD patients to investigate how the functional networks associated to the dopamine transporter (DAT) and NET relate to interindividual differences in fatigue severity. Based on previous findings, we hypothesised that DAT- and NET-enriched FC would correlate with clinical ratings of fatigue in regions of the motor and cingulate cortices.

II. MATERIALS AND METHODS

The study involved 29 consecutive patients (17 men; mean age 64.9y, range [49-77y]) affected by PD, recruited at the Neurology Unit, Movement Disorders Division, University of Verona, Italy. Inclusion criteria were: age 30–80 years, diagnosis of idiopathic PD [9], mild-to-moderate PD (Modified Hoehn & Yahr stage I–III). Participants with pacemakers or ferromagnetic implants and patients with

dementia (Montreal Cognitive Assessment test score<21), or severe psychiatric disorders were excluded. Fatigue was assessed using the Fatigue Severity Scale (FSS), a nine-item easy to administer scale [10] recommended for screening and grading severity in PD [11]. To control for the main potential confounding factors of fatigue, scales for psychiatric disturbances (Hospital Anxiety and Depression Scale), apathy (Apathy Evaluation Scale), excessive daytime somnolence (Epworth Sleepiness Scale) and sleep disorders (Parkinson's disease sleep scale) were administered. Disease severity was assessed by means of UPDRS part III. All examinations were performed with patients ON their dopaminergic treatment. The total dose of dopaminergic drugs was converted to the common metric so-called levodopa equivalent daily dose (LEDD). All participants gave written informed consent to the research protocol, which was approved by the ethical committee of the University Hospital of Verona, conforming to the Helsinki declaration.

Patients' main clinical and demographical characteristics are reported in Table I.

TABLE I

PD=Parkinson's disease; FSS=Fatigue Severity Scale; LEDD=levodopa equivalent daily dose

A. MRI acquisition protocol

Images were acquired at the University Hospital of Verona, on a 3T Philips Elition S scanner equipped with a 32-channels head coil. The MR brain imaging protocol included the following sequences: a structural T1-weighted Turbo Field Echo (TR/TE 8.2/3.7ms, 1x1x1mm^3 Acc. Factor Compressed SENSE 3); 10 minutes of rs-fMRI acquired with single shot Echo-Planar Imaging (TR/TE 1100/30ms, FA 64°, 2.4x2.4x2.4mm^3, Acc. factor: MultiBand 4, SENSE 1.9, anterior-posterior phase encoding direction, 500 volumes); two spin echo Echo-Planar Imaging sequences acquired for distortions correction purposes and geometrically matched with the rs-fMRI sequence (Acc. factor: SENSE 1.9, anterior-posterior and posterior-anterior phase encoding directions).

B. MRI data analysis

Pre-processing: Structural and functional images were processed using a combination of the following software: Advanced Normalization Tools software [12] and FMRIB Software Library (FSL) [13].

The T1-weighted image was bias field corrected with N4 [14], skull-stripped and registered to the FSL's MNI atlas, using a nonlinear diffeomorphic registration [12]. The T1-weighted image was also used to extract a subject-specific estimate of the total intracranial volume with FreeSurfer [15].

Rs-fMRI data were pre-processed in the native space following these steps: slice timing, readout distortion (FSL's TOPUP [16]) correction and affine realignment of volumes to the central image of the acquisition. The estimated motion parameters were exploited to compute the framewise displacement [17] for each patient. To remove possible sources of noise, we performed multiple regression of the six head motion parameters, their temporal derivatives, mean white matter and cerebrospinal fluid signals [18]. Rs-fMRI volumes were high-pass filtered (cut-off frequency = 1/128 Hz) and then non-linearly co-registered to the MNI space exploiting the subject-specific T1-weighted image (via FSL's boundary-based registration [19]). Finally, rs-fMRI data were smoothed with a Gaussian kernel of 5 mm^3.

REACT analysis: For the REACT analysis [7], we used publicly available molecular templates of the DAT [20] and NET [21] neuroreceptor systems. The DAT template derived from ^{123}I-Ioflupane Single-Photon Emission Computerized Tomography images from 30 healthy subjects without evidence of nigrostriatal degeneration. The NET template was obtained by averaging the [^{11}C]MRB Positron Emission Tomography brain parametric maps from a cohort of 10 healthy subjects. Both the templates were normalized by scaling the map values between 0 and 1. Then, the occipital areas, used as reference regions for quantification of the molecular data in the kinetic model, were masked out.

To investigate changes in functional connectivity related to the DAT and NET systems, the REACT pipeline employs a two-steps multiple regression analysis [22]. Specifically, in the first step, the two molecular templates are used as a set of spatial regressors to weigh the subject-specific rs-fMRI volumes and estimate the dominant BOLD fluctuation related to each molecular system. In the second step, the subject-specific time series obtained before are used as temporal regressors to estimate the subject-specific spatial maps associated to each molecular system. Thus, after running REACT, two spatial maps reflecting the specific transporter-enriched FC are obtained for each subject. The REACT analysis was conducted within the grey-matter mask.

Statistical analysis: The subject-specific target-enriched FC spatial maps were used as input to a non-parametric permutation-based statistical test using FSL's PALM to investigate the linear relationship between both DAT- and NET-enriched FC and FSS [23]. To speed up the permutation test we set the number of the permutations to 500 and we used the tail approximation approach [23]. FSS scores were used as predictors, while age, sex, LEDD and total intracranial volume as covariates of no-interest. The threshold-free cluster enhancement [24] was used to identify statistically significant clusters (p-value<0.05) of voxels while maintaining familywise-error control. Threshold-free cluster enhancement parameters were set respectively to H = 2, E = 2, C = 6. Next, we identified networks of the Schaefer's functional atlas [25] overlapping with clusters of voxels resulted statistically significant in the permutation test. Within these networks we conducted a partial correlation analysis to assess the relationship between FSS scores and averaged target-enriched FC values, considering age, sex, LEDD and total intracranial volume as covariates.

III. RESULTS

Figure 1 reports the spatial maps of the clusters that resulted statistically significant after permutation testing (p-values<0.05, threshold-free cluster enhancement and familywise-error corrected). For the NET-enriched FC (Figure 1, top panel), these clusters were located around the supplementary motor area, left postcentral gyrus, left precuneus and left middle-cingulate cortex and right rolandic operculum, regions belonging to sensorimotor and salience networks in the Schaefer's atlas. For the DAT-enriched FC (Figure 1, bottom panel), these clusters were located in the precuneus and posterior-cingulate cortex, regions belonging to the default mode network in the Schaefer's atlas.

In Figure 2, left panel, we provide for illustrative purposes the partial correlation results between FSS scores and NET-enriched FC within the sensorimotor and salience networks (left panel) and, in the right panel, between FSS and DAT-enriched FC within the default mode network.

FSS scores and NET-enriched FC were anticorrelated (Pearson's r=-0.48), while between FSS scores and DAT-enriched FC a positive correlation was found (Pearson's r=0.33).

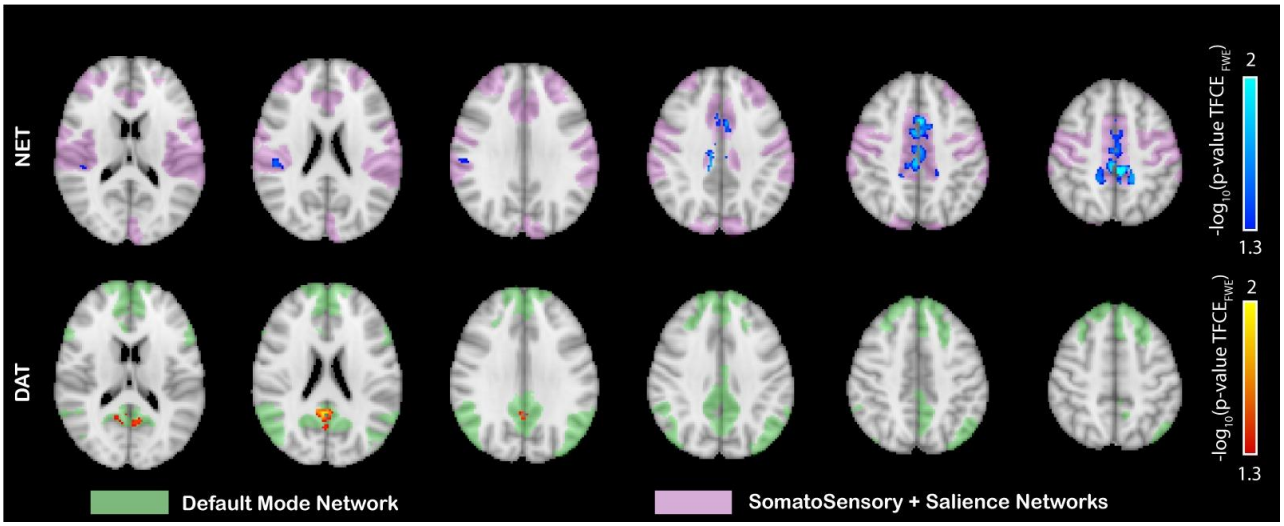

Fig. 1: Clusters of statistically significant NET-enriched FC (top row), overimposed to Schaefer's functional salience and sensorimotor networks in green. In the bottom row, clusters of statistically significant DAT-enriched FC are overimposed to Schaefer's functional default mode network in green. The color scales represent -log(p-value), after correction for multiple comparisons. The statistical maps are overlaid onto the MNI atlas. Abbreviations: NET=noradrenaline transporter; FC=functional connectivity; DAT= dopamine transporter; TFCE= threshold-free cluster enhancement; FWE=familywise-error.

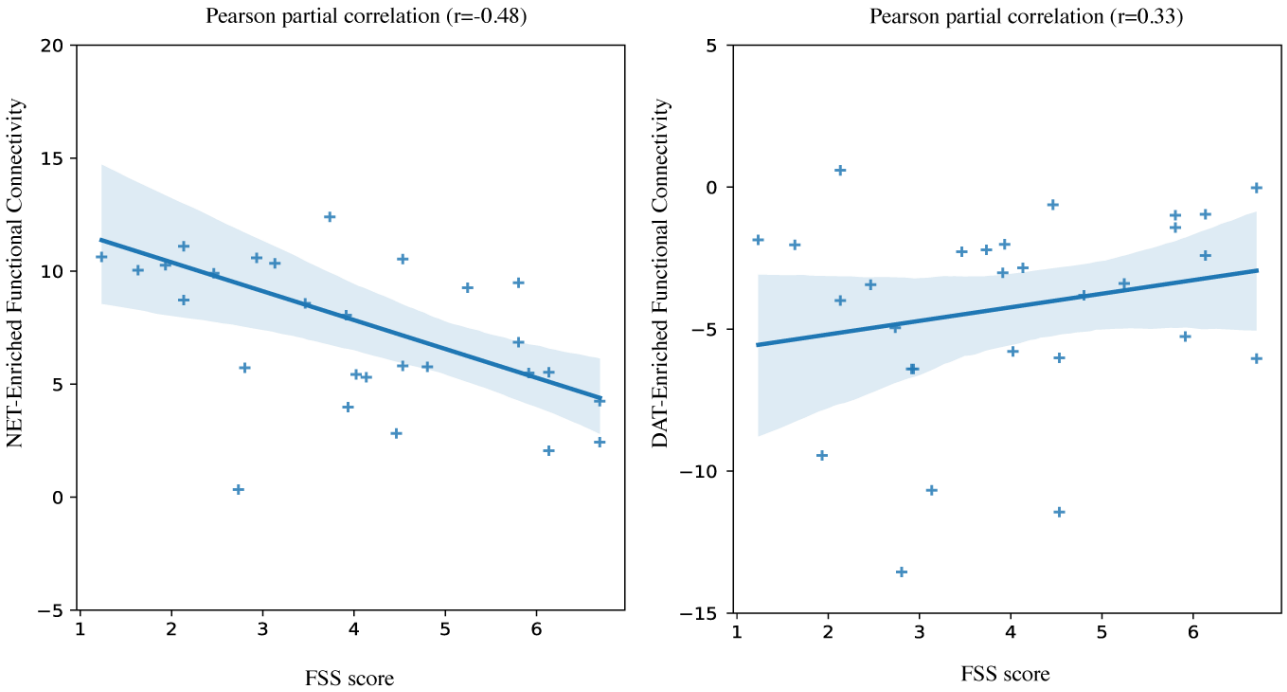

Fig. 2: The left panel reports the partial correlation results between FSS scores and NET-enriched FC within the sensorimotor and salience networks. In the right panel, the partial correlation results between FSS and DAT-enriched FC within the default mode network are shown. Abbreviations: NET=noradrenaline transporter; FC=functional connectivity; DAT= dopamine transporter; FSS=Fatigue Severity Scale.

IV. CONCLUSION

In this study we used a recently developed multimodal approach to investigate associations between clinical ratings of fatigue and FC measured at rest associated with the NET and DAT circuits in patients with PD. We found a negative linear relationship between NET-enriched FC and FSS in regions of the sensorimotor and salience networks and a positive linear relationship between DAT-enriched FC and FSS in regions of the default mode network. Since previous studies reported FC decreases within the sensorimotor network and FC increases within the default mode network in PD patients with fatigue [5], [6], we hypothesize that these FC alterations could be directly related to NET- and DAT- functional circuits.

In addition, our results on NET-enriched FC are in agreement with previously reported FC decreases in NET-related functional circuits in patients with multiple sclerosis and cognitive fatigue [8]. Although in a different clinical population with a different form of fatigue, the results highlight the potential role of NE in explaining the pathogenesis of fatigue.

Taken together, our findings provide preliminary empirical evidence supporting potential dysfunctions in the functional networks associated to the dopaminergic and noradrenergic systems in PD patients with fatigue.

Moreover, our work highlights the value of the multimodal integration of features derived from Positron Emission Tomography imaging and rs-fMRI through REACT as a way forward to advance our understanding of the neural mechanisms underlying fatigue in PD and test the effects of newly targeted treatments.

***Abstract*—In the framework of biomedical imaging, ultrasound tomography has recently proven to be an attractive solution for non-invasive, non-destructive diagnostic imaging. More in detail, this technique exploits mechanical waves which are safe for the patient and can be considered for frequent screening. The aim of this technique is to retrieve the mechanical information of breast inner tissue via the analysis of pressure waves acquired by sensors surrounding the region of interest. In this paper a stepped breast-cancer-imaging approach via ultrasound tomography is proposed. The tumour extension and localisation are retrieved via solving a set of linear inverse scattering problems in a step-by-step fashion. The proposed approach seems to be promising in terms of malignancy identification.**

***Keywords*—Ultrasound tomography, tomographic imaging, MIMO systems, inverse scattering, coherent imaging, biomedical imaging.**

I. Introduction

Breast tumour represents a type of cancer with the highest incidence among adult women (higher than 29% as reported in [1]). During the last decades several research groups focused on the development of new strategies for efficient early breast cancer diagnosis by means of either quantitative or qualitative imaging.

Numerous conventional techniques for breast cancer imaging (BCI) are based on the use of ionizing radiations such as X and γ rays (e.g., computed tomography, positron emission tomography, etc.). These former approaches share the same drawback of limited time exposition due to the use of ionising radiations [2]. A further conventional technique for breast cancer diagnosis is the magnetic resonance imaging (MRI), which exploits static magnetic fields and radio-frequency pulses to perform this investigation and thus it is safe from patient's perspective. Despite a good spatial resolution, MRI presents long acquisition time and high costs. Mechanical properties of the breast in terms of density, attenuation and propagation speed are substantially different between healthy and malignant tissues [3]. For this reason ultrasound waves can be exploited for breast cancer imaging. Conventional ultrasound (US) considers a hand-held probe that scans the region under investigation. Thus, this aspect is one of the main bottlenecks of conventional US imaging.

In this framework a recent solution is represented by ultrasound tomography (UST). This technique considers the analysis of pressure waves generated and measured by US sensors placed around a region of interest [4], [5]. Most recent UST prototypes exploit several US sensors and in some cases the UST is used in combination with other imaging techniques, e.g. microwave tomography [6], [7].

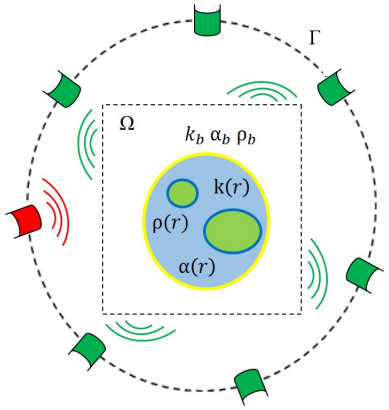

Fig. 1: Sketch of the 2D ultrasound tomography. Γ is the curve containing the ultrasound transducers. Ω is the region under investigation. The quantities κ, ρ and α are the acoustic compressibility, density and attenuation of the objects located inside the background medium with parameters κ_b, ρ_b and α_b.

The problem of retrieving the mechanical properties of breast inner tissues is non-linear and ill-posed [8], [9]. Therefore, most inversion algorithms exploit strong a-priori information and advanced regularisation strategies to obtain reliable recoveries [10], [11]. Among the most adopted linear approximations, it is worth to mention the well-known Born approximation (BA), which assumes that the presence of the target slightly perturbs the field [12].

In this paper some two-dimensional (2D) numerical simulations of an UST system for breast cancer imaging purposes are proposed. The forward solver is carried out via K-Wave, a Matlab toolbox designed for photo-acoustic simulation in time domain[13]. The considered scenarios include simplified phantoms mimicking breast inner tissues (fat and fibroglandular). Once acquired the US scattering data, a qualitative inversion to retrieve tumour extension is obtained via the Born approximation in a three-step procedure. The results show the possibility to retrieve information about position and size of the malignant tissue.

The remainder of the paper is the following: in Section II a brief mathematical recall of the problem at hand is provided, while in Section III the considered methodology and related imaging results are presented and discussed. Some conclusions

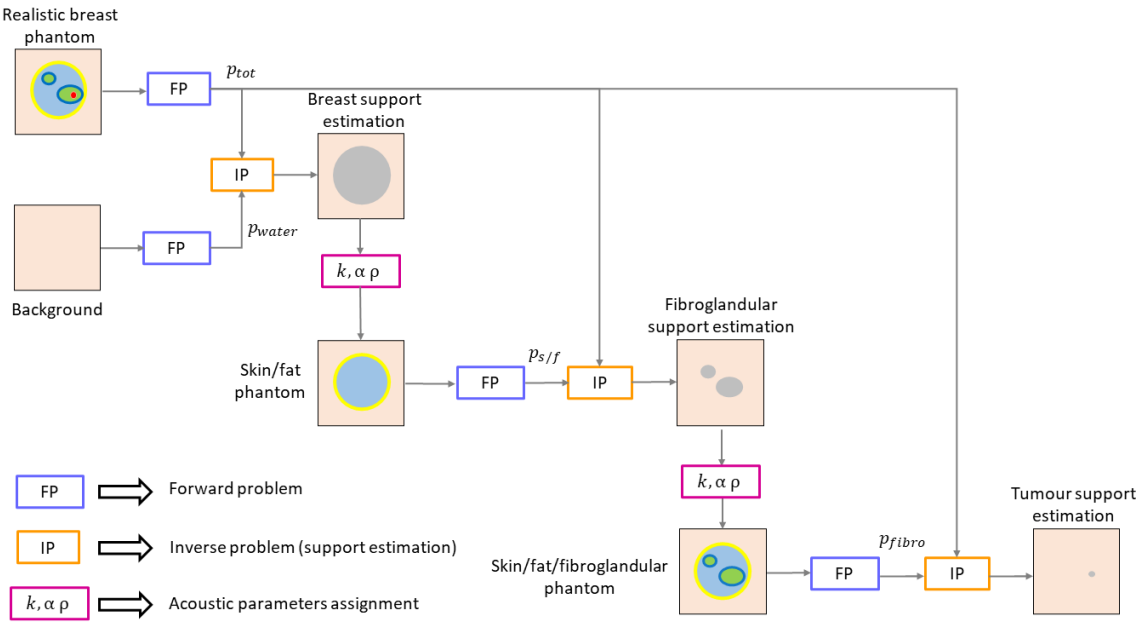

Fig. 2: Block diagram of the proposed tumor detection scheme. At each support estimation step, a new phantom is generated by assigning some average mechanical properties to the identified tissues.

end the paper in Section IV.

II. Mathematical Formulation

Let us assume a 2D simplified scenario as shown in Fig. 1. The integral equation governing the scattering phenomena is a function of the mechanical properties of both targets and background, i.e. density, compressibility and attenuation. Omitting the frequency dependence and considering an homogeneous background, the scattering field equation can be written as [14]:

$$p_{scat}(\mathbf{r}) = k_b^2 \iint_{\Omega} g(\mathbf{r},\mathbf{r}') \left[\chi_1(\mathbf{r}') - j\frac{2\delta\alpha(\mathbf{r}')}{k_b}\right] p_{tot}(\mathbf{r}')d\mathbf{r}' + \iint_{\Omega} g(\mathbf{r},\mathbf{r}')\nabla\cdot[\chi_2(\mathbf{r}')\nabla p_{tot}(\mathbf{r}')]\, d\mathbf{r}', \quad \mathbf{r}\in\Gamma, \quad (1)$$

where p_{scat} and p_{tot} are the scattered and the total pressure fields, respectively. The quantity $k_b = \frac{\omega}{c_b}$ is the lossless background wavenumber, ω is the angular frequency and c_b is the propagation speed in the background. The operator $g(\cdot,\cdot)$ refers to the background Green's function and Ω refers to the imaging domain. The two quantities $\chi_1(\mathbf{r})$ and $\chi_2(\mathbf{r})$ represent the contrast function for the compressibility and density defined as:

$$\chi_1(\mathbf{r}) = \frac{\kappa(\mathbf{r})-\kappa_b}{\kappa_b}, \qquad \chi_2(\mathbf{r}) = \frac{\rho^{-1}(\mathbf{r})-\rho_b^{-1}}{\rho_b^{-1}}, \quad (2)$$

where κ and ρ are the compressibility and density, and the subscript b refers to the same quantities related to the background. The quantity $\delta\alpha(\mathbf{r})$ is defined as the difference between the object and background attenuation ($\delta\alpha(\mathbf{r}) = \alpha(\mathbf{r}) - \alpha_b$).

The task of retrieving the quantities $\chi_1(\mathbf{r})$, $\chi_2(\mathbf{r})$ and $\delta\alpha(\mathbf{r})$ is a non-linear and ill-posed, and therefore, typically a-priori information are exploited in order to reduce the complexity of the inversion algorithm.

The aim of the proposed analysis is to retrieve a reliable estimate of the breast cancer location and extension. To this purpose, by adopting the BA and observing that the first integral in Eq. (1) has a stronger impact on the scattered pressure field, it is possible to write:

$$p_{scat}(\mathbf{r}) \approx k_b^2 \iint_{\Omega} g(\mathbf{r},\mathbf{r}')\mathcal{I}(\mathbf{r}')p_{tot}(\mathbf{r}')d\mathbf{r}' = \mathcal{L}\left[\mathcal{I}(\mathbf{r})\right], \quad (3)$$

with $\mathbf{r}\in\Gamma$ and:

$$\mathcal{I}_{norm}(\mathbf{r}) = \frac{|\,\mathcal{I}(\mathbf{r})\,|}{\mathcal{I}_{max}}, \quad (4)$$

in which $\mathcal{I}_{max} = \max[\,|\,\mathcal{I}(\mathbf{r})\,|\,]$.

$\mathcal{I}_{max}$ is a qualitative indicator providing information about the contrast of the profile under test. Although this reconstruction does not provide any physical quantity, due to different acoustic parameters exhibit by the healthy and malignant tissues, it is still possible to detect anomalies possibly related to breast cancer.

III. Proposed Method and Imaging Results

In the following, the breast is approximated by phantoms composed of different homogeneous tissues of circular shape. In particular, water is assumed as background and a 1.5-mm-thick layer is considered for the skin. Likewise, some circles and ellipses were used to simulate fat, fibroglandular and tumour tissues with homogeneous mechanical properties, as shown in Fig. 3(a,b). The parameters adopted in the following simulations were chosen based on [15] and the corresponding values are reported in Tab. I.

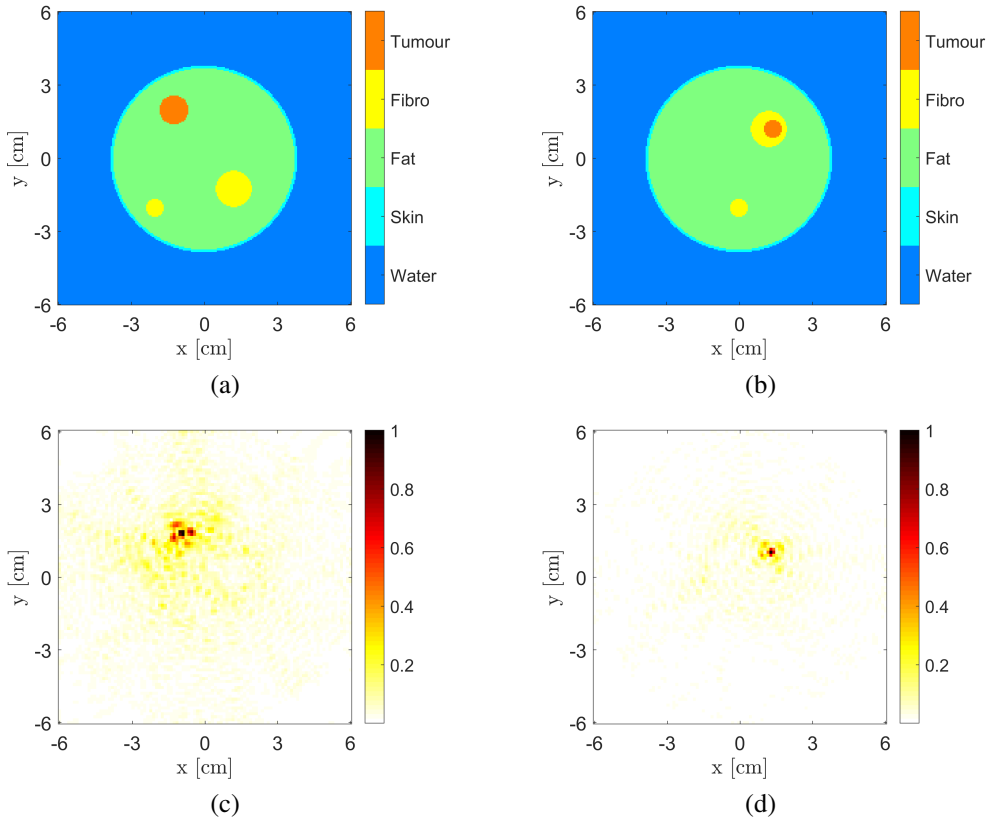

Fig. 3: Results of the proposed tumor detection strategy. (a,b) Numerical breast phantoms and (c,d) corresponding estimates of tumour support maps (indicator of Eq. (4)).

The whole breast is assumed to be a 10-cm-diameter circle. It is worth to note that the attenuation depends on the frequency according to the following relation:

$$\alpha(f) = \alpha_0 f^b, \tag{5}$$

where it was assumed $b = 1$.

The K-Wave forward simulation considers a monochromatic ultrasonic source at the operative frequency of 200 kHz. Regarding the US transducers, a total of 83 elements located on a circle of 6-cm radius surrounding the breast were considered in a multiview-multistatic configuration. Therefore, per each view, a total of 83 measures (including the monostatic contribution) was taken into account. It is worth to note that only the steady-state signals were considered.

The proposed solution for addressing the inverse problem consists of a three-step iterative procedure based on the BA. The workflow reporting the overall scheme is shown in Fig. 2. At the first step, a linear inversion via BA is carried out for the support estimation of the breast. To this aim, both the field in presence of the breast (p_{tot}) and the background one (p_{water}) are required. From this initial qualitative recovery and assuming the skin thickness as known, the estimated support is used to create a new phantom with both estimated skin and adipose tissues. Regarding the assigned mechanical properties (density, compressibility and attenuation coefficient), the values reported in Table I were adopted. Starting from this profile, a new forward simulation is performed and the related pressure field is obtained ($p_{s/f}$). At this step, a new linear inversion is carried out to retrieve information about the support of fibroglandular tissues, and the procedure goes on until tumour support estimation is reached.

TABLE I: Propagation speed ($c = \frac{1}{\sqrt{\kappa\rho}}$), density ($\rho$) and attenuation ($\alpha_0$) of breast inner tissues

Tissue	$c\ [\frac{m}{s}]$	$\rho\ [\frac{kg}{m^3}]$	$\alpha_0\ [\frac{dB}{cmMHz}]$
Skin	1735	1137	0.75
Fat	1430	951	0.5
Fibroglandular	1560	971	1.2
Tumor	1600	990	2.6

Fig. 3(c,d) show the spatial maps of the indicator defined in Eq. (4), which represent the estimates of the tumour support in the case of the two numerical phantoms of Fig. 3(a,b). It is worth to note that the proposed scheme manages to identify the malignancy with good accuracy both in case the tumour is surrounded by fibroglandular tissues or by adipose one.

IV. Conclusion

In this paper a three-step method based on the BA for breast cancer detection via ultrasound tomography was proposed. The approach considers a cascade of inversion blocks each adding progressively new information regarding the extension of the interior breast tissues. A preliminary numerical analysis was proposed by testing the method in two different scenarios including a malignancy either surrounded by fibroglandular tissue or by adipose one. In both cases, the proposed solution is able to retrieve tumor location correctly with good accuracy.

Future work includes testing the methodology in more realistic scenarios and considering its robustness against model error.

***Abstract*—State-of-the-art technologies usually adopted to characterize human motion rely on wearable sensors, motion capture systems and markers. These system provide useful and accurate quantitative kinematic measures. Unfortunately, marker-based systems require expensive laboratory settings with several infrared cameras, limiting their use in uncontrolled environments. This could modify the naturalness of subjects movements and induce discomfort. Also, markers are intrusive and their number and location must be determined a priori. Recent advances on pose estimation and semantic features detectors based on computer vision and deep neural networks are opening the possibility of adopting efficient video-based methods for extracting movement information from RGB video data. In this contest, in the last few years, we introduced and tested the effectiveness of a video-based markerless pipeline for the quantitative analysis of human motion in the rehabilitation domain. In this paper, we summarize the implemented pipeline, we highlight possible application fields where its use can be beneficial also providing examples of applications.**

***Keywords*—Markerless, Human motion analysis, Computer Vision, Deep Learning**

I. Introduction

Human motion understanding is a relevant task in many fields of science and medicine. Predicting and describing quantitative and qualitative human behavior while performing different actions is essential in neuroscience to understand the brain behaviour in both physiological and pathological conditions [6], [1]. Moreover, it is helpful for human-computer interaction applications [12], [23], for human-robot interaction [10] and for augmented reality applications for gaming and rehabilitation [27]. Lastly, human motion understanding is largely adopted to study and predict how people interact [14].

Nowadays, the gold standard techniques commonly adopted to accurately describe and study human motion rely on wearable sensors, motion capture systems and markers placed on the body skin [16]. However, markers are intrusive and they may limit natural movements [5], making the analysis of motion patterns challenging in some application fields such as infants motion analysis [18], sports biomechanics and musicians motion characterization.

For these reasons, recently, RGB video analysis has been considered to become a possible alternative to marker-based systems [7], [24]. This is due to the increasing progress of deep learning and computer vision algorithms [29]. In particular, recent advances on pose estimation algorithms and on semantic features detectors based on deep neural networks are opening the possibility of adopting efficient methods for tracking human pose and extracting motion information starting just from video data [25]. In this context, we studied, implemented and tested a markerless pipeline able to extract quantitative information related to human motion and we compared the measures obtained with our pipeline to those commonly obtained using gold standard marker-based systems. We used our pipeline to address different problems and we report here the results obtained in two cases: (i) the characterization of preterm infants motion patterns and (ii) gait analysis.

II. Proposed markerless pipeline

Our aim is to create a markerless system able to describe in a quantitative way human motion. We tested our pipeline in applications related to the medical and the rehabilitation domains with the aim to support physicians in their medical evaluations and to allow them to timely plan appropriate rehabilitation treatments. In this context, an important requirement to take into account is the need for interpretable methods: for this reason, we can not rely on end-to-end architectures and we need to build a multi-level system to better understand the results of each step. In this way it is also possible to use this system in different application scenarios with just small changes. Specifically, we divide the pipeline into the following steps.

1) *Landmark points detection*: we leverage Convolutional Neural Networks (CNN) and we detect the positions of meaningful landmark points in the image plane. This can be done thanks to the high number of pre-trained pose estimators [4], [2] and semantic features detectors [25], [17] developed in the last few years.

2) *From 2D to 3D*: if the acquisition setup includes multiple viewpoints, the information from the different views can be combined in order to reconstruct the 3D positions (X, Y, Z) of each landmark point. This is particularly useful because the standard marker-based approaches to study human motion provide 3D information. In this case we include the use of biomechanical modeling software such as Opensim [9] to describe the motion.
3) *Motion characterization*: depending on the problem addressed, it is necessary to define and extract the set of parameters helpful to describe the motor patterns.

A. Landmark points detection

We start from the same logic behind gold standard marker-based systems and we detect the position of meaningful landmark points in the videos of humans. To do that, it is first necessary to locate them in 2D image planes. Depending on the application, we start by relying on: (i) pose estimation algorithms [4], [2]; (ii) pre-trained semantic features detectors [17], [25] fine tuned on specific keypoints depending on the motion patterns to characterize.

Inputs to our procedure are frames extracted from RGB videos. Independently from the algorithm adopted, the outputs are the positions of the keypoints in the image plane. Specifically, for each image we have $\{(x, y, c)_l\}$, where $(x, y)_l$ is the position of the $l-$th keypoint in the image and c_l is a number in the interval $[0, 1]$ and represents the probability the $l-$th keypoint had been correctly detected. With c_l we are able to quantify the uncertainty behind the detection of each point in each image. In Figure 1 we show an example of keypoints detected in the image plane.

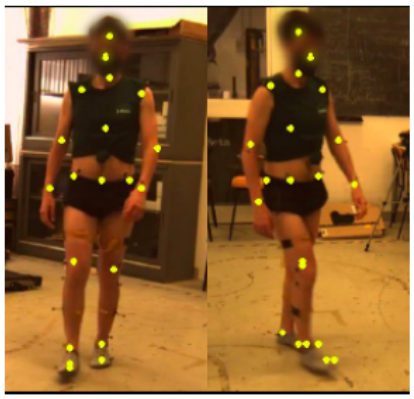

Fig. 1: Examples of keypoints extracted in the image plane.

B. From 2D to 3D

In the literature there are algorithms for 3D reconstruction specific for the human pose. There are methods relying on single images (*e.g.*, [28]); others that work under the hypothesis that calibration is not available, and generally require very large datasets (*e.g.*, [11], [3]). Other works approach the problem using a similar prior as calibrated reconstruction (multi-view calibrated inputs during training) but in a data-driven fashion (*e.g.*, [15]). Unfortunately, the previously mentioned approaches do not appear to be appropriate for our purpose. In fact, we need a method as precise and accurate as possible. For this reason we opt for a geometric approach relying on stereo vision [13]. The choice of a general purpose geometric approach is also motivated by its simplicity and high generalization potential. For these reasons, we include in our analysis the 3D reconstruction step only when a multi-view camera system (two or more cameras) is available. In particular, in [19] we studied the error made by adopting our implemented markerless pipeline in the localization of the 3D positions of the markers with respect to their actual positions tracked with a motion capture system (Optotrak 3020). The markers were placed on the violin and on the bow of violin players. We highlighted that the error done in the localization of the markers with our pipeline is in the order of a few millimeters (below 6 mm in at least 70% of the cases).

C. Motion characterization

Starting from the 2D or 3D signals that represent the evolution over time of the positions of each landmark point, it was possible to extract quantitative parameters that characterize the motion patterns. The relevant parameters to computer depend on the application domain as highlighted in Section III.

III. Applications

In this section, we report two examples of application of our markerless pipeline different but both related to assessment in the rehabilitation domain.

A. Infants motion analysis

Here we report the results of the application of our proposed markerless approach to study the motion of 142 preterm infants, 59 with a clinical diagnosis of neuromotor disorders. This work was carried out in collaboration with the Istituto Giannina Gaslini (Genova, Italy) and was presented in [22]. The analysis of preterm infants' spontaneous movements is essential for an early diagnosis of neuro-motor disorders. Inspired by the neuro-motor literature and following the General Movements theory [26], we computed quantitative motor parameters to describe infant's motion. We included generic parameters such as the mean, standard deviation, median, maximum and minimum speed, acceleration and jerk; the total covered distance and the Euclidean distance between the starting and the final position of each keypoint; the entropy, the peak magnitude, the sum of the spectrum and the spectral half point of the power spectral density of the total covered distance and of the speed of each keypoint. Furthermore, we computed specific parameters such as the skewness, the periodicity, the area out of moving average and the cross-correlation between the motion of hands and feet [22]. We used these parameters to train and test different binary classifiers (*e.g.*, Support Vector Machine, Random Forest and Long short-term memory) in order to identify infants likely to manifest neuro-motor disorders. In this way, we obtained a maximum

accuracy of 85.7% in the discrimination of infants with and without neuro-motor disorders.

B. Gait analysis

Here we report the results of the application of our proposed markerless approach for 2D and 3D gait analysis. In particular, we used our pipeline to characterize the gait of stroke survivors [21], unimpaired adults [20] and people with multiple sclerosis. Part of this work was founded by Fondazione Italiana Sclerosi Multipla (FISM – 2019/PR-single050) and carried out in collaboration with San Martino Hospital (Genova, Italy), Dipartimento di Neuroscienze, Riabilitazione, Oftalmologia, Genetica e Scienze Materno-Infantili (DINOGMI).

Our goal was to evaluate the appropriateness of our markerless pipeline as an alternative to classical marker-based systems. To do that, we performed gait analysis with gold standard systems and with our proposed markerless approach on the same dataset and we statistically compared the results obtained both in 2D and in 3D.

a) 2D analysis: Firstly, we focused on the 2D experimental assessment and we compared the quality of our estimated parameters with the ones obtained with a standard marker-based analysis and reported promising results: most of the 2D parameters may be computed by our markerless method at a comparable precision [21]. For this work, we adopted a subset of the dataset presented in [8], where RGB videos of the gait of 10 stroke survivors (mean age $\pm$ standard deviation: 62.75 $\pm$ 12.29 years old) were acquired with the aim of visual assessment and not for an organized computer-aided analysis.

We did not find statistically significant differences between the elevation angles computed with marker-based system and markerless one. Furthermore, we succeeded in highlighting the differences between the spatio-temporal parameters of the impaired leg and the unimpaired leg in hemiparetic stroke survivors, similarly to analysis carried out by conventional methods.

b) 3D analysis: We extended our analysis and we performed a comparison in 3D [20]. We acquired an *ad hoc* multimodal dataset of 16 unimpaired participants with a gold standard marker-based motion capture system and a multi-view RGB cameras system to be able to perform a geometric 3D reconstruction. We computed the spatio-temporal parameter and the joint angles relying on the biomechanical modeling open source software Opensim [9] with both marker and video data. Also in this case we did not observe relevant differences among the two approaches. For this reason, we adopted the pipeline to characterize and monitor kinematic patterns in Multiple Sclerosis people. In Figure 2 we show the knee, hip and foot angles in the sagittal plane of a person with Multiple Sclerosis with asymmetric gait. The right ankle has a reduced dorsi-plantar flexion and a decreased knee flexion in the swing phase.

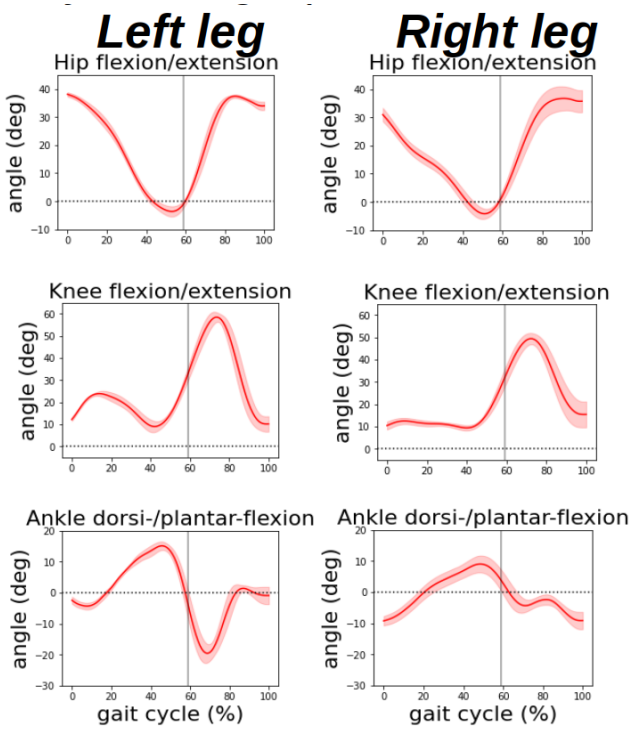

Fig. 2: Mean and standard deviation of hip, knee and foot angles in the sagittal plane for the left and right leg of a person with Multiple Sclerosis. We considered a total of 20 gait cycles.

IV. Strengths and Weaknesses of our Markerless Approach

Here we summarize the main advantages of markerless methods for human motion analysis.

- In general, the overall process to perform markerless analysis requires less preparation for the final users and it is not operator dependent. While the practitioner during marker-based data acquisition needs to place markers very carefully on the body skin in order to reduce as much as possible the bias, markerless systems are fully automatic, and are less operator dependent.
- The naturalness of movements is not affected by cumbersome markers placed all over the body skin. Thanks to the non-invasive nature of markerless systems, it is possible to adopt them to study human motion in application fields where the invasiveness of markers do not allow or reduce the possibilities to perform analysis (such as with infants, music players and athletes).
- It is less expensive. We estimated that the cost for markerless analysis is almost 20 times lower with respect to marker-based systems and it can be based on mobile phone or computer camera recordings.
- Markerless analysis has the potential to be performed in non-controlled, unconstrained environments, satisfying the need of a technique adoptable also at home. However, at this stage, we tested the pipeline only in controlled environments (*e.g.*, laboratories and hospitals) with one person involved in the scene.

On the other side, they present some limitations that should be further explored.

- If from one side there are few and well defined marker-based system for human motion analysis, on the other

side there are many different RGB cameras with different resolutions, sensors type and frame rates. For these reasons and for the variability of the application environment, it is difficult to create a standard reproducible system based on RGB cameras.
- Due to intrinsic physical limitation of camera sensors (spatial limitation related to pixel size), the level of detail achievable with this type of analysis is limited.
- A too low temporal resolution (frame rate) of the camera combined with fast movements may lead to motion blur and, consequently, to small errors in the detection of the keypoints in the image plane. One immediate way to reduce the motion blur is to adopt RGB cameras with a high temporal resolution (*i.e.*, high acquisition rate).

In conclusion, markerless analysis represent an interesting alternative not yet fully explored to marker-based techniques.

***Abstract*—The bilateral visuo-parietal-motor network is responsible for fine control of hand movements. However, the subregions devoted to maintaining contraction stability in the presence/absence of visual feedback remain unclear. It is widely recognized that continuous sensory feedback plays a crucial role in accurate motor control in everyday life. Feedback information is used to adapt force output and to correct errors. While the primary motor cortex contralateral to the movement (cM1) plays a dominant role in this control, converging evidence supports the idea that the ipsilateral primary motor cortex (iM1) also directly contributes to hand and finger movements. Similarly, when visual feedback is available, the primary visual cortex (V1) and the visuospatial network and their interactions with the motor network are essential for accurate motor performance. To clarify this problem and investigate the regions involved in a visuomotor task, we performed functional magnetic resonance imaging (fMRI) measurements during isometric compression of a compliant rubber bulb, at 10% of maximum voluntary contraction, both with (visuomotor task) and without visual feedback (motor task). Here, by using a multivariate approach focusing on intrinsic connectivity between voxels through group ICA of fMRI Toolbox (GIFT), we have answered the following two main questions:**

1) which are the networks involved during a motor task (i.e. without visual feedback) and a visuomotor task (i.e. with visual feedback)?

2) Is there any hemodynamic signal complexity difference between the visuomotor and the motor task?

Interestingly, we have found that during the visuomotor task, the involvement of the visuospatial network (FEF), the ipsilateral primary motor area (iM1), the contralateral primary motor area (cM1), the sensorimotor network (SMN) the Executive Control Network (ExCN), the Silence Network (SN), the Default Mode Network (DMN), the Basal Ganglia (BG), the Cerebellum (Cb) and Precuneus are essential for the fine motor control of the movement while maintaining the grip force level indicated by the visual feedback together with higher complexity estimated by Higuchi's Fractal Dimension.

The study shows that the brain networks show greater hemodynamic complexity in the presence of visual feedback, due to the processing of the visual stimulus and the maintenance of the required level of force.

***Keywords*—functional Magnetic Resonance Imaging (fMRI), Fractal Dimension (FD), Resting State Networks (RSN), Motor, Visuomotor**

I. Introduction

A key component of human interaction with our surrounding environment is the planning and execution of motor actions to coordinate movements of the body. Grasping and manipulation of objects in a controlled and precise manner is an essential action that depends upon smooth coordination and integration of diverse sensory components such as visual cues, tactile and cutaneous feedback, grip force control and internal representations. [1] The organization of the brain's activity during the coordination of precision or force gripping, using either dynamic or isometric contractions, has been investigated by numerous functional magnetic resonance imaging (fMRI) studies as a foundation for studying more complex motor tasks. This body of work has identified a bilateral fronto-parietal cerebellar network, primarily comprised of primary sensorimotor cortex (M1/S1), dorsal and ventral premotor cortices (PMd and PMv), supplementary and cingulate motor areas (SMA and CMA), prefrontal cortex, parietal association cortex and the cerebellum. However, during unimanual motor and somatosensory tasks, the activity of ipsilateral M1 (iM1) is neither quiescent nor idling but substantially perturbed by the task, typically in the form of a reduction in mu frequency (8– 13 Hz) M/EEG power or fMRI signal below baseline levels. Second, the visual feedback signal control emphasises this aspect, especially during fine movement control. [1]

From a metrological point of view, another key point is that all the studies using fMRI to study motor control and execution have used the mass-univariate voxel-based approach, which focuses on segregating and localizing processes, failing to account for the integration across functions within more extensive networks. In addition, the mass-univariate voxel-based analysis also relies on subtraction methods between conditions, emphasising more significant differences than similarities between processes. Functional connectivity analysis is an alternative multivariate method to assess the functional architecture of the central nervous system that integrates brain signals across multiple regions. This approach uses correlations between distant regions as the dependent variable. Independent component analysis (ICA) is often used to identify clusters of regions that show high correlations of signal change within a given time window. These clusters are assumed to reflect intrinsic connectivity networks. Consistent intrinsic networks have been repeatedly identified using ICA. These include networks that connect homologous regions processing visual, auditory, and sensory-motor output. But also, a higher cognitive function such as the default mode network (anterior and posterior midline and inferior parietal); the lateralized dorsal frontal-parietal network, putatively involved in attention; the saliency network, which comprises the insula and the anterior cingulum; the frontal network involving prefrontal, frontotemporal, and cingulate cortex, thought to reflect executive control; the left-lateralized ventral,

frontal, and parietal network, involved in language processing and the precuneus, basal ganglia, and a cerebellum network. Importantly, similar networks are detected when participants are engaged in a task (goal-driven behavior). In addition, differences between specific task conditions are modelled as a reconfiguration of connections within and between networks. It has been argued that the task-based spatial ICA data-driven approach is advantageous over conventional mass-univariate analysis of signal amplitude change. This is because it does not rely on assumptions regarding the time course, the temporal characteristics, and the shape of the hemodynamic response function. In this work, we analyzed fMRI data using a multivariate data-driven approach focusing on intrinsic connectivity between voxels through group ICA of fMRI Toolbox (GIFT), asking the following main questions:

1. which are the networks involved during a motor task (i.e. without visual feedback) and a visuomotor task (i.e. with visual feedback)?
2. Is there any hemodynamic signal complexity difference between the visuomotor and the motor task and in which brain networks?

II. MATERIALS AND METHODS

A. Partecipants

Sixteen right-handed volunteers (age = 26±4 years, 7 females) performed an isometric contraction of a pneumatic rubber bulb [2] opposing the thumb to the first two fingers of their right-hand.

B. Experimental Paradigm

Individual's maximal voluntary contraction (MVC) of this grip was measured prior to the experiment using a mechanical hand dynamometer (0–100 kgs, Lafayette 78010, Indiana) [2]. Three quick contraction were performed where subject's held maximum contraction for 5 s and the mean force value across trials was used as their MVC. Prior to the experiments, the pneumatic equipment was calibrated so that the conversion of applied force to current was known. The contraction force was continuously recorded throughout all experiments at 100 Hz sampling rate. During the experiment, subjects were instructed to maintain the isometric contraction for the 5-second trial duration 10% of MVC. Throughout the experiment subjects viewed a visual display, which was projected onto a screen situated behind them at the rear of the scanner bore, via a mirror mounted on the MRI headcoil. Subjects kept their eyes open at all times and maintained fixation upon a vertical, white force-gauge that was centrally displayed upon a grey background throughout.

Subjects were instructed to smoothly increase the contraction force and to then maintain this target force level as accurately as possible until the end of the trial, signaled by the disappearance of the two segments aside the gauge. At the trial offset, subjects were instructed to terminate the contraction and completely relax their hand for the duration of the inter-stimulus interval lasting either 5, 7 or 9 s. Isometric contractions at the force levels were executed in two experimental conditions:

1) Visuomotor condition (VM), where a horizontal, black force indicator bar appeared centrally in the force gauge upon trial onset. The vertical position of this horizontal indicator provided continuous visual feedback information to the subject about the exerted contraction force. The force indicator was removed from the visual display at trial offset.

2) Motor condition (M), where subjects were asked to perform the isometric contraction without the display of the horizontal force indicator.

Although matching the target force level was obviously more difficult in this M-task, subjects had been familiarized with the task during a single-run of each of the tasks conducted outside of the MRI scanner immediately before the fMRI experiment and were reasonably competent at performing the task at the required force levels. Experimental cues were visually presented to participants via a projector display and the visual display was controlled using the Psychophysical toolbox running in MATLAB (MathWorks). Immediately before fMRI scanning each subject performed a practice run. During fMRI, two experimental runs of each of the VM- and M-task conditions were acquired in an inter leaved order that was randomized across subjects. All experiments were conducted at the Birmingham University Imaging Centre using a 3T Philips Achieva MRI scanner. An eight channel phased-array head coil was used to acquire T1-weighted anatomical image (1 mm isotropic voxels) and four task-related whole-brain T2*-weighted, functional EPI data (365 volumes, 3x3×4 mm voxels, 32 slices, TR=2000 ms, TE=35 ms, SENSE factor=2, flip angle=80°). Cardiac and respiratory cycles were continuously recorded (pulse oximeter and respiratory belt).

C. fMRI Pre-processing and analysis

fMRI analysis by Statistical Parametric Mapping (SPM-Toolbox)

The fMRI data were analyzed using SPM12 (Wellcome Department of Imaging Neuroscience, London; https://www.fil.ion.ucl.ac.uk/spm/). Pre-processing of the data included slice time correction, spatial realignment to correct for movement artefacts and motion by distortions interactions and normalized to the MNI standard space. The data were re-sampled given a 2x2x2 voxel size and smoothed using 6 FWHM Gaussian Kernel to account for residual inter-subject differences and to accommodate assumptions of random field theory used for family wise error corrections. We first estimated the effect size for each participant on each of the four conditions (recall 2x2 design) using the general linear model. Each condition was modelled by a separate regressor; the onsets of each trial corresponded to the time when a correct response was given. All the regressors were convolved with three bases functions: the canonical HRF, its derivatives and dispersions. To correct for signal changes due to head movement, the 6 realignment parameters were included in the design matrix. An additional set of regressors was added for force contraction.

fMRI analysis by Group ICA of fMRI Toolbox (GIFT)

Data were decomposed into functional networks using a group-level spatial ICA as implemented in the GIFT toolbox (https://trendscenter.org/software/gift/). The individual datasets were temporally concatenated and reduced for computational feasibility through three stages of principal component analysis (PCA) in order to reach the final dataset, which was then decomposed by ICA with Infomax [3] algorithm into 100 (ICs=100) spatially independent components.

In GIFT, after each subject's functional data were reduced, the data were then concatenated into groups and put through another data reduction step. The number of subjects to put into

each group is called partitions with the number of datasets in a partition being equal to the one-fourth of the number of data-sets selected for. After reduction within each partition the data were stacked into one group and put through the final data reduction. At this stage, the number of components was estimated using the minimum description length criteria (MDL).

Task-related networks

In order to compute the degree of task-relatedness of component we regressed the corresponding time-courses against the design matrix, using the temporal multiple linear regression implemented in GIFT. We performed temporal sorting fourth times one for each conditions of interest: Visuomotor (VM), Motor (M), selecting in turn the regressors associated to each condition. Stats on beta weights option in Utility of GIFT toolbox after temporal sorting was used, it allows one to test the significance of the ICs obtained. The resulting beta weights (β) reflect the degree to which the task events of interest modulated a component. β for each task condition was tested against zero using one-way ANOVA (Regressor). Twenty-eight independent components (ICs) were selected for the final analysis; only the ICs with a p-value that survived to False Discovery Rate (FDR) correction were considered. ICs were named accordingly to the template (Functional ROIs- https://findlab.stanford.edu/functional_ROIs.html) they were spatially correlated with or based on visual inspection of the corresponding spatial map.

Higuchi's fractal dimension

Neurophysiological processes are generally non-stationary and non-linear in nature, therefore it is useful to use the Higuchi fractal dimension (FD) (Higuchi 1988) as it is a quantitative measure of signal dynamics. It is a non-linear measure of the complexity of the waveform in the time domain: in practice, the original curve or signal can be divided into smaller parts with or without overlap, called "windows". FD values are calculated for each window, with or without an overlay. Individual FD values can be averaged across all windows for the entire curve, and the average FD value can be used as a measure of curve complexity [4].

Higuchi's FD [5] has been used to characterize the complexity of fMRI BOLD activity in the time domain [6].

Statistical Analysis

Statistical analysis on beta weights as implemented in GIFT toolbox was performed to identify differences between conditions (M vs. VM). The resulting beta weights (β) reflect the degree to which a component was modulated by the events of interest, i.e. how well did the IC's time course correlate with the condition time-course. To test for FD differences in each ICs between M and VM task, paired t-tests was performed. FDR was used to correct for multiple comparisons [7].

III. RESULTS

One hundred ICs were identified. Of these, 28 were determined to be task-related after One-Way Anova (Regressor). In the Tab.1 the results, after One Way ANOVA (Regressor) implementation are reported. P-values and networks for all the components FDR corrected in each condition of interest are present. The components common to the tasks are highlighted.

In Fig.1 all the fifteen components task-related are shown. Tab.1 and Fig.1 allow to identify the components related to each network active during the two tasks (VM and M): the visual network is mainly active during the VM task (IC 2, 3, 70), but it shows the presence of this network also during the M task (IC 74), underlined in Tab.1 as a component common to the two tasks. The sensorimotor network instead has more components common to VM and M task (IC 40, 92), and only one (IC7) active exclusively during the VM task. The same applies to the Executive Control Network (IC 4, 54) and to the Cerebellum (IC 27, 45, 60). The Frontal Eye Fields is more active during the visuomotor task (IC 44, 46), with the IC 46 also active during the motor task. Finally, the activations are totally different between the two tasks regarding the Silence Network, the Basal Ganglia, the Precuneus and the Default Mode Network, the latter only of the four to have an active component between the two tasks, the IC 42, the ventral one.

The hemodynamic FD analysis highlighted sixteen ICs with statistical differences between M and VM tasks significance. Fig.3 shows the ICs, grouped by the network showing the grand average and standard error for the FD and the relative spatial map. At the univariate level, the FD values of the VM task differ from those of the M task. Higher FD values were observed for the VM than for the M task.

Significant components (Fig. 3) include the VN, both pVN and hVN, the SMN, both bilateral M1 and iM1, the FEF, the ExCN and Cb. The components belonging to the same networks were averaged between them and compared in the two task.

TABLE I: TASK-RELATED COMPONENTS.

IV. Conclusion

This approach used in this study is more advantageous than conventional univariate analysis, as it does not rely on assumptions about temporal characteristics and the shape of the hemodynamic response function. In general, the study shows that the brain networks, active in both tasks, show greater hemodynamic complexity in the presence of visual feedback due to the processing of the visual stimulus and the maintenance of the required level of force. Understanding the mechanisms underlying fine motor movements is essential for rehabilitation strategies, helping elucidate neuronal mechanisms underlying neurodegenerative illnesses such as Parkinson's disease and other movement disorders and improving Brain-Computer Interface (BCI) application, among others.

***Abstract*— Radiofrequency Echographic Multi Spectrometry (REMS) is non-ionizing technique to diagnose osteoporosis on lumbar spine and femoral neck. In this prospective study, a new REMS-based parameter, named Fragility Score (FS), was used to identify bone fragility from lumbar spine REMS scans. FS parameter is a direct indicator of the status of bone microarchitecture and estimates skeletal frailty.**

The aim of this study was to investigate the effectiveness of the FS to discriminate between fractured and non-fractured patients with respect to the T-score values measured by Dual-energy X-ray Absorptiometry (DXA) and REMS.

Collected data from 376 Caucasian women were analysed and the occurrence of the incident fragility fractures was recorded during the follow-up period up to 5 years. Subsequently, the ability of the FS to discriminate between two patients group (with and without incident fragility fracture) in comparison to that of the DXA- and REMS- T-score was evaluated through ROC analysis.

The obtained results showed that FS provided an higher AUC value (0.770) with respect DXA- and REMS- based T-scores, (AUC=0.656 and AUC=0.691, respectively).

In conclusion, FS has proven to be a useful tool for the identification of incident fragility fractures, and its integration into clinical practice would enable early detection and monitoring of frail patients as well as fracture prevention.

***Keywords*—incident fragility fracture, REMS, Fragility Score, lumbar spine acquisition.**

I. INTRODUCTION

Radiofrequency Echographic Multi Spectrometry (REMS) is a non-ionizing technology for bone health status assessment [1]-[2] and fracture prediction [3]. The operating principle of REMS is based on the examination of native raw, unprocessed radiofrequency (RF) ultrasound signals that are collected during a simple echographic scan of the reference anatomical sites (proximal femur and/or lumbar spine) [1]. The bone health status is evaluated by comparing the acquired signal spectra with previously developed reference spectral models for the considered pathological and healthy conditions [4]-[5]. The large amount of information that has been gathered from the internal bone structure includes both quantity- and quality-related data, thereby it is possible to estimate bone strength and predict fracture risk [6]. Therefore, this technology does not only provide a quantitative measurement of bone density, but it can also provide information about bone quality [3]. On the base of several scientific evidences that demonstrate the high REMS accuracy in the diagnosis of osteoporosis and fracture risk prediction [1]-[2]-[3]-[6]-[7]-[8]-[9], REMS technology was included in the National Health Ministry Guidelines on Fragility Fractures (FF) from the Italian Institute of Health [10] as appropriate diagnostic tool able to improve the management of frail subjects.

To improve the FFs management, a new parameter based on REMS technology has been developed, the Fragility Score (FS), that allows the assessment of the quality of bone microarchitecture. FS is a direct indicator of the status of bone microarchitecture and estimates skeletal frailty independent of BMD (bone mineral density) [11], [12]. It ranges from 0 to 100 depending on the degree of frailty.

The aim of this prospective study was to investigate the effectiveness of the FS to identify bone fragility from lumbar spine REMS scans. In particular, the ability of the REMS-based FS to discriminate between fractured and non-fractured women with respect to the DXA (Dual X-ray Absorptiometry)- and REMS-based T-score values has been estimated. In clinical practice, T-score represents a reference parameter for the assessment of the osteoporosis diagnosis. It is expressed in terms of standard deviations (SDs) and obtained by comparing the measured BMD value with the average BMD of a reference healthy population of young individuals (30 years). As established by theWorld Health Organization (WHO), the patients were classified as “healthy” (normal BMD) if their T-score $\geq$ -1, “osteopenic” if -2.5 < T-score < -1, “osteoporotic” if T-score $\leq$ -2.5 or “severely osteoporotic” if T-score $\leq$ -2.5 in the presence of one or more fragility fracture.

II. MATERIALS AND METHODS

A. Study design and enrolment

The clinical information was gathered from female patients who met the following inclusion criteria: Caucasian women with age below 65 years and a medical prescription for lumbar spine. The 376 enrolled patients underwent a lumbar spine scan both with DXA and REMS. Subsequently, the occurrence of incident fragility fractures was recorded during the follow-up period lasting up to 5 years.

B. DXA and REMS acquisitions

DXA scans were carried out in accordance with standard clinical practices: the spinal scan was performed with the hip and knee flexed at 90° by using the following device: Discovery W (Hologic, Waltham, MA, USA). For all lumbar spine acquisitions, arm and table controls were used to position the laser’s cross hair 2.5 to 5 cm below the iliac crest and to

centre at the patient's mid-line, in order to obtain the correct position of the lumbar spine (*i.e.*, with the ribs attached to T12 on the image). Each of all the DXA reports were made anonymous.

REMS scans of the lumbar spine, were carried out by placing the echographic transducer in a trans-abdominal position under the sternum, in order to visualize L1 lumbar vertebra and then moving it until L4 according to the on-screen and audible indications provided by the device software. REMS scans were performed employing the EchoStation device (Echolight S.p.a., Lecce, Italy), equipped with a convex transducer operating at the nominal frequency of 3.5 MHz and used as recommended by the manufacturer. Transducer depth and focus scan were adjusted for all lumbar spine acquisitions in order to place the target bone interface (*i.e.*, vertebral surface) in the focal zone of the ultrasound beam and at least 3 cm away from the bottom of the B-mode picture.

All the REMS reports, together with all the echographic data (images and RF signals), were anonymised before the subsequent analyses.

According to Di Paola et al. [1], before the analysis, all DXA and REMS medical reports were checked in a rigorous way in order to avoid any type of errors than could occur during DXA and REMS scans. Erroneous REMS reports were excluded, while inaccurate DXA reports were re-analysed, if possible, or excluded [1].

C. REMS-based FS operating principle

According to the main operating principle of REMS technology, the first step is represented by an echographic acquisition of the anatomical reference sites. Immediately after the scan, an automatic processing of the acquired echographic signals allows to identify and analyse the target bone structure and the internal region of interest. Subsequently, the native raw unfiltered echographic signals acquired during the echographic scan are analysed in order to retain the maximum information about the characteristics of the investigated tissues. In order to calculate the FS value, the same RF data acquired for bone mineral density evaluation at the femur and/or lumbar spine are used. After data acquisition, through dedicated spectral and statistical analyses on raw signals related to the region of interest (ROI), the spectral profiles of the patient are classified as "frail" or "non-frail" on the basis of the comparison with dedicated reference spectral models representative of fractured and non-fractured patients.

In particular, on each patient dataset, the data analysis involved the following steps:

1. Automatic vertebral identification, using the segmentation method described in Conversano *et al.* [4].
2. Automatic ROI identification for each vertebrae image (according to the method described in Conversano *et al.*) by using a specific RF signal portion for each scan line crossing the bone surface.
3. Classification of each RF signal portion as "frail" or "non-frail" based on the correlation between its frequency spectrum, as determined by a FFT computation, and each of the two age-matched models stored in a reference database that was previously acquired [12].
4. Calculation of the FS value for each vertebra (defined as the percentage of the analysed vertebra segments that were classified as "frail" in the previous step) [12].
5. Calculation of the FS value for the patient under examination as the average of the single vertebra values [12].

D. Statistical Analysis

Receiver Operating Characteristic (ROC) curves analysis allowed to evaluate and compare the ability of the:

- T-score values measured by DXA and REMS to discriminate between the patients with and without incident fragility fracture;
- FS values to discriminate between patients with and without incident FF.

To test the statistical significance of the difference between the areas under ROC curves De Long [13] test was used.

III. Results

A. Patients' characteristics

In the entire lumbar spine dataset (376 enrolled patients), 59 patients (18.6%) experienced an incident fragility fracture after a median follow-up of 3.5 years (range 2-5).

Table 1 lists of the means and standard deviations of the anthropometric characteristics for the overall dataset of fractured and non-fractured patients.

TABLE I: ANTHROPOMETRIC CHARACTERISTICS

Female Lumbar Spine (LS)	*Mean ± SD*		
	Overall dataset	*Fractured patients*	*Non-fractured patients*
Number of patients	376	59	317
Age (y)	55.6 ± 6.0	56.4 ± 6.8	55.4 ± 5.8
Height (cm)	152 ± 6.3	163 ± 5.7	161 ± 6.4
Weight (kg)	64 ± 9.6	63.9 ± 10.1	64 ± 9.6
BMI (kg/m^2)	24.7 ± 3.5	24.9 ± 3.9	24.6 ± 3.5

FS values showed to be significantly higher in the fractured group than in non-fractured counterpart, similar to DXA and REMS-measured T-score (as it is shown in **Table II**). *P-values* in table II refer to the comparison between patients with and without incident fragility fracture, evaluated using the t-test.

TABLE II: FS, DXA- AND REMS-T-SCORE

Female Lumbar Spine (LS)	*Mean ± SD*			
	Overall dataset	*Fractured patients*	*Non-fractured patients*	*p-value*
Number of patients	376	59	317	
DXA T-score	-1.7 ± 1.3	-2.3 ± 1.1	-1.6 ± 1.3	p<0.0001
REMS T-score	-1.7 ± 1.4	-2.5 ± 1.3	-1.6 ± 1.3	p<0.0001
FS	28.6 ± 8.2	37.9 ± 12.5	26.9 ± 5.7	p<0.0001

B. Performance of DXA- and REMS- T-score in the prediction of fragility fractures

The AUC obtained from DXA- and REMS T-score values in the discrimination between patients with and without an incident fragility fracture were equal to 0.656 and 0.691, respectively. The AUC obtained by REMS- T-score was significantly higher than that obtained using DXA (**p<0.005**).

Moreover, ROC curves analysis allowed to evaluate and compare the ability of the FS and DXA – and REMS based T-score values to discriminate between the two groups of patients. The results showed that the AUC by the FS, equal to 0.770, was superior than the AUCs obtained using the T-score values, equal to 0.656 for DXA and 0.691 for REMS. The FS AUC was significantly higher than that obtained using T-score values for both DXA and REMS technology (**p<0.005)**.

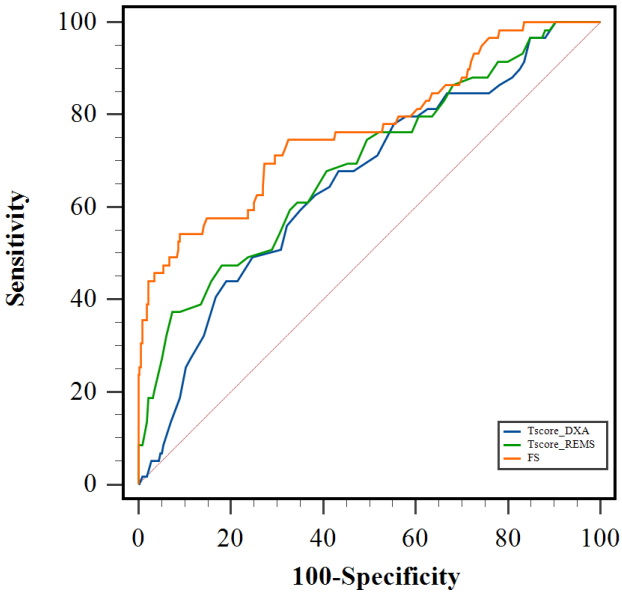

Fig. 2: shows a ROC analysis comparison between FS (orange line), and the DXA- (blue line) and REMS- (green line) T-score values in identifying patients who have or have not had incident fragility fractures.

IV. Discussion

The need to identify parameters and technologies that can predict the occurrence of fragility fractures is of great interest to the medical community, especially due of the enormous economic and social burden related to these fractures. In this study, the usefulness of the FS measured by REMS in identifying patients at risk for fragility fractures over a 5-years period was evaluated. Measurements were performed at the lumbar spine, one of the reference anatomical sites considered for the diagnosis of osteoporosis. The performance of the FS was evaluated and compared with respect to the DXA and REMS T-score value. T-score is considered the clinical parameter for the diagnosis of osteoporosis and primary clinical indicator to predict the fracture risk [6]. In this work the highest predictive capability of the FS, with respect to T-score measured both with DXA and REMS, to recognize patients with incident fragility fractures has been demonstrated. The fracture risk prediction capability of T-score DXA and REMS is similar to that assessed in previous studies [3].

V. Conclusion

Finding characteristics and technologies that could, in a clinically viable context, predict the occurrence of fragility fractures is currently of great interest [6]-[14]-[15]. This need is primarily motivated by the related reduced people quality of life and the high economic and social costs associated with fragility fractures, which are predicted to increase as people live longer [16]-[17].

In this context, the preliminary data obtained from this study demonstrated that the FS can be an effective parameter to identify incident fragility fractures. The integration of this tool into clinical routine would allow for early identification and monitoring of frail patients as well as for fracture prevention.

Indeed, this study has demonstrated the capacity of the FS to better discriminate than DXA- and REMS-based T-scores between fractured and non-fractured patients in a 5-year longitudinal study.

VI. Declarations

A. Statement of human and animal rights

Azienda Sanitaria Locale (ASL) Lecce's national Ethics Review Board granted the study approval (ID: 2258/2011). The 1964 Helsinki Declaration and its following revisions, as well as any other comparable ethical norms, were followed during every procedure.

B. Informed consent

All participants in the study have given their informed consent for inclusion and publication.

***Abstract*—Functional Near-Infrared Spectroscopy (fNIRS) and functional Magnetic Resonance Imaging (fMRI) are employed as imaging techniques to non-invasively assess brain activity. Current fNIRS-fMRI integration studies have addressed the temporal correlation of these two modalities, but often miss a quantitative method to assess spatial correspondence. In this context, we propose a novel surface-based approach to quantify spatial correspondence of non-simultaneous fNIRS and fMRI measurements referred to a motor task, as well as the temporal correlation of averaged brain responses. This method proposes a robust definition of region-of-interests over the cortical surface based on statistical activation maps. Results indicate that there is a high reliability between fMRI and fNIRS data according to cortical surface representations, both considering spatial and temporal correspondence. Specifically, moderate-to-substantial spatial agreement (0.58-0.71 Dice Coefficient) and moderate-to-strong temporal correlation (0.69-0.82) were found at subject level. These results strengthen at group level. As prospective applications, we find the support of clinical longitudinal applications, such as the investigation of disease progression and treatment efficacy of rehabilitation procedures.**

***Keywords*—fNIRS, fMRI, multimodal imaging, spatial agreement.**

I. Introduction

Among non-invasive functional neuroimaging techniques, functional Magnetic Resonance Imaging (fMRI) is considered the gold standard [1] given its optimal spatial specificity and resolution and its in-depth penetration (volumetric measure). However, fMRI acquisitions cannot be performed over all clinical populations (i.e., participants with MRI incompatible devices/prosthesis, suffering from claustrophobia) and/or in ecological settings (i.e., in an open environment during the execution of a wide variety of tasks), hence giving rise to the adoption of alternative technologies such as optical imaging.

In this framework, functional Near-Infrared spectroscopy (fNIRS) has gained relevance allowing to quantitatively measure brain activity in an open environment, including people not eligible for MRI acquisition, and exploiting a higher temporal resolution. However, fNIRS is intrinsically limited to superficial measurements, and suffers from lower spatial resolution with respect to fMRI, being dependent on source-detector distances. For this reason, appropriate ex-post fNIRS data integration preliminarily to the comparison with both anatomical and functional MRI is warranted to determine fNIRS reliability.

Previous studies evaluated fNIRS-fMRI correspondence both performing simultaneous [2]–[6] or separated acquisitions [1], [7]–[10] during task execution. Despite the temporal correlation between fNIRS and fMRI being widely investigated, the spatial correspondence between the two techniques has been often overlooked or only qualitatively assessed according to fNIRS optodes localization and anatomical MRI [11]–[14].

In this context, the aim of our study was two-folded.

As a preliminary step, we propose a novel surface-based approach for ex-post data integration between non-simultaneous fNIRS fMRI acquisition.

Namely, instead of individually processing fNIRS and fMRI data in their native spaces (i.e., surface channels space for fNIRS and volumetric space for fMRI), we projected individual source maps of both fNIRS and fMRI onto MRI cortical surface.

This allowed us to perform the second aim of our work which focused on the reliability assessment of fNIRS data with respect to the fMRI. Specifically, we performed a vertex-wise quantitative spatial comparison, using cluster overlap methods. Besides the spatial correspondence, we finally assessed temporal comparison between fNIRS $\Delta[HbO_2]$ and $\Delta[HbR]$ and BOLD signals to confirm our methods results with respect to literature ones.

II. Materials and Methods

A. Participants

Eighteen healthy volunteers (age mean±SD 30.55±4.7, 7 males) were enrolled in this study. Written informed consent was signed by each participant. The study was approved by the IRCCS Fondazione Don Gnocchi Ethical Committee.

B. Motor Task Paradigm

We employed a block-design experimental paradigm using E-Prime 3.0 (https://pstnet.com/products/e-prime/). The motor paradigm consisted of AB-AC block-design alternating 2 conditions: active periods (B, C, 10 seconds), in which the subjects performed hand movements by squeezing a rubber ball and resting periods (A, 20 seconds), consisting of white-cross fixation. The B and C active conditions were pseudo-randomized in equal numbers of Left (L, condition B) and Right (R, condition C) hand movements.

C. Acquisition Protocols

Subjects underwent separate fMRI and fNIRS sessions and were randomized according to the order of acquisition.

The MRI protocol was acquired on a 3T Siemens Prisma scanner equipped with a 64-channel head-neck coil. The protocol included: 1) a 3D high-resolution T1-weighted MPRAGE sequence (TR = 2300 ms, TE = 3.1 ms, isotropic resolution = 0.8x0.8x0.8 mm^3) used as anatomical reference for both fMRI and fNIRS datasets; 2) a functional sequence with TR = 2000 ms, TE = 30 ms, resolution 3x3x3 mm^3, 310 measurements, BOLD sampling frequency = 0.5 Hz.

The fNIRS protocol was acquired using a continuous-wave system at 760 and 850 nm wavelengths with 1.95 Hz sampling rate (NIRScoutX 32x32, NIRx Medizintechnik, Berlin, Germany) which uses 32 LED sources and 32 avalanche photodiode detectors. The resulting configuration consisted of 102 measurement channels able to cover the entire subject's scalp surface.

D. fNIRS and fMRI Preprocessing and ex-post integration

The 3D MPRAGE images were skull stripped and corrected for bias field using FSL (FMRIB Software Library v6.0) and successively preprocessed using the FreeSurfer (http://surfer.nmr.mgh.harvard.edu/) recon-all pipeline.

The functional dataset was preprocessed using FreeSurfer FS-FAST (https://surfer.nmr.mgh.harvard.edu/fswiki/FsFast) and included motion correction, smoothing, and sampling on the subject's left and right hemisphere cortical surfaces, obtained from the processing of the anatomical dataset. Using Matlab (2017b, MathWorks) the data were saved as vectors containing BOLD time series per surface vertex and were successively imported in Brainstorm [15] using user-defined scripts to perform integration with fNIRS data.

The fNIRS dataset was preprocessed using standardized pipeline implemented in Nirstorm package of Brainstorm (https://github.com/Nirstorm/nirstorm) comprising removal of bad signal channels, conversion of raw intensity signal in optical density variations, motion correction, linear trend removal using the Temporal Derivative Distribution Repair Algorithm [16] and band-pass filtering [0.01-0.08]. Similarly, to fMRI preprocessing, anatomical 3D MPRAGE data were used in order to project fNIRS signals onto individual subjects' cortexes. Briefly, the optical properties from the work of Tak et al. [17] and Eggebrecht et al. [18] were used to implement a Monte Carlo (MC) simulation (5·107 photons) using a five-layered model, and volumetric fluences were interpolated onto the cortical surface using Voronoi-based method [19].

E. fNIRS fMRI measure reliability

fNIRS and fMRI integration and statistical activation maps were computed in the same environment constituted by the Brainstorm interface using user-defined Matlab scripts. Specifically, fNIRS and BOLD signals were separately analyzed through the Generalized Linear Model (GLM) to contrast L and R task conditions and generate the respective t_{value} cortical maps of significant activation. Group-level statistical maps were computed following normalization of subject-specific contrasts onto ICBM152 template [20]. fMRI and fNIRS ROIs were considered significant if the t_{value} map was associated to $p<0.05$, thus resulting in 2 different ROIs for HbO_2 and HbR. The functional ROIs were anatomically constrained (acfMRI and $acfNIRS_{HbO2}$ $acfNIRS_{HbR}$) to pre- and post-central parcels derived by the Desikan-Killany atlas [21] considering both contralateral and ipsilateral activation (Fig. 1).

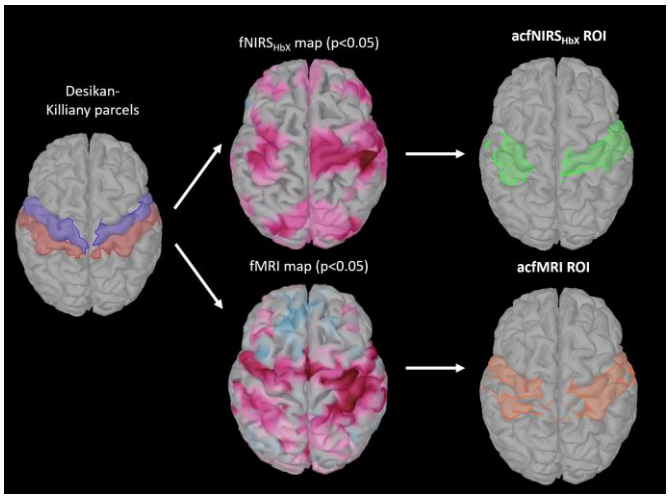

Fig. 1: Surface-based approach to define anatomically constrained functional ROI (acfROI) over t_{value}-maps of fNIRS ($acfNIRS_{HbX}$), fMRI (acfMRI) and their intersection ($acf_{\cap}$); t_{value} maps were associated to significant activation ($p < 0.05$).

The spatial extents of acfNIRS and acfMRI ROIs were compared using cluster overlap methods to assess global reliability of the measures [22]. Specifically, the Dice Coefficient (DC) was computed as follows:

$$DC(acfMRI, acfNIRS) = \frac{2 \cdot acf_{\cap}}{acfMRI + acfNIRS_{HbX}}$$

where $acf_{\cap} = acfMRI \cap acfNIRS_{HbX}$ represent the common regions between fMRI and fNIRS, and HbX being referred either to HbO_2 or HbR. A DC comprised between $0 \leq DC \leq 0.2$ was considered as slight agreement, fair between $0.21 \leq DC \leq 0.4$, moderate between $0.41 \leq DC \leq 0.6$, substantial between $0.61 \leq DC \leq 0.8$ and almost perfect between $0.81 \leq DC \leq 1$ [23].

Furthermore, the temporal Pearson's correlation between normalized BOLD and fNIRS $\Delta[HbO_2]$ or $\Delta[HbR]$ block average responses was performed over acfMRI and acfNIRSHbX respectively. Correlation values were considered weak between 0 and 0.3 (0 – -0.3), moderate between 0.3 and 0.7 (-0.3 – -0.7) and strong between 0.7 and 1 (-0.7 – -1).

Spatial and temporal comparisons were performed both at subjects' and group-level.

III. RESULTS

A. Spatial comparison – Dice Coefficient

The results derived from the spatial comparison between acfMRI and acfNIRS are reported in Table 1 at single-subject level and Table 2 for group level.

At subject level, moderate-to-substantial DC and moderate DC were found respectively for HbO2 and HbR relatively to the contralateral hemisphere with respect to the hand performing the movement. Fair-to-moderate DC and fair DC were instead respectively found for HbO2 and HbR regarding the ipsilateral activation maps.

At group level, we found a substantial DC for brain activation maps relative to the contralateral hemisphere for both HbO2 and HbR. Lower agreement, resulting in fair-to-

moderate DC for HbO2 and slight-to-fair DC for HbR was instead observed for ipsilateral hemisphere.

Table 1. Subject-level spatial agreement of fMRI BOLD vs. fNIRS HbO_2 and HbR maps across $acf_\cap$ ROIs. Results are reported as mean and standard deviation Dice Coefficient across subject-specific $acf_\cap$ ROIs. Legend: L=Left, R=Right, $acf_\cap$ = functional ROIs intersection; n.a.= either fNIRS/fMRI maps or their intersection is not available.

$acf_\cap$	$acfMRI \cap acfNIRS_{HbO2}$ *Mean±SD*		$acfMRI \cap acfNIRS_{HbR}$ *Mean±SD*	
	Left Hand	Right Hand	Left Hand	Right Hand
L precentral	0.47±0.22	0.61±0.23	0.37±0.26	0.52±0.26
R precentral	0.58±0.23	0.4±0.2	0.53±0.25	0.31±0.2
L postcentral	0.42±0.26	0.71±0.18	0.33±0.27	0.49±0.29
R postcentral	0.66±0.15	0.35±0.19	0.55±0.27	0.25±0.18

Table 2. Group-level spatial agreement of fMRI BOLD vs. fNIRS HbO_2 and HbR maps across $acf_\cap$ ROIs. Results are reported as Dice Coefficient between $acf_\cap$ ROIs over fMRI vs, fNIRS maps. Legend: L=Left, R=Right, $acf_\cap$ = functional ROIs intersection; n.a.= either fNIRS/fMRI maps or their intersection is not available.

$acf_\cap$	$acfMRI \cap acfNIRS_{HbO2}$		$acfMRI \cap acfNIRS_{HbR}$	
	Left Hand	Right Hand	Left Hand	Right Hand
L precentral	0.6	0.79	0.31	0.76
R precentral	0.7	0.41	0.61	0.15
L postcentral	0.45	0.8	0.19	0.62
R postcentral	0.81	0.38	0.62	n.a.

B. Temporal comparison – Correlation

The temporal correlation results between BOLD signal and either HbO or HbR signal computed over acfROIs are reported in Table 3 and Table 4 respectively for single-subject level and group level.

At subject level, moderate-to-strong correlation was found for contralateral activation between BOLD and HbO_2 signal, while moderate (inverse) correlation was found between BOLD and HbR.

Correlation between BOLD and HbO_2 was moderate-to-strong also for ipsilateral activation; however lower values were found between BOLD and HbR, ranging between weak-to-moderate correlation.

At group level, strong correlation was found both considering HbO2 and HbR signals for both contralateral and ipsilateral activation, except when comparing MRI BOLD and fNIRS HbR signals across the ipsilateral activation obtained during the right hand movement.

Table 3. Subject-level correlation results for fMRI BOLD vs. fNIRS HbO_2 and HbR signals across $acf_\cap$ ROIs. Results are reported as mean and standard deviation correlation values across subject-specific $acf_\cap$ ROIs. Legend: L=Left, R=Right, $acf_\cap$ = functional ROIs intersection; n.a.= either fNIRS/fMRI maps or their intersection is not available.

IV. DISCUSSION AND CONCLUSION

In this work we proposed a novel surface-based approach to integrate and compare fMRI vs. fNIRS data projected onto cortical surfaces. The validity of our approach was tested on a motor task, since providing well localized and robust activations with both fNIRS [24] and fMRI [25]. Resulting analyses involved the assessment of fNIRS vs. fMRI spatial correspondence, which is often overlooked or not directly quantified in literature, as well as their temporal correlation.

Spatial correspondence was assessed through DC, yielding a moderate to substantial agreement for contralateral activation at subject-level, while fair to moderate for ipsilateral activation. This trend was accentuated at group-level, namely increasing for contralateral activation, while decreasing or remaining constant for ipsilateral activation.

In line with other fNIRS-fMRI integration studies [1]–[4], [7], [11], [12], [26], we found a high temporal correlation of block averaged BOLD responses with either HbO_2 or HbR. This result was evidenced both across task conditions and contralateral vs. ipsilateral hemisphere activation. The temporal correlation was moderate to strong at subject-level, while strong at group-level.

Taken together, results indicate that there is a high reliability between fMRI and fNIRS data according to cortical surface representations, especially when considering group-level analysis.

A quantitative assessment of the spatial correspondence between fNIRS and fMRI improves the evaluation of tasks reproducibility across modalities. Previous fNIRS-fMRI integration studies mostly assessed the temporal correspondence between BOLD and fNIRS signals, while confining the assessment of spatial agreement between the measured activation maps to fNIRS channels correspondence over significant fMRI maps [3], [9], [11]–[14]. Similarly, other approaches have considered the definition of statistically-driven ROIs around the most activated voxels in fMRI maps [1], [2], [26], or based on thresholding methods with respect to significant fMRI regions [7], [27].

Few studies have quantitatively assessed fNIRS-fMRI spatial correspondence. Among them, Cai et al. [8] validated the spatial accuracy of an fNIRS image reconstruction algorithm by employing thresholded fMRI z-maps over cortical surface to define activated/non-activated regions as

gold standard for the comparison with fNIRS maps. Conversely, Eggebrecht et al. [18] considered the voxel-wise spatial correspondence as localization error between fMRI maps and high-density diffuse optical tomography (HD-DOT).

Compared to other fNIRS-fMRI integration studies, our approach proposes a robust definition of cortical ROIs based on the computation of statistical activation maps. Employing cortical surface representations increases the flexibility of the proposed approach, since allowing the integration of other functional or structural cortical parcellations to compute acfROIs.

Moreover, the proposed ex-post analysis methods were applied to non-simultaneous fNIRS and fMRI acquisitions, but it can be directly extended also to simultaneous acquisitions. As well, the proposed approach can be extended to the comparison of fNIRS/fMRI data with other surface-based neuroimaging techniques, such as magnetoencephalography, electroencephalography and HD-DOT.

Establishing a direct fNIRS vs. fMRI spatial correspondence, together with assessing their temporal correlation, promotes the translation of well-established fMRI task into fNIRS routines.

Hence, the proposed approach can support clinical longitudinal applications, such as the investigation of disease progression and treatment efficacy of rehabilitation procedures. Indeed, fNIRS can provide multiple measurements of cerebral activity in those experimental setting where fMRI is not an available or feasible approach. For instance, fNIRS may represent a low-cost and ecological monitoring throughout rehabilitation steps, while confining fMRI acquisitions only at predefined time points, such as pre- and post-rehabilitation stages.

***Abstract*—Melanoma is a serious form of skin cancer which originates from melanocytes. The diagnosis of melanoma occurs through histological examination, which is a destructive and labor-intensive technique where a "blind" sectioning without landmarks is performed.**

X-ray phase contrast computed micro-tomography (micro-CT) overcomes these limitations by providing virtual sections of the excised tissue along arbitrary planes without causing its destruction. However, up to date, synchrotron radiation (SR) micro-CT seems to be the only way to obtain high-resolution phase contrast 3D data. In sight of introducing x-ray virtual histology in the clinical practice, compact laboratory x-ray phase contrast micro-CT solutions are needed.

This study aims to move towards a new concept of 3D x-ray virtual histology in the clinical trial of melanoma diagnosis by showing preliminary results from a compact and cheap lab-based micro-CT setup based on the edge-illumination principle. A thorough comparison of SR micro-CT against laboratory micro-CT of the very same melanoma tissue is presented and discussed. Conventional histological images are also included.

Although the achieved spatial resolution and the scanning speed are not comparable to those obtained with SR, the proposed lab-based micro-CT solution still provides a comprehensive understanding of the morphological and functional aspects of the melanoma tissue in a non-destructive way, thus justifying further destructive exams such as conventional histology. This lays promising foundations for a wider clinical translation of the proposed approach.

***Keywords*— Melanoma, x-ray Virtual Histology, synchrotron radiation Computed micro-Tomography, lab-based Computed micro-Tomography.**

I. INTRODUCTION

DESPITE advances made over the past decades, melanoma remains the most aggressive type of skin cancer due to its aggressive nature of rapidly spreading to other organs and becoming metastatic. Even though it accounts for only 5% of all skin cancer, it is responsible for the majority of deaths in this category [1].

Melanoma develops when DNA damage from burning or tanning due to UV radiation changes and mutates in the melanocytes, which are the cells in the upper layer of the skin that produce a pigment known as melanin, resulting in uncontrolled cellular growth. The skin phenotype plays an important role with higher risk for fair-skinned persons: in 2006 American Caucasians accounted for 70% of melanoma cases [2], while black population had an increased mortality as a results of late detection and a different biology [3].

First melanoma signs are often associated with a change in an existing mole and the development of a new pigmented or unusual-looking growth on the skin. The detection of melanoma is based on the revised ABCDE rule of pigmented lesions (Asymmetry, irregular Border, change in Color, Diameter, Evolution): when one or more of the features listed above are identified in a mole, biopsy material is removed and analysed in laboratory. Although non-invasive in-vivo approaches such as e.g., optoacoustic and ultrasonography techniques [4] have been proposed, histological examination of bioptic material is still the standard for diagnosis of pathological tissues, mainly based on cancer cells recognition and diffusion in the excised tissue which can occur also at higher penetration depths. However, the histological staining process is based on a complex and time-consuming chemical preparation of the excised biopsy, followed by sectioning the pathological tissue into thin slices for viewing under the light microscope.

To overcome the lack of reproducibility and destructiveness of the histological technique, x-ray Virtual Histology (xVH) exploits x-ray Computed micro-Tomography (micro-CT) in the production of 3D high-contrast maps of the soft tissue specimen. By virtually sectioning the whole excised sample, xVH allows to investigate structures (e.g., lesions) and computing parameters (e.g., max infiltration depth) that could be lost or damaged during the histological sectioning process.

Synchrotron Radiation Computed micro-Tomography (SR micro-CT) is the optimum technique in term of high-resolution and high-contrast properties for xVH. However, it lacks the possibility of an easy integration in the clinical workflow due to its limited-access policy and high cost of maintenance.

This work aims to show the potentiality of a lab-based phase-contrast micro-CT technique to perform xVH on a soft tissue suspected-melanoma biopsy. As a preliminary result, we focus on enhancing the contrast-to-noise ratio by working on two aspects: a physical property (edge illumination principle) and a computational method (denoising with deep learning). SR micro-CT and histology images are considered in this study.

II. Material and Methods

A. Staining and embedding

One surgical excision of a human suspected melanoma tissue was embedded in paraffin (standard histology paraffin block of about 2.5x3.5x1.0 cm^3) and then sectioned using a microtome. The resultant skin tissue remains inside the paraffin block for micro-CT analysis.

B. Histological examination

Paraffin embedded melanoma sections were stained with haematoxylin & eosin (HE). Histological images were acquired using a D-Sight 2.0 digital microscope with a 200× magnification.

C. Lab-based Computed micro-Tomography

The paraffin block including the melanoma specimen was investigated by means of x-ray phase-contrast micro-CT at PEPILab [5] (Fig. 1). The acquisition was performed with a Hamamatsu microfocus x-ray source (tube voltage: 50kV, tube current: 120µA) and a Pixirad-1/Pixie-III detector [6]. The sample and the detector were placed respectively 355 mm and 635 mm far from the x-ray source. Two structured absorbing masks (M1: sample mask, M2: detector mask) were introduced in the micro-CT setup to exploit the edge illumination principle: the source-to-M1 distance and the sample-to-M2 distance were 315 mm and 255 mm. The mask aperture was 10 µm wide and the mask pitch was 61 µm. The pixel size obtained was 12 µm. Five points were sampled over the illumination curve and 6 dithering steps were considered. A total of 720 projections were acquired over a 360 degrees rotation of the sample with an exposure time of 3000 ms per projection.

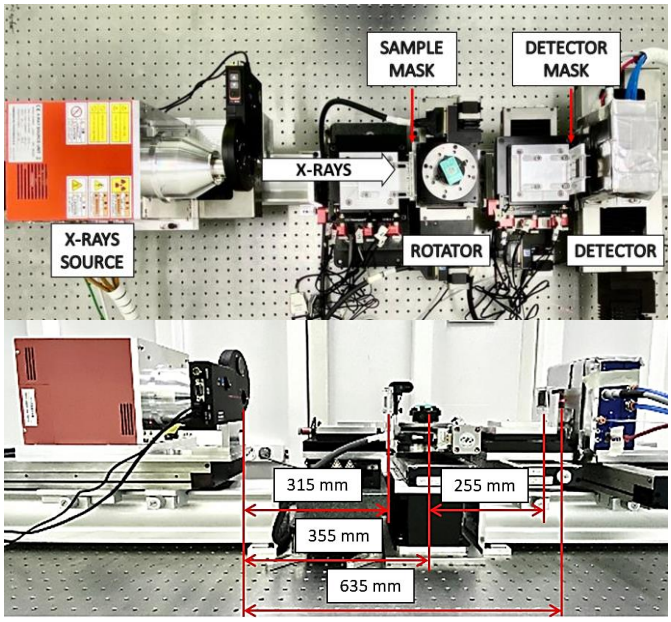

Fig. 1: Compact phase contrast micro-CT setup at PEPILab.

After being processed for phase retrieval, the stack of projections was split into 4 sets of projections and each set was reconstructed using TIGRE Toolbox [7]. Noise2Inverse denoising method [8] was applied by considering each set of reconstructed slices to get the final reconstructed volume. The Mixed-Scale Dense (MSD) convolutional neural network was used.

D. Synchrotron Radiation Computed micro-Tomography

The very same human melanoma excision was scanned at SYRMEP beamline [9] of Elettra synchrotron facility. The 2.4 GeV storage ring operating mode flux was filtered with a 1.0 mm Si filter to obtain an x-ray average energy spectrum of 23.6 keV. The pixel size was set to 1.6 µm and the sample-to-detector distance was set at 150 mm to improve the contrast-to-noise ratio by exploiting the propagation-based principle [10]. The paraffin block was placed orthogonally between the x-ray source and the detector (a Hamamatsu ORCA-FLASH 4.0 Digital CMOS camera coupled to a 17 µm GGG scintillator). 1800 projections over a 180 degrees sample rotation were collected with an exposure time of 100 ms per projection.

Projection digital images were filtered with a phase retrieval algorithm [11] and a δ/β ratio of 150. Tomographic axial slices were reconstructed using SYRMEP Tomo Project software [12] and, since two vertical scans were acquired to cover the whole mole, the two stacks were registered and stitched together with a Python script.

E. Quantitative image analysis

In order to compare the results obtained with two phase-contrast based micro-CT techniques, a quantitative evaluation was performed by computing the contrast-to-noise ratio (CNR). As shown with different colours in Fig. 2, several 20x20 pixels region-of-interests (ROIs) were considered to estimate the detectability of skin layers (epidermis, dermis, and subcutaneous fat) and pathological elements (lesion and ulceration), while confronted to the background (BKG). ROIs in Fig. 2 appear having different size due to different image pixel size (12 µm and 1.6 µm, respectively). CNR was computed as in Eq. (1):

$$CNR = \frac{|\mu_{ROI} - \mu_{BKG}|}{\sqrt{\frac{1}{2}(\sigma_{ROI}^2 + \sigma_{BKG}^2)}} \quad (1)$$

where μ is the mean and σ is the standard deviation of the gray levels within the ROI.

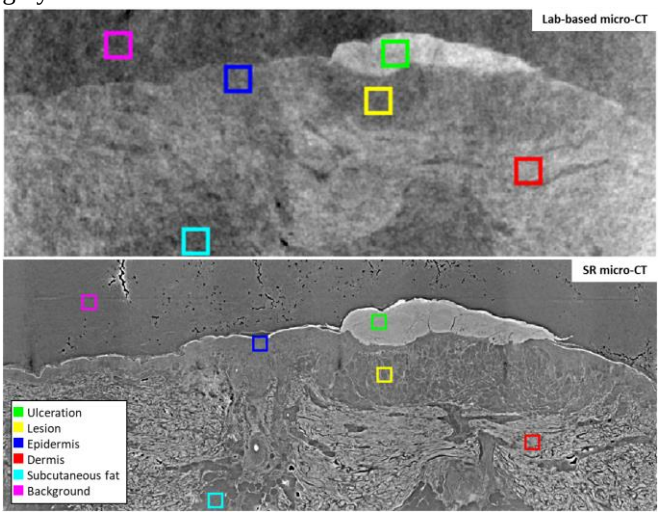

Fig. 2: Highlighted ROIs in micro-CT images used for quantitative analysis: each color marks a specific element of the skin tissue, while magenta is used as reference (background).

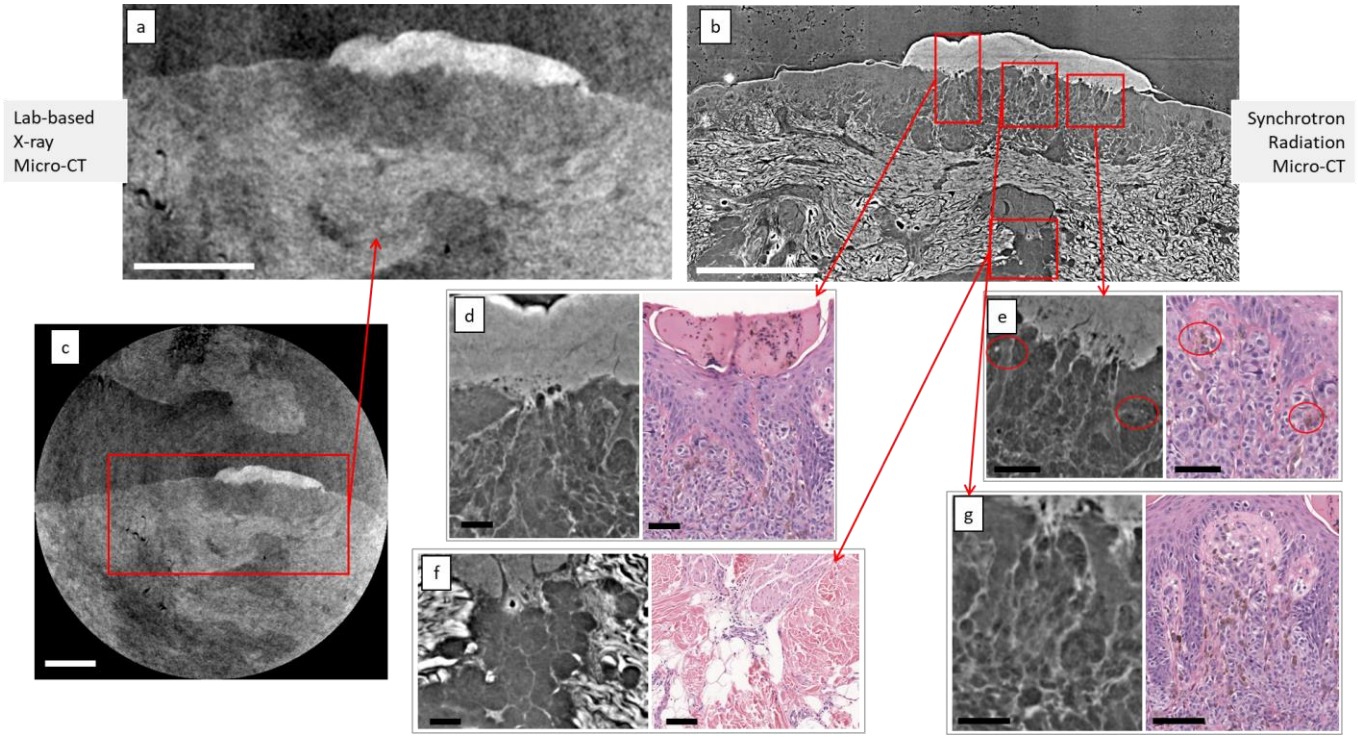

Fig. 3: The same lesion area of melanoma with (a) the lab-based and (b) the SR micro-CT techniques. (c) A lab-based micro-CT slice of the whole excision. Selected SR micro-CT and histology matches: (d) the full-thickness loss of the epidermis, (e) melanin pigment in malignant melanocytes nests, (f) dermis and subcutaneous fat and (g) the presence of malignant melanocytes in epidermis and dermis. White scale bar = 1mm, Black scale bar = 100µm.

III. Results And Discussion

From the whole 3D reconstructed datasets of micro-CT techniques¸ two slices were extracted and matched together via visual inspection. These slices are reported in Fig. 3.a and Fig. 3.b.

A. X-ray virtual histology with lab-based micro-CT

As visible for Fig. 3.c, the first aspect to consider is the challenging discrimination of the soft tissue from the paraffin due to the high density and internal artefacts introduced by the paraffin.

The application of the adopted phase retrieval to the edge-illumination technique revealed boundaries of the skin structure, thus allowing the identification of the top two layers, i.e. the epidermis and dermis (Fig. 3.a). The hypodermis, which is mainly composed by subcutaneous fat and blood vessels, is not properly observable due to its low density. Even the distinction between epidermis and dermis is not well defined with this technique, but it is an unnecessary information when finalizing the diagnosis.

On the contrary, the blood density ensures the high visibility of the ulceration above the epidermis. Considered that the ulceration is a result of the uncontrollable proliferation of neoplastic cells due to expansive activity of the tumor, this aspect is an important marker for tumor manifestation.

To support this thesis, a wide inflammatory process lays below the ulceration, causing even the destruction of the epidermis in some parts which are visible only in the SR image (Fig. 3.b). The thickness of melanoma lesion, which is one of the fundamental parameters for evaluation of staging, is easily assessable even at this level of magnification.

B. X-ray virtual histology with SR micro-CT

By exploiting the propagation-based characteristics of the synchrotron setup, the high-contrast SR micro-CT allows to enhance soft tissue properties making easier to detect morphological and pathological aspects on a microscopic scale. As shown in Fig. 3.b, the SR micro-CT image categorizes skin layers in different shades of gray: the epidermis is the outer layer in dark gray, while dermis is the fibrous part in light gray, and subcutaneous adipose tissue is of a dense dark gray.

In Fig. 3.f it can be noticed that histology fails to appreciate the subcutaneous fat, which appears as background. Due to its weak structure, it is easily damageable by undergoing the mechanical compression of sectioning causing tears and rips in the histological tissue.

By virtually sectioning the 3D micro-CT dataset, the chosen slice in Fig. 3.d testifies the absence of an intact epidermis and the association between consumption of epidermis and ulceration [13]. Failing to recognize this could decrease the degree of severity and thus lead to a less rigorous prognosis [14]. However, an experienced pathologist can predict and capture the full-thickness loss of epidermis overlying melanoma by evaluating the infiltration of the epidermis by malignant melanocytes in the histological section. This fundamental aspect for staging, diagnosis and prognosis cannot be solved by SR micro-CT image due to its spatial resolution.

A great inflammation under the ulceration as in Fig. 3.b is a clear symptom of cancerogenesis, but it is difficult to differentiate malignant melanocytes from lymphocytes.

However, xVH provides good contrast to enhance high dense material giving complementary morphological information to the histology technique which highlight cells' nuclei in purple.

For this purpose, Fig. 3.g shows the structure of stratum basale, which is a single layer of basal cells, visible as a purple bow in the histological image and as a light gray coloured bow in the micro-CT one. Then, clusters of melanoma cells are observable as purple and gray nests in histology, while they appear as dark gray regions bounded by a white membrane in the micro-CT image. Melanin pigment is also visible in both images and even in Fig. 3.e as brownish elements in the histology image, and as white dots in the micro-CT one.

However, these aspects cannot be investigated by lab-based micro-CT which cannot reach a similar spatial resolution. Further improvements are needed to increase the visibility of tissue components at the microscopic scale.

C. *X-ray virtual histology quantitative analysis*

Table I reports the quantitative results obtained for the two micro-CT techniques.

TABLE I: RESULTS OF THE QUANTITATIVE ANALYSIS

Tissue element	*CNR Lab-based micro-CT*	*CNR SR micro-CT*
Ulceration	7.28	8.92
Lesion	2.10	1.30
Epidermis	2.41	1.13
Dermis	5.40	2.02
Subcutaneous fat	0.30	1.86

All results from both techniques are above the unity with only one exception, thus meaning an overall good visibility of the tissue. For both techniques, ulceration and dermis tend to have the highest CNR due to their high densities, while the lesion does not have a high CNR value due to its non-uniform composition. Due to the noisy paraffin background used as reference, lab-based technique reveals higher CNR values than SR ones, but this does not imply higher image definition. Consequently, the lowest CNR measure for lab-based method comes for subcutaneous fat because of the similar noisy pattern as the reference background.

IV. CONCLUSION

A suspected melanoma excised tissue was examined by histology and measured with two different micro-CT setups. While the SR micro-CT technique reaches a very high-resolution comparable to that achievable via large magnification in conventional histology, the compact phase-contrast lab-based micro-CT technique shows promising results when considering its use to assess the correct malignancy of the suspected melanoma. In addition, the computed quantitative measurements support the need of phase-contrast while performing xVH in both scenarios (synchrotron and laboratory) instead of conventional absorption X-ray scanning.

The proposed phase-contrast laboratory micro-CT cannot reach the performances of the considered SR micro-CT setup, due to the limited spatial resolution and low scanning speed, but still provides a comprehensive understanding of morphological and functional aspects of the melanoma tissue in a non-destructive way. Once fully operating and optimized, the inclusion of a lab-based micro-CT setup in a clinical context would help to provide information about the pathological stage of the disease.

ACKNOWLEDGEMENT

Authors acknowledge Elettra-Sincrotrone Trieste S.C.p.A. for providing access to the synchrotron radiation facility and for using SYRMEP beamline. This work is carried out in the framework of the PEPI project, supported by Istituto Nazionale di Fisica Nucleare (National Scientific Commission 5 for Technological and Inter-disciplinary Research, No. 22260/2020).

Abstract— **Dilated cardiomyopathy (DCM) is one of the leading causes of heart failure. Left ventricular ejection fraction (LVEF) is one of the most used features for assessing heart health and predicting outcomes in DCM patients. However, it does have numerous pitfalls. Recent studies suggest that global longitudinal strain (GLS) and heart rate variability (HRV) can be used to predict DCM. Furthermore, numerous studies have demonstrated how essential it is to deploy interpretable machine learning models to aid clinicians in the cases when the diagnosis is challenging. Therefore, we aimed to investigate discriminatory power of GLS and LVEF as a feature of logistic regression models for identification of DCM. The study encompassed 138 DCM and 138 healthy controls (HC). The models were produced by logistic regression algorithms considering the set of selected HRV features and GLS ($LogReg_{GLS}$) or LVEF ($LogReg_{LVEF}$). The results showed that the accuracy of produced $LogReg_{GLS}$ model was 86%, higher than the one observed in case of $LogReg_{LVEF}$ model (83%). The produced nomograms also supported the hypothesis of the relevance of the GLS and LVEF features, indicating that these two measurements are the most useful in identification of DCM. In conclusion, our findings highlight the value and efficacy of interpretable machine learning models and suggest that GLS may have more discriminatory power in differentiating between DCM and healthy participants than LVEF.**

***Keywords*—Interpretable Machine Learning, GLS, HRV, DCM**

I. Introduction

DILATED cardiomyopathy (DCM) is a progressive cardiac muscle disease. DCM is a significant cause of heart failure and the most common reason for heart transplantation worldwide [1].

The left ventricular ejection fraction (LVEF) is the most commonly used characteristic in DCM patients to assess heart function and predict outcomes [2]. However, it does have some inherent disadvantages, such us LVEF decrease that occurs only in advance fase of cardiac disease, low reliability in patients with left ventricular hypertrophy and volume reduction, extremely low inter- and intra-observer variability, and problematic endocardial boundary identification [2]. Therefore, there is still a need for the identification of reliable non-invasive biomarkers for early DCM differential diagnosis. Recent studies have reported left ventricular global longitudinal strain (GLS) and heart rate variability (HRV) as promising features for diagnosis and prediction of various heart diseases [3]–[12].

GLS is a myocardial deformation analysis parameter that could play an important role in the prediction of cardiovascular outcomes [13]. When compared to LVEF measurement alone, GLS has demonstrated superior efficacy in detecting the overall degeneration of the left ventricle [3].

As a result of the interaction between sympathetic and parasympathetic activity, the HRV measurement is instead utilized to quantify cardiac autonomic activity. Prognostic information, which might not be contained within GLS and LVEF, may be provided by the pathophysiologic changes linked to heart disorders and the accompanying changes in HRV [14].

The design of machine learning models for computer-aided diagnosis that take advantage of the collected HRV characteristics in conjunction with other available clinical data is gaining scientific attention [15]. However, clinicians are still dissatisfied with the limited interpretability of the produced models because they cannot be evaluated on the level of single input features. For this reason, interpretable models that not only provide output information about a specific disease but also aid in intrinsically evaluating the model's plausibility are more desirable in medicine [16]. Therefore, by using interpretable models end-users and healthcare professionals can examine the rationale behind prediction models before accepting or rejecting the output [15]. Because of their high degree of interpretability and ease of use in practice, approaches such as linear/logistic regression, classification trees, and naive Bayes models are used in several sectors of healthcare, including toxicology [16], [17], endocrinology [18], neurology [17], and cardiology [19]–[21].

Logistic regression is a statistical model that shows the relationship between input parameters and can be interpreted using nomograms to determine the likelihood of an event occurring. A nomogram is a graphical representation of numerical relationships and is a basic- and self-explanatory visualization that is both helpful and powerful in diagnosing a disease. The logistic regression nomogram not only enables prediction but also illustrates the model's structure and the relative contributions of the features on the class probability. This is especially important when investigating the GLS, HRV, and LVEF thresholds to introduce new aids for DCM diagnosis, especially when the research is still in its early stages.

Therefore, the aim of this study was to investigate discriminatory power of GLS and LVEF as a feature of logistic regression models for identification of DCM.

II. METHODS

A. Study population and protocol

The study encompassed 138 DCM (81M/57F, aged 61± 15 y) and 138 healthy controls (HC), (66M/72F, aged 59±19 y). The DCM patients were enrolled after clinical assessment. Coronary angiography was systematically performed in patients older than 35 and with cardiovascular risk factors and/or without a familial history of DCM. Patients with known trigger factors, such as toxic insults from alcohol or drug abuse, and tachyarrhythmias were excluded from the study. The LVEF has been obtained by the Simpson biplane method [22] and the GLS has been obtained by speckle tracking echocardiography. The measurement of GLS was performed offline using dedicated software (TomTec Arena v2.0, TomTec Imaging Systems, Unterschleißheim, Germany). The investigators visually assessed the detected endocardial border and, if necessary, manually adapted the tracing to ensure the correct tracing of the contours. The study was conducted according to the principles of the Declaration of Helsinki. All participants released their written informed consent.

B. Heart Rate Variability acquisition and processing

All subjects underwent a 24h Holter ECG recording using the ambulatory electrocardiographic recorder SpiderView (Sorin Group, Italy) with a sampling rate of 200Hz. The RR intervals were extracted and labeled by using SyneScope analysis software (Sorin Group, Italy). The RR interval records were cut into 5 min segments without overlap. Each RR 5-minutes segment was included in the analysis only if the longest ectopic beats subsequence (labeled with "ectopic" by the ECG Holter) or the longest artifact subsequence does not exceed 10s (so-called Hearth rate Total variability [4]). The segments were interpolated with cubic spline and resampled at 2 Hz. Subsequently, for each segment, linear and non-linear HRV features were extracted. In particular, the linear parameters MeanRR, SDNN, RMSSD, NN50 and pNN50 evaluating the RR variability were calculated directly from the RR sequence, whilst in the frequency domain, the absolute powers in Low (LF=0.04-0.15Hz) and High (HF=0.15-0.40Hz) frequency bands, related to the vagal and sympathetic nerve control on the heart rhythm, were estimated from the interpolated HRV signal. Moreover, the normalized low and high- frequency powers (LFn, HFn) and their ratio (LF/HF) were calculated from the latter parameters. The non-linear analysis was carried out by calculating Poincaré plot parameters (SD1, SD2) reflecting the short and long-term variability [23] and extracting Fractal Dimension (FD) and beta exponent (betaExp) [24] quantifying the complexity of the system generating the signal.

C. Feature selection and classification

For feature selection, we used Information Gain [25] method, which has been widely applied in machine learning tasks to improve classification performance. The cut-off of Information Gain's estimates of the informative attribute was set to 0.07. The models were produced by logistic regression algorithms considering the set of selected HRV features, age, and sex, one with GLS ($LogReg_{GLS}$) and the other with LVEF ($LogReg_{LVEF}$). The classification accuracy (CA), area under the curve (AUC), F1, precision, and recall of the dataset were estimated using 5-fold cross-validation, and average metric values were calculated. Finally, the nomograms have been created and used to interpret and validate the obtained models.

III. RESULTS

The results of features selection analysis showed that the most informative features for classification between DCM and HC listed from higher to lower Information Gain coefficients were GLS, SD1/SD2, RMSSD, betaExp, and LFn for $LogReg_{GLS}$ model and LVEF, SD1/SD2, RMSSD, betaExp and LFn for $LogReg_{LVEF}$. The selected features were used as the set of variables to produce LogReg models.

The classification performance of produced LogReg models based on HRV features and GLS in one case and based on HRV features and LVEF in the other are reported in Table 1. The CA, AUC, F1, precision, and recall were higher in the model based on HRV features and GLS ($LogReg_{GLS}$) compared to the logistic regression model constructed with the HRV features and LVEF ($LogReg_{LVEF}$).

TABLE I: CLASSIFICATION PERFORMANCE OF PRODUCED $LOGREG_{GLS}$ AND $LOGREG_{LVEF}$ MODELS

Model	*AC*	*AUC*	*F1*	*Precision*	*Recall*
$LogReg_{GLS}$	0.86	0.89	0.85	0.86	0.86
$LogReg_{LVEF}$	0.83	0.87	0.83	0.83	0.83

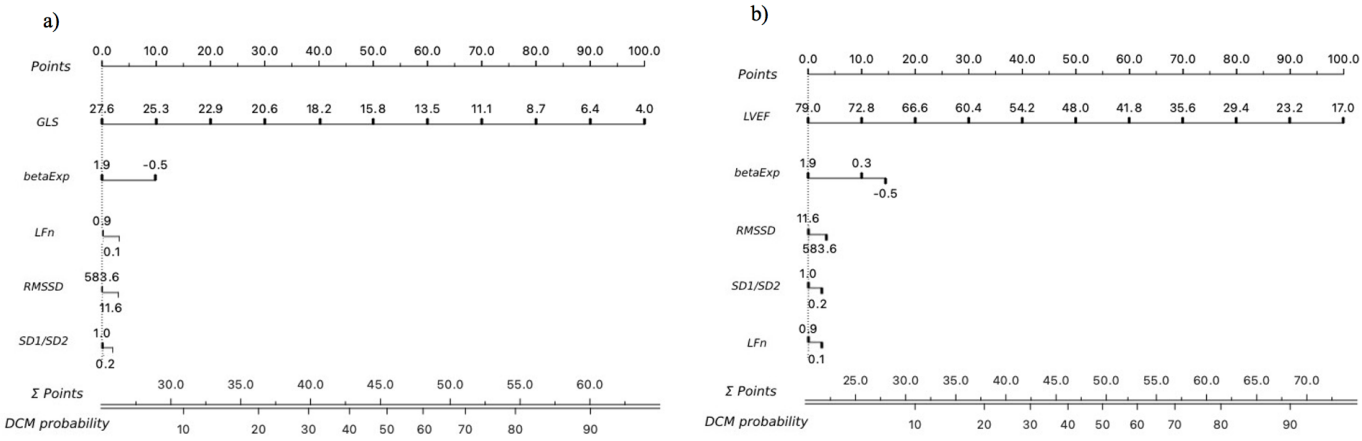

Fig. 1: Nomograms for DCM output class for (a)$LogReg_{GLS}$ and (b)$LogReg_{LVEF}$ models.

Confusion matrices obtained for $LogReg_{GLS}$ and $LogReg_{LVEF}$ are reported in Table 2. Confusion matrices show that DCM patients were correctly classified with 88.3% (Table 2A) and 86.3% (Table 2B) with $LogReg_{GLS}$ and $LogReg_{LVEF}$, respectively.

The produced nomograms for $LogReg_{GLS}$ and $LogReg_{LVEF}$ are reported in Figure 1 and the features are listed in order of importance. The produced nomograms can be interactively used to determine the likelihood of being in the DCM or HC group. In particular, for each of the features a score (point) corresponding to the specific features value is assigned. Subsequently the sum of the points of all considered features is converted into the probability that the subject belongs to the specific group. For example, in the Figure 1a, if the patient has a GLS value equal to 17.5 (43 points on the scale), betaExp equal to 0.9 (4 points), LFn equal to 0.5 (1 point), RMSSD equal to 87.5 (1.5 points) and SD1/SD2 equal to 0.4 (0.5 points), the total sum of points is equal to 50, which corresponds to probability of 65% that the specific subject is affected by DCM.

TABLE II: CONFUSION MATRICES OBTAINED BY (A) $LOGREG_{GLS}$ AND (B) $LOGREG_{LVEF}$ MODELS

A)		*Predicted*		
		DCM	*HC*	*Σ*
	DCM	88.3%	16.9%	138
Actual	*HC*	11.7%	83.1%	138
	Σ	128	148	276
B)		*Predicted*		
		DCM	*HC*	*Σ*
	DCM	86.3%	20.4%	138
Actual	*HC*	13.7%	79.6%	138
	Σ	124	152	276

IV. DISCUSSION

Dilated cardiomyopathy (DCM) is one of the leading causes of heart failure [1]. Left ventricular ejection fraction (LVEF) is the most often utilized feature for assessing heart health and forecasting outcomes in DCM patients. It does, however, have some inherent problems. On the other hand, there is growing scientific and clinical interest towards GLS parameter [10]–[12], [26] as a predictive feature in various heart diseases, including DCM. Additionally, several studies have shown how crucial it is to use interpretable machine learning models to support clinicians in the challenging diagnosis of different diseases [17]–[21]. Therefore, this study aimed to investigate discriminatory power of GLS and LVEF as a feature of logistic regression models for identification of DCM.

Our results showed that SD1/SD2, RMSSD, betaExp, LFn, and GLS in one case and LVEF in the other case are the most informative features for differential classification of DCM from HC. The $LogReg_{GLS}$ model accuracy was 86%, better than the accuracy of the $LogReg_{LVEF}$ model (83%). Therefore, we may conclude that the $LogReg_{GLS}$ model slightly outperformed the $LogReg_{LVEF}$ model, partially confirming that GLS could bring more information than LVEF in the diagnosis of DCM.

The importance of GLS, LVEF, and HRV features has been confirmed yet again by the nomograms. We can observe that the clinical parameter, GLS or LVEF, appears to be the most significant in the differential classification between DCM and HC in both nomograms, supporting the literature that suggest these two measures are the most helpful in the diagnosis of this condition [2], [10], [27]. Furthermore, the models empirically identified two thresholds, 50 for LVEF and 17 for GLS, for the diagnosis of DCM, which is in line with thresholds reported in recent studies [26], [27].

The nomograms also revealed the importance of the HRV features. In particular, betaExp measures the relationship between the frequency and power spectrum of the RR interval, providing an index of the HRV signal's long-term scaling properties [28], which may change in DCM. LFn is often associated with the joint action of the vagal and sympathetic system [29] that can alter in DCM patients. RMSSD is an indicator of the irregularities of the heart rhythms, also characteristic of DCM. Finally, SD1/SD2 describes diastolic blood pressure, which appears to be more variable in DCM patients than in healthy subjects [30].

Furthermore, the results support that nomograms can be an easy-to-use tool by the physicians to estimate the probability of presence of specific disease based on explainable classification process.

In conclusion, our findings highlight the value and efficacy of interpretable machine learning models and suggest that GLS may be more effective in differentiating between DCM and healthy participants than LVEF.

***Abstract*—Chronic pain is a major cause of disability worldwide. While acute pain may serve as a protective function, chronic pain and the associated changes in neural processing negatively impact function and quality of life. This neural plasticity may include changes to the autonomic nervous system (ANS) potentially detectable as changes in various physiological signals. Our aim is to evaluate differences in the physiological signals reflecting ANS changes, by comparing healthy subjects and patients with chronic low back pain during standardized pain stimuli. We extracted several features from photoplethysmography (PPG), electrodermal activity (EDA), and respiration, both at rest and during a repeated pinprick test. We found significant group differences in some PPG parameters at rest and in response to the repeated pinprick test. Chronic pain patients had consistently higher basal sympathetic activity, as well as a blunted autonomic response when subjected to nociceptive stimuli.**

***Keywords*—Pain assessment, physiological signals, autonomic nervous system.**

I. Introduction

Pain is an "unpleasant sensory and emotional experience associated with, or resembling that is associated with, actual or potential tissue damage" [1]. Different types of pain can be experienced. One of the main distinctions is between acute and chronic pain.

Acute pain is the pain arising from the activation of nociceptors when a thermal, mechanical, or chemical nociceptive stimulus affects the body. Noxious stimuli activate neural transduction at the peripheral, spinal, and brain level, collectively falling under the concept of "pain neuromatrix". Acute pain has a protective function to the body, acting as an alarm bell for a potential threat [2].

On the other hand, chronic pain is defined as persistent or recurrent pain that lasts for more than three months [3]. It is now well known that chronic pain leads to a significant neural plasticity [4], with substantial functional and anatomical changes to reach a new equilibrium different from that of healthy subjects [5]. Chronic pain does not serve a protective function, being maintained despite the absence of the inciting stimulus, and is associated with physiologic and psychosocial changes [6].

Manifestations of physiologic change may include activity of the Autonomic Nervous System (ANS). Pain and ANS are anatomically and functional linked, as pain influences the activity of ANS and vice versa [7]. In the case of chronic pain, previous studies have observed decreased ANS reactivity, potentially leading to a reduced ability of the body to promptly respond to internal and external stimuli [8].

ANS activity can be evaluated by monitoring some physiological signals, commonly called "autonomic" signals precisely because of the ANS' regulation of them. Examples of these signals are Photoplethysmography (PPG), representing the blood volume changes occurring at each heartbeat, Electrodermal Activity (EDA), referring to variations of the electrical properties of the skin due to sweat secretion, and Respiration (Resp).

Autonomic signals have been extensively used in "emotion recognition" studies so far, representing a new way to analyse emotions, and increasingly bridging the gap in human-computer interaction [9]. Gaining greater facility with measurement of fluctuations and variability of autonomic signals under the condition of pain transduction is twofold: from a clinical point of view, this may allow insight into the impact of nociceptive activation on physiology, both in the acute and chronic phase ; from a more technical point of view, it would allow to better tailor algorithms to more sensitively detect a wide variety of painful stimuli in different individuals, and to distinguish the extent of neural remodeling inherent in an individual with chronic disease.

The aim of this study is to explore differences in autonomic signals by comparing healthy control (HC) subjects and chronic Low Back Pain (cLBP) patients i) under rest conditions and ii) when stimulated with a noxious stimulus. This is a further work based on the Intelligent Human Machine System (IHMS) laboratory's exploration work in the past [10], [11].

II. Materials and Methods

A. Protocol

The study involves enrolment of both HC subjects and cLBP patients. The inclusion criteria in common for the two samples are the following:

- 18 years or older
- No evidence of neurological and/or cognitive impairment
- No history of myocardial infarction or other serious cardiovascular condition in the prior 12 months
- Ability to speak sufficient English to complete questionnaire measures.

In addition, HC subjects had to be free of any history or diagnosis of chronic pain. cLBP patients were required to have a history of cLBP for at least 3 months, with an average pain intensity higher than 3/10.

The study protocol was approved by the Institutional Review Board of Brigham and Women's Hospital, Boston, MA, USA, (protocol code2019P002781, 18/11/2019). The protocol included Quantitative Sensory Testing, where defined nociceptive stimuli are applied in a clinical lab setting to assess pain transduction across a variety of modalities.

For the purpose of this study, two experimental conditions have been evaluated:

- Rest: as a baseline, the participant is asked to remain quiet for 1 minute while the signals are recorded
- Repeated pinprick test (i.e., repeated, mildly to moderately painful, punctate mechanical stimuli): the participant is non-invasively stimulated with a weighted, fine metal probe on the right hand, 10 times in a row at 1 Hz frequency. The stimulus intensity is tailored to an individual's pain sensitivity, choosing a probe weight that induces mild pain upon single stimulation.

B. Autonomic signals

In the following, the recorded autonomic signals are presented, together with the pre-processing applied to each of them.

All signals used in this study have been recorded with the Flexcomp system, with a sampling frequency of 256 Hz.

PPG sensor is placed on the left hand's middle finger. The recorded signal has been subjected to a 5th order Butterworth band-pass filter, with [0.5 12] Hz as cut-off frequencies. The filtered PPG signal has been then segmented into PPG pulses by detecting systolic feet [12]. Each pulse was then normalized with a z-score procedure.

EDA has been recorded through electrodes placed on the left hand's ring and index finger. EDA signal has been subjected to a 5th order low-pass Butterworth filter, with 1 Hz as cut-off frequency. We applied a z-score normalization procedure on a subject basis and then we extracted the tonic and phasic component by using the *cvxEDA* algorithm [13].

Respiratory signal was recorded using a band placed around the low chest. The signal has been subjected to a 4th order Butterworth low-pass filter, with 0.1 Hz as cut-off frequency. We implemented the Advanced Counting Method to detect the respiration cycle [14].

C. Autonomic parameters extraction

For the baseline recording, features have been extracted by the whole recording (i.e., 1 minute).

For the repeated pinpricks test, the recording has been segmented into four phases:

- Pre-test: 5 seconds before the beginning of the test
- Between 1st and 5th repetition (5 seconds)
- Between 5th and 10th repetition (5 seconds)
- Post-test: 5 seconds after the end of the test

Twelve parameters have been extracted from the analysis of PPG pulses:

- Heart Rate Variability (HRV) analysis - we estimated the Interbeat Intervals (IBIs) as time differences between two consecutive systolic feet (i.e., the minimum point of a PPG pulse). The obtained IBIs time series has been then filtered by using the approach described in [15]. Extracted HRV parameters are mean value of IBIs (meanIBI), standard deviation of normal heartbeats (SDNN), root mean squared of successive differences (RMSSD), Poincaré plot standard deviation perpendicular (SD1) and along (SD2) the line of identity.
- Morphological analysis: by analysing the morphology of each PPG pulse, we estimated PPG pulse amplitude (PulseAmpl), area under the curve between systolic foot and successive systolic peak (A1), area under the curve between the systolic peak and the successive systolic foot (A2), area under the PPG pulse (A), time between systolic foot and the successive systolic peak (T1), time between systolic peak and the successive systolic foot (T2) [16].

For the EDA, we estimated a total of 8 parameters:

- Whole EDA signal: mean (meanEDA) and standard deviation (stdEDA), and the symbolic information entropy (SIE) [17]
- Tonic component: mean (meantonic) and standard deviation (stdtonic)
- Phasic component: relevant peaks have been retrieved as those peaks with a slope (by analysing the first derivative) higher than 0.01. From the relevant peaks, the mean (meanampEDR) and standard deviation (stdampEDR), together with the frequency (freqEDR) expressed as number of peaks per minute have been retrieved.

For the Resp signal, we retrieved the mean respiration rate (meanRR). Since we used the Advanced Counting Method as an automatic algorithm to detect the respiration cycle, we discarded those estimates exceeding 30 breaths/min.

D. Statistical analysis

To compare the parameters during the rest condition between HC subjects and cLBP patients, we used a Mann-Whitney U test. To assess any statistical differences in different phases during repeated pinprick test, we used a Wilcoxon signed-rank test for paired data by comparing rest and pain phases. We applied a Bonferroni correction for the multiple comparison for the repeated pinprick test, having 6 comparisons in total, thus resulting in a corrected significance level of 0.05/6 = 0.008.

III. RESULTS

A. Dataset

Twenty-three subjects were enrolled in this study, 15 HC subjects (age 27.20 ± 11.58, 4 M, 11 F) and 9 cLBP patients (age 43.67 ± 14.97, 4 M, 5 F). Recordings failed for one cLBP patient, who therefore was not included in the analysis.

B. Baseline recording

Results about the comparison between HC subjects and cLBP patients are presented in Table 1.

By analysing the baseline recordings, mean IBI, A2, A, and T2 were significantly different between HC subjects and cLBP patients, such that all these parameters are significantly lower for cLBP patients than for HC subjects.

C. Repeated pinpricks test

We compared the four different phases of the repeated pinpricks test separately for HC subjects and cLBP patients.

Below, and in Figure 1, are the significant changes in autonomic variables:

- Mean IBI for HC subjects: significantly higher values were detected during the 5th-10th rep phase, compared to pre- and post-test, and a significant decrease from 1st-5th rep to post-test.
- SDNN, RMSSD, and SD1 for cLBP patients: significant lower value from the pre-test to post-test.
- A for cLBP patients: significant decrease from the pre-test to 1st-5th rep and 5th-10th rep.
- T2 for HC subjects: significant increase by comparing 1st-5th rep with 5th-10th rep and post-test.
- meanEDA and meantonic for HC subjects: significant lower values in pre-test compared to all the other phases.
- stdEDA and stdtonic for HC subjects: significant decrease from 1st-5th rep to post-test.
- SIE for cLBP patients: significant decrease from 1st-5th rep to post-test.
- stdampEDR for HC subjects: significant decrease from 5th-10th rep to post-test.
- freqEDR for cLBP patients: significant decrease from pre-test to 1st-5th rep and 5th-10th rep, and a significant increase by comparing 1st-5th rep and 5th-10th rep with post-test.
- meanRR for HC subjects: significant decrease by comparing pre-test with post-test. For cLBP patients: significant increase from 1st-5th rep to the post-test phase.

Numerical values are reported in the Appendix.

IV. Discussion

We carried out a study to assess the different autonomic activity by comparing healthy control subjects and chronic low back patients both in a rest condition and when subjected to an acute noxious mechanical stimulus.

In the rest condition, only certain parameters extracted from the PPG were statistically different between HC subjects and cLBP patients. In particular, mean IBI was significantly lower in cLBP patients. This is in line with previous study findings on chronic pain patients [18]. Greater basal sympathetic nervous system outflow could potential lead to a higher basal heart rate (corresponding to a lower meanIBI) [19].

Some PPG morphological parameters, namely A2, A, and T2, were also found to be significantly lower in cLBP patients compared to HC subjects. Both A2 and A are related to T2, that is the time difference between the systolic peak and the successive systolic foot. This can be also the basis for the lowering of the meanIBI: chronic pain induces a change in the second part of the cardiac cycle, during the diastolic phase. Morphological parameters have been studied in relation to stress, finding similar results as the ones reported in this study [20].

Regarding the analysis of physiologic parameters during the repeated pinpricks test, HC subjects and cLBP patients showed a different autonomic reaction. Overall, cLBP patients appeared to exhibit a blunted degree of change, in agreement with some previous studies [21].

With regards to EDA, while HC subjects showed a dynamic change in several parameters, cLBP patients only demonstrated change in the SIE parameter, related to the complexity of the signal, and the frequency of EDA peaks (freqEDR). Specifically for freqEDR, since EDA is influenced only by the sympathetic branch of the ANS, it is supposed that a noxious stimulus should increase the number of EDA peaks [22]. Conversely, for cLBP patients the frequency of EDA peaks diminished during a noxious stimulus. This also suggests the possibility that a maladaptive functional neural rearrangement may have taken place over time in cLBP patients.

The study presents some limitations that can hamper the generalizability of the results. Firstly, our dataset consisted in an unbalanced number of subjects for the two populations (15 HC vs 8 cLBP). Some changes may have not been detected because of the small number of patients with cLBP. More subjects for both populations should be involved in this study. Another limitation is given by the short phases related to noxious stimuli test. A strategy to gain more robust results could be to repeat the same nociceptive stimulus or to making last longer. Finally, the different age distributions for the two groups can be a significant confounding factor for our analysis.

As future studies, we are planning to compare reactions in the two populations to different noxious stimuli and to develop automatic methods to assess pain.

V. Conclusion

We carried out a study to explore differences in the autonomic activity, as measured by a set of physiologic measures, between HC subjects and cLBP patients both at rest and during a noxious stimulation. Our findings suggest a higher basal sympathetic activation at rest for cLBP patients,

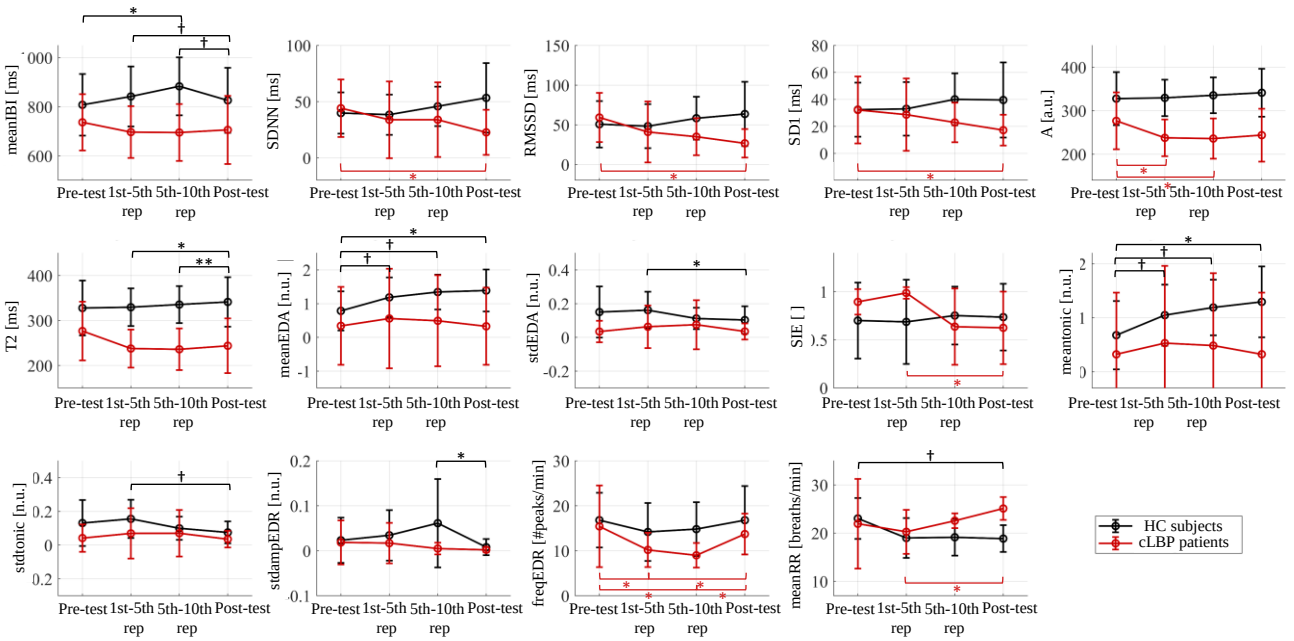

Figure 1 - Statistically significant changes during repeated pinpricks test in healthy controls and cLBP patients.
*** p-value < 0.05, **p-value < 0.01. †Bonferroni correction : p-value (=0.05/6) < 0.008**

but a less dynamic response when subjected to a noxious stimulus.

APPENDIX

Tables related to the results of the repeated pinprick tests are reported as Appendix.

***Abstract*—Machine learning (ML) and deep learning (DL) applications have gained popularity in the field of neuroimaging in recent years. Here, we present a comparison between a state-of-the-art gradient boosting technique, the extreme gradient boosting (XGBoost), and a recently developed DL method, TabPFN, to assess the prediction of cognitive deficit in a large pathological population through structural and functional MRI markers. Overall, our results showed that conventional ML might still be the preferable choice for noisy tabular datasets (like neuroimaging data), also for their better explainability.**

***Keywords*—machine learning, classification, artificial intelligence, neuroimaging, MRI**

I. Introduction

SUPERVISED learning denotes the class of methods where input features of the data and the corresponding target labels are provided to a learning system, aiming to learn the mapping between input and label in order to make individual-level predictions on unseen data. Over the last decades, machine learning (ML) algorithms have been widely used in the field of neuroimaging. Many have argued that predictive methods are key for translating neurobiological findings to clinical practice [1], [2]. In neuroimaging research, the application of advanced ML techniques can help to disentangle the hidden complex patterns in high-dimensional data, in order to better understand how biological systems behave and to predict outcomes or future behaviour [3]. Recently, major methodological advances in the analysis of the neuroimages have been made thanks to the availability of large, shared, data repositories [4]. Magnetic resonance imaging (MRI) is essential to better understand the mechanisms underlying cognitive decline and deficits in many neurological conditions, including multiple sclerosis (MS) [5]–[7]. In MS - an inflammatory, demyelinating and neurodegenerative disease of the central nervous system - in particular, both anatomical and functional markers can provide invaluable information about patients' cognitive status: i) anatomical MRI volumes have proved to be good prediction markers of cognitive disability and progression [7], [8]; ii) functional markers - extracted from blood oxygen level dependent (BOLD) functional MRI (fMRI) time series - have also been recently used to study and predict cognitive changes [9]. Cognitive impairment is common (30-70% depending on disease duration and phenotype) in MS and has a strong impact on daily social activities and quality of life of these patients. Thus, there is an increasing attention in monitoring the cognitive status of MS patients [5]. In this regard, symbol digit modalities test (SDMT) has been recommended as a valid screening test, due to its brevity, reliability and sensitivity [5]. Among the many ML techniques, classification problems are dominated by gradient boosted decision trees (GBDT) [10] mainly due to their relatively short training time and robustness. Among these, the extreme gradient boosting (XGBoost) [11] has beenrecently applied to neuroimaging data with state-of-the-art performances [8]. On the other hand, deep learning (DL) methods, e.g. deep neural networks (DNN), despite excelling on many ML applications, do not have a significant advantage over conventional ML methods on tabular data. Nonetheless, efforts have been made to transfer the DL paradigm into tabular data classification [12]. Recently, a new DL method for tabular datasets, TabPFN, was proposed [13]. Here, we extracted anatomical and functional features from a large dataset of MRI scans of patients with MS. Aim of this study was to compare the performances in predicting cognitive impairment on the basis of SDMT between the state-of-the-art conventional ML method for tabular data, XGBoost, and the most recent advancement of DL targeting tabular data problems, TabPFN.

II. Methods

A. Dataset

MRI data from MS patients were retrieved from a large online database (https://database.inni-ms.org) based the availability of at least one anatomical 3D T1-weighted (3D-T1w) scan and one resting-state functional MRI (rs-fMRI) scan. As a result, MRI data from the exams of 489 MS patients were pooled together from four different acquisition sites. Details about the anatomical and functional data preprocessing (along with clinical and demographical data and acquisition parameters) can be found in [8] and [14], respectively. Patients

with excessive head motion on rs-fMRI time series (i.e. mean framewise displacement > 0.5 mm) were excluded from the dataset (i.e. 5 patients). Anatomical features comprised segmented brain volumes (i.e. cortical gray matter, white matter, thalamus, nucleus accumbens, putamen, nucleus caudate, globus pallidus, amygdala, hippocampus, cerebellum and lesion load); functional features comprised intra-network functional connectivity averaged across seven pre-defined large-scale functional networks [15] (i.e. visual, somatomotor, dorsal attention, ventral attention, limbic, frontoparietal and default mode). Cognitive status was assessed by means of SDMT, where the score is the number of correct answers (ranging from 0 to 110): thus, higher SDMT scores represent better performances. The scores were adjusted for demographical data (age, sex and years of education) using normative data based on a sample of 200 healthy Italian adults [16], and then Z-scores were calculated. For the classification task, MS patients were subdivided into cognitively impaired (CI) and cognitively preserved (CP) based on their SDMT Z-score. One standard deviation below the mean (i.e. SDMT Z-score $\leq$ -1.0) was selected as the cut-off for cognitive deficit [9]. Moreover, patients with a SDMT Z-score ranging in the interval [-1.1, -0.9] were excluded from the dataset due to uncertain assignment between the two classes. Thus, 240 MS patients were classified as CP and 215 as CI, and 29 patients were excluded.

B. XGBoost

XGBoost is a scalable and end-to-end tree boosting algorithm. The system is built with an ensemble of decision tree models and a gradient boosting framework, meaning that, starting from a single weak tree, the process additively generate weak models to improve performance [11]. XGBoost is widely used to achieve state-of-the-art performances on both classification and regression tasks. One of its major benefits regards the great interpretability due to its recursive tree-based decision system, which allows assessing the importance gain, i.e., the improvement in performance brought by each feature. The model provides a large number of hyperparameters that require adequate tuning.

C. TabPFN

TabPFN is a single trained transformer that has been pre-trained to approximate probabilistic inference for a novel prior in a single forward pass, and has thus learned to classify unseen tabular data with performances competitive with state-of-the-art classification methods [13]. TabPFN is built on prior-data fitted networks (PFNs). PFNs approximate bayesian inference given any prior and approximate the posterior predictive distribution directly (PPD). The priors are defined via parametric distributions and are based on bayesian neural networks and structural causal models to model complex feature dependencies and potential causal mechanisms underlying tabular data [17].

D. Train, validation and test

The models have been trained, validated and tested using the following stratified split approach: 80% of the entire dataset (i.e. 364 randomly chosen patients) was used as the training/validation set, and the remaining 20% (i.e. 91 patients) was used as the test set. On the training/validation set, a stratified nested 5-fold cross validation (CV) strategy was adopted to estimate the generalization performance of the models and to perform, at the same time, hyperparameter tuning [18]. In more detail, the inner loop was used to grid-search the best hyperparameter configuration of the model for each outer fold, and the outer loop to estimate the generalization performance on the validation test. This framework was repeated twice and separately for anatomical and functional features. The performances were quantified in terms of area under receiver operating system (AUROC). Moreover, since the outcomes may vary depending on how the training/validation set is randomly split in each fold of the nested CV, the latter has been repeated 10 times. Since both anatomical and functional features have large variability across MRI centers due to differences in scanner manufacturers and imaging protocols, both were (separately) harmonized with a state-of-the-art methodology (i.e. ComBat) in order to minimize site effects [19]. We included age, sex, and group as biological covariates in the harmonization process to preserve them from the removal of scanner-related effects in the presence of different age and sex distributions between sites. To avoid data leakage, the harmonization process was performed separately on the training/validation and test set. No additional preprocessing was applied on the feature set, since TabPFN model works best when the dataset has not been preprocessed [13].

Although XGBoost has an internal procedure to calculate feature importance, in order to standardize the methods and make the models more comparable, we used the permutation feature importance technique, which is defined as the decrease in the model score when a single feature is randomly shuffled. It is worth noting that permutation importance scores could assume also negative values when better scores result after feature shuffling; in this case, those features are likely to negatively impact the prediction. All the experiments were carried out with custom-made scripts in python (v3.7.13) and using xgboost (v1.6.2) and tabpfn (v0.1.8) packages on a linux workstation equipped with two 8-core Intel (R) Xeon (R) Bronze 3106 @1.70 GHz, for a total of 16 CPU threads and 128 GB RAM.

TABLE I: MODELS PERFORMANCE

Anatomical features	*XGBoost*	*TabPFN*
Training/validation score	0.64 (0.02)	0.64 (0.01)
Test score	0.63 (0.02)	0.61 (0.01)
Functional features	*XGBoost*	*TabPFN*
Training/validation score	0.55 (0.01)	0.55 (0.02)
Test score	0.55 (0.04)	0.51 (0.01)

Performance on the dataset using anatomical and functional features. Results are reported as mean AUROC (standard deviation).

III. RESULTS

Performances from XGBoost and TabPFN are summarized for both anatomical and functional features in Table 1. For the

prediction of the cognitive class (CP and CI) using only anatomical features, XGBoost reached a mean AUROC of 0.64 (0.02) on the training/validation set and 0.63 (0.02) on the unseen test set, whereas TabPFN reached a mean AUROC of 0.64 (0.01) on the training/validation set and 0.61 (0.01) on the unseen test set. Fig. 1 reports anatomical feature rankings for both models. Using functional features, XGBoost reached a mean AUROC of 0.55 (0.01) on the training/validation set and 0.55 (0.04) on the unseen test set, whereas TabPFN reached a mean AUROC of 0.55 (0.02) on the training/validation set and 0.51 (0.01) on the unseen test set. Fig. 2 reports functional feature rankings for both models. When we repeated the training of the TabPFN without those features with a negative estimated importance score (i.e. dorsal attention, frontoparietal and default network), the model showed an improved AUROC of 0.56 (0.01) on the training/validation set and of 0.53 ($4 \cdot 10^{-3}$) on the unseen test set.

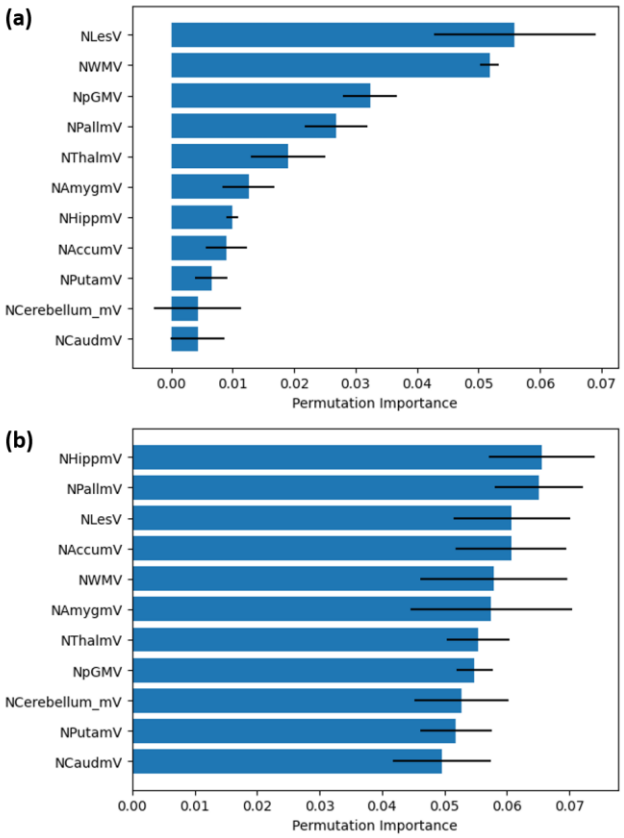

Fig. 1: Anatomical feature ranking from permutation feature importance for XGBoost (a) and TabPFN (b). Average values are reported (using 10 repetitions of 5-fold nested cross-validation inner loop on the training set and selecting the best model for each repetition). Abbreviations: NAccumV, normalized mean accumbens volume; NAmygmV, normalized mean amygdala volume; NCaudmV, normalized mean caudate volume; NCerebellm_mV, normalized mean cerebellum volume; NpGMV, normalized cortical grey matter volume; NHippmV, normalized mean hippocampus volume; NWMV, normalized white matter volume; NPallmV, normalized mean pallidus volume; NPutamV, normalized mean putament volume; NLesV, normalized lesion volume; NThalmV, normalized mean thalamus volume.

IV. Conclusion

ML tools are broadly applied to neuroimaging data nowadays. Although classification models for tabular datasets are still dominated by gradient-boosted decision trees, many progresses have been made to adapt advanced deep learning architectures (e.g. transformers) for predicting classes. In this work, we compared the XGBoost model, a state-of-the-art model for tabular datasets, with TabPFN, a novel transformer-based deep learning architecture specifically built and trained to solve tabular classification problems, to explore the

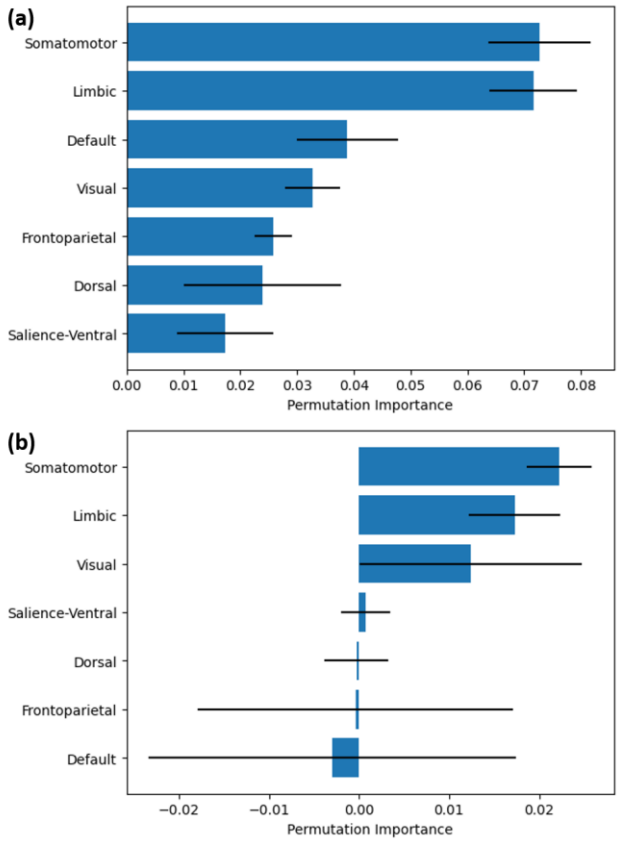

Fig. 2: Functional feature ranking from permutation feature importance for XGBoost (a) and TabPFN (b). Average values are reported (using 10 repetitions of 5-fold nested cross-validation inner loop on the training sett and selecting the best model for each repetition).

predictive abilities on two sets of typical MRI-derived anatomical and functional features, in order to predict the cognitive status of MS patients on an individual level. Both the models were trained, validated and tested using a combined CV/hold-out scheme (80% of the entire dataset for the training/validation set and 20% for the test set). Moreover, since performances may depend on how the training/validation set is split, the (nested) CV scheme was repeated 10 times using different random splits. Overall, our results showed that TabPFN classification performances are comparable to, but not better, than XGBoost. Indeed, for both anatomical and functional features, XGBoost provides equal results on the training/validation set (mean AUROC = 0.64 for the anatomical dataset and mean AUROC = 0.55 for the functional dataset), but better results on the unseen test set (mean AUROC = 0.63 vs 0.61 for the structural dataset and mean AUROC = 0.55 vs 0.51 for the functional dataset), even when we excluded from the feature set those features yielding a negative impact on the model (mean AUROC = 0.53). Beyond reporting which model would be showing the best performance, we were also interested in knowing if the two

models estimated similar importance scores for the features. Our findings showed that, for anatomical features, there is a discrepancy between the two models; in fact, while the XGBoost estimated high importance scores only for a few features (i.e., lesion volume, pallidus volume, cortical grey matter volume and white matter volume), the TabPFN model importance score estimates were more similar, i.e., there was no evidence for a subset of features clearly predominant with respect to the others. However, findings in the feature importance estimated with XGBoost were consistent with previous literature reporting cognitive dysfunction associated with volume abnormalities in lesion load [21], pallidus, gray and white matter volumes [8], [21]. On the other hand, the feature rankings for the functional dataset were more similar, with the somatomotor and limbic networks having the two highest importance scores for both datasets; indeed, these two functional networks have been previously showed to be related to clinical disability [22], [23]. Still, differences were present, e.g. the default network was ranked third in the XGBoost model, but, on average, negatively impacted the TabPFN prediction. Although the permutation importance technique is model-agnostic, i.e., it can be applied to any predictive model, these discrepancies between feature importance estimations could be partially explained by the intrinsic differences between the two models and how they treat the input features (besides the stochastic nature of both algorithms). In fact, XGBoost adds decision tree models sequentially to correct errors made by existing models while giving more importance to features useful to have better overall performances, whereas TabPFN, having a transformer-based architecture (i.e., a neural network), initializes random weights to input data and updates them given the data distribution and their prior probability [13]. In conclusion, our comparative study showed that gradient-boosted models, such as XGBoost, may still be the preferable choice for noisy tabular datasets, such as those derived from neuroimaging data. Moreover, neural network architectures like TabPFN, given their black box nature, pose issues about explainability, whereas XGBoost has a relatively straightforward method to automatically evaluate feature importance.

ETHICAL APPROVAL

Ethical approval was received from the local ethical standards committee of each participating center, and written informed consent was obtained from all participants at the time of data acquisition.

***Abstract*—Olfactory stimuli are powerful cues capable of modulating behavioral and physiological responses to other stimuli, such as visual stimuli. In this study, we investigated the integration of autonomic-driven information into the central nervous system dynamics during a contextual presentation of neutral faces and hedonic odors. To this aim, we simultaneously acquired the electrodermal activity (EDA) and EEG signals from a group of 20 healthy volunteers. We applied a novel methodological approach to identify event-related potentials (ERPs) with and without a concomitant EDA-related sympathetic response. Then, we investigated the effect of both sympathetic responses and contextual odors on ERP components involved in the processing of faces. Preliminary results showed a significant increase of the N170 amplitude in the left parieto-temporal region when a sympathetic response was present, compared to ERPs associated with no sympathetic responses, irrespective of odors' valence. This may suggest that sympathetic responses identified from EDA have an effect on the early central processing of faces with background odors, possibly reflecting enhanced arousal triggered by salient features of the stimuli.**

***Keywords*—Face processing, ERP, sympathetic responses, hedonic olfaction**

I. Introduction

Facial expressions are powerful non-verbal means through which the emotional state or the identity of a person can be efficiently decoded [1]. However, when expressions are ambiguous, their interpretation relies on the integration with other sensory modalities [2]. Previous research indicated contextual odors as powerful emotional triggers for the processing of faces, with odors' valence and arousal playing a key role as modulatory factors [3]–[5]. Moreover, their influence is not limited to subjective ratings but extends also to the physiological response as measured by EEG event-related-potentials (ERPs).

ERPs are EEG changes time locked to sensory, motor or cognitive events that provide a noninvasive approach to study psychophysiological correlates of mental processes. These waveforms are characterized by some key features, namely components, that can reflect early "sensory" or late "cognitive" responses [6]. Previous studies highlighted a contextual effect of emotional odors occurring at different stages of face processing, including the N1/P1 [7], N170 [8], VPP [9], and LPP [10] components.

Parallel to ERP analyses, other studies focused on the autonomic response elicited by contextual visual/odor stimulation [11], [12]. Particularly, enhanced peripheral sympathetic activations have been observed following the presentation of either visual or olfactory stimuli and that reflected the perceived level of arousal [11]–[13]. In this light, it would be of particular interest integrating the sympathetic responses with ERP measures for analyzing the multimodal integration of visual-odor processing.

Here, we investigate the effect of peripheral sympathetic responses on the central processing of neutral faces modulated by hedonic odors. We combine standard ERP analysis with the information provided by electrodermal activity (EDA). EDA is the most commonly used index to assess peripheral sympathetic activity, as the eccrine sweat glands generating it are mainly controlled by afferent sudomotor sympathetic fibers [13]. Accordingly, we apply a rigorous deconvolution procedure based on [14] to estimate the EDA underlying sudomotor nerve activity (SMNA), and identify the occurrence of significant sympathetic responses associated with the presentation of the stimuli. We exploit these events to compare ERPs with and without a sympathetic response [15]. Moreover, we evaluate the influence of contextual odors on both types of ERPs.

II. Material and methods

A. Subjects

The study was conducted according to the guidelines of the Declaration of Helsinki, and approved by the Bioethics Committee of the University of Pisa Review No. 14/2019, May 3rd, 2019. Twenty healthy volunteers (age 27 $\pm$ 3, 5 females) with similar olfactory threshold according to the double-blind forced-choice olfactory test [16] were enrolled in the study. Volunteers were not allowed to have any food or drink in the 30 minutes preceding the experiment.

B. Experimental setting

We selected three different odorants: i.e., banana (isoamyl acetate), isovaleric acid, and n-butanol, to convey positive, negative, and neutral valence, respectively [17]–[19]. We additionally used clean air as a control condition. For each subject, we prepared $1ml$ isointense solutions diluting pure odorant substances in distilled water according with the ratios of 1/20 (banana, n-butanol) and 1/10 (isovaleric acid) respectively. Odorants were delivered through an in-house built computer-controlled olfactometer at a constant flow rate of $60ml/min$. Before starting the experiment participants rated the odorants in terms of valence (from -2 to +2) and arousal (from 1 to 5) according to the Self-Assessment Manikin (SAM) test [20].

Moreover, we selected 128 different neutral face images from the Chicago Face Database [21]. Particularly, according to previous studies, we balanced the stimuli across gender, age, and ethnicity, to mitigate potential confounding effects related to the intrinsic characteristics of the actors [10]. The pictures were shown on a 15" laptop screen with a refresh rate of 60Hz and a resolution of 1920x1080. The pictures' size was 15cm in width and 10cm in height, and they were displayed at about 50cm from the eyes of the participants .

Each subject underwent an experimental protocol made of 128 trials of concurrent odor/image administration. A schematic representation of each trial is reported in Fig.1, which consisted of: (1) 3s of gray background; (2) 3s of fixation cross; (3) 1.5s of neutral face image presentation; (4) 6s of inter-trial rest during which subjects rated the facial expression in terms of valence and arousal according to the SAM test. Odorants were administered from phase (1) to (3), while during (4) clean air was used to washout the odor. Each odor condition comprised a total of 32 trials.

The experimental timeline for the olfactory/visual stimulation was controlled using the PsychoPy software [22]. The EDA signals were acquired at a sampling frequency of 50Hz with a Shimmer3 GSR+ unit (Shimmer, USA). The EEG signals were recorded at the sampling frequency of 500Hz using a high-density 128-channel geodesic EEG System 300 from Electrical Geodesic, Inc. (EGI). Electrodes were grounded through two additional channels placed between Cz and Pz and referenced through Cz. We always kept electrode impedances below $20k\Omega$ during the acquisitions.

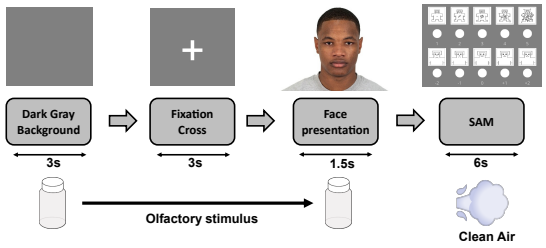

Fig. 1: Experimental protocol. For each trial a random odor among banana, n-butanol, isovaleric acid and clean air was delivered starting from *Dark Gray Background* to *Face presentation*. A wash-out with clean air was performed during *SAM*.

C. EDA processing and sympathetic activity estimation

EDA is comprised of a slow-varying tonic component overimposed to a fast-varying phasic component. In particular, the phasic component manifests as a series evoked-responses called skin conductance responses, whose elicitation is driven by sympathetic neural bursts (i.e., the sudomotor nerve activity - SMNA) [13].

We applied the cvxEDA algorithm to estimate the SMNA from each EDA signal (see [14]). According to the experimental protocol, we divided the SMNA signal into 128 different epochs of 5 seconds starting from the onset of each face presentation. Afterwards, we labeled and discriminated those epochs containing at least an SMNA burst (*symp-evoking*) from those not showing any neural sympathetic response (*symp-absent*).

D. EEG processing

We preprocessed the EEG signal using EEGLAB [23] with a pipeline comprising: (1) zero-phase antialiasing filter (filter cut-off = 30Hz) and downsampling to a sampling frequency of 100Hz, (2) a zero-phase high-pass filter (cut-off = 0.1Hz) to improve data stationarity, (3) bad channel removal with poor correlation with their neighboring channels (i.e., ρ <0.8) [24], (4) channel recovery through spherical spline interpolation, (5) re-referencing to average. Then, preprocessed EEG was epoched in the (-200,1000)ms range around the face-stimulus onset. For each epoch we removed a baseline estimated in the (-200,0)ms time-range. Epochs contaminated by irreducible artifacts were identified by visual inspection and removed. Finally, we decomposed EEG data through ICA [25], and we removed components resembling noise sources (e.g., EMG, eye blinks).
Once the preprocessing was completed, we selected the epochs with the same odor condition and averaged those with the presence of the SMNA bursts (*symp-evoking*) and those with the absence of SMNA bursts (*symp-absent*) (see Section II-C) estimating two stimulus-locked ERPs for each odor condition.

ERP components were then analyzed on specific regions of interest (ROIs) of the scalp with the guidance from previous literature [7]–[9], [26], [27]. More specifically, we extracted (1) the P1 component in the 120-160ms interval after stimulus onset in the occipital region around O1 and O2 (10 electrodes); (2) the N1 component at the same latency as P1, in the central region around Cz (15 electrodes); (3) the N170 component in the 160-200ms interval at both the left and the right parieto-temporal regions (7 electrodes near P7 and P8, respectively); (4) the Vertex Positive Potential (VPP) in the 160-200ms interval in the same ROI of the N1 component; (5) P2 component at 220-300ms in the same occipital region of P1; (6) the Late Positive Potential (LPP) in the 300-500ms range around Pz (9 electrodes). For each subject and for each component, we extracted the mean amplitude within the respective time interval and ROI.

E. Statistical analysis

Due to their nature, the subjective ratings of both odors and faces were not normally distributed. Therefore, we investigated possible differences in the perceived valence and arousal among the 4 different odorants (i.e., clean air; banana, n-butanol, and isovaleric acid) through non-parametric Wilcoxon sign-rank tests. The same procedure was applied to test for possible modulation of the valence and arousal ratings of faces by the 4 different odorants. P-values were adjusted for multiple comparisons with Bonferroni correction (6 comparisons).

Concerning the ERP analysis, after checking for data normality, we performed a two-way within-within ANOVA (first way: *symp-absent* vs *symp-evoking*; second way: odorant) to test the effect of sympathetic responses and odors on the amplitudes of each of the six ERP components described in section II-D. False positives were controlled with false-discovery rate (FDR) [28]. Post-hoc comparisons were conducted with a t-test (Bonferroni corrected; 3 comparisons).

III. Results

A. SAM statistical analysis results

1) Odor rating: Subjects rated isovaleric acid as significantly more unpleasant (mean $\pm$ standard error (SE); valence = -0.62 ± 0.18) and more arousing (arousal = 2.81 ± 0.22) with respect to banana and n-butanol. We did not find any significant difference between the valence and arousal ratings of banana (valence = 0.38 ± 0.20; arousal = 2.33 ± 0.21) and n-butanol (valence = 0.10 ± 0.18; arousal = 1.86 ± 0.17).

2) Face rating: We did not find any significant difference in the subjective ratings of faces among odors for both valence (clean air = -0.05 ± 0.05; banana = -0.14 ± 0.06; n-butanol = -0.03 ± 0.05; isovaleric acid = -0.09 ± 0.07) and arousal (clean air = 2.17 ± 0.16; banana = 2.23 ± 0.17; n-butanol = 2.18 ± 0.16; isovaleric acid = 2.15 ± 0.17).

B. ERP statistical analysis results

Since the banana odor did not elicit a SAM scoring significantly different than the n-butanol, we limited the ERP analysis to the study of clean air, n-butanol, and isovaleric acid effects. In addition, in this way, we increased the statistical power by reducing the number of comparisons.

We observed a significant difference between *symp-absent* and *symp-evoking* on the N170 amplitude at the ROI around P7 ($F_{1,19} = 4.62, p < 0.05$) (Fig.2). Particularly, the presence of a sympathetic response resulted in the increase of the N170 amplitude, irrespective of the valence of the odors. Moreover, we found a significant effect of the odor on the N1 ($F_{2,38} = 6.28, p < 0.05$) and VPP ($F_{2,38} = 7.19, p < 0.05$) components' amplitude at the ROI centered on Cz (Fig. 3). Post-hoc analysis highlighted a more negative N1 component during the administration of isovaleric acid, with respect to clean air. Moreover, the VPP amplitude during the administration of both isovaleric acid and n-butanol was significantly lower with respect to clean air. We did not find a significant interaction between the effect of odor and sympathetic responses for any of the ERP components investigated.

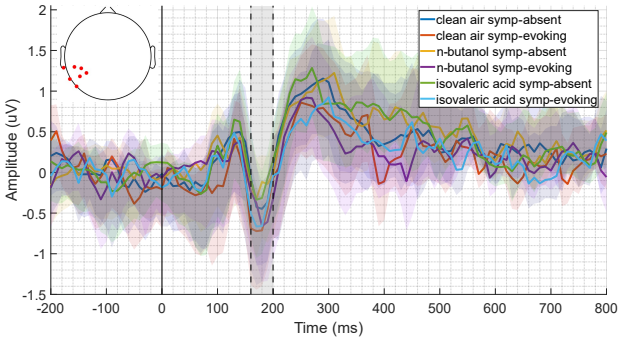

Fig. 2: ERP grand-averages for the clean air symp-absent (blue), clean air symp-evoking (red), n-butanol symp-absent (yellow), n-butanol symp-evoking (purple), isovaleric acid symp-absent (green), and isovaleric acid symp-evoking (light blue) conditions, averaged across 7 electrodes around P7 (scalp map on the left). The gray area highlights a higher N170 amplitude observed during *symp-evoking*, compared to *symp-absent*.

IV. Discussion

In this study, we provided a novel methodological approach based on the analysis of the EDA signal to integrate peripheral sympathetic activity information onto ERP analysis of key components associated with the processing of faces and contextual hedonic odors. Although preliminary, our results showed a significant difference between ERPs with and without a sympathetic response at the early stages of face processing.

We did not find any significant difference in the ratings of faces for both valence and arousal among odors. Yet, we observed an effect of olfactory stimulation on the N1 e VPP ERP components. Particularly, the amplitude of the VPP was lower during the administration of both isovaleric acid and n-butanol, with respect to clean air. This is in line with previous studies reporting an overall effect of olfactory stimuli, irrespective of their valence [9]. Considering N1, we observed a higher amplitude during the administration of isovaleric acid, with respect to clean air. Higher N1/P1 amplitudes have

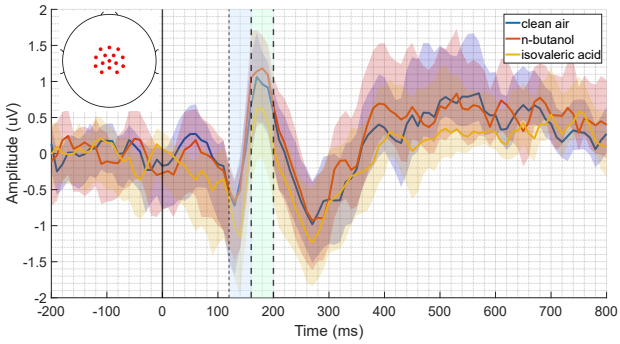

Fig. 3: ERP grand-averages for the clean air (blue), n-butanol (red), and isovaleric acid (yellow) conditions, averaged across 15 electrodes around Cz (scalp map on the left). The N1 amplitude was higher during isovaleric acid, compared to clean air (blue area). Conversely, the VPP amplitude was lower during both isovaleric acid and n-butanol, compared to clean air (green area)

been associated with the enhanced allocation of attention towards faces [7]. In this light, we may suggest that isovaleric acid had a greater arousing effect on the early processing of visual stimuli, compared to the other odorants. This is further corroborated by our findings on the SAM ratings of odors, showing isovaleric acid as being perceived as more arousing and unpleasant compared to banana and n-butanol.

The amplitude of the N170 increased for the P7 cluster in the presence of a sympathetic response. Previous studies have found a significant correlation between the N170 amplitude and the perceived level of arousal associated with faces, irrespective of their valence, such that arousing stimuli were associated with increased ERP responses [29]. Further, during the N170 window, it is hypothesized that multiple cortical processes underlie the fine-graining categorization of faces based on their main characteristics, such as expression, eye gaze, and identity [27]. Hence, we may suggest that the higher N170 amplitude observed during sympathetic responses reflects enhanced arousal associated with salient features of the stimuli.

Of note, banana was rated neutral rather than positive. In this light, we cannot exclude that such an effect may be related to the flow rate at which odors were delivered (i.e., $60ml/min$), which is lower than flow rates commonly used in the literature (e.g., 1-6l/min) [30]. In this light, future works could evaluate the influence of low flow rates on key features of perceived odors.

Although preliminary, our results suggest that integrating peripheral sympathetic information in the analysis of the central responses to the contextual presentation of visual and olfactory stimuli may be of interest for future studies investigating potential effects at the source level through the application of more sophisticated techniques.

***Abstract*—Hand gesture recognition through surface electromyographic (sEMG) signals represents a well-consolidated approach for a natural and intuitive prosthesis control. Several studies showed how the classification performance can differ between healthy subjects and amputees, due to the high complexity and variability of amputations. Nonetheless, the evaluation of the goodness of Machine Learning classifiers in terms of adaptability to the subjects has never been studied deeply, and only few studies involved a sufficient number of amputees in their analysis. In this paper, the performance of four state-of-the art classifiers in decoding both motor intention and forces were evaluated, using a hierarchical classification approach. Algorithms have been tested on 29 healthy subjects and 15 trans-radial amputees. Results showed high performance for both the Non Linear Regression Classifier and the Random Forest with bootstrap aggregation, for both the gestures and the forces classification problem. No significant differences were found between the two classifiers, suggesting that they may be used interchangeably.**

***Keywords*—EMG pattern recognition, prosthesis, Upper limb.**

I. Introduction

THE loss of a limb represents an event that can impact most everyday activities. The need to restore part of amputees' capabilities directly translates into the need of improved prosthesis control algorithms, capable of decoding the user intent and allowing a natural and intuitive control. In this context, sEMG pattern recognition has established itself as one of the most widespread technique to decode the user motor intention [1], [2]. Over the years, hand prostheses and their control strategies considerably evolved, allowing the amputees to move from purely cosmetic to single function devices capable of opening/closing the hand [3], up to robotic hands [4] and wrists [5] with multiple degrees of freedom [6]. Several pattern recognition approaches for gesture and force recognition have been proposed over the years. The most popular are Support Vector Machine (SVM) [7]–[9], Linear Discriminant Analysis (LDA) [7], [10]–[12], Non Linear Regression (NLR) [13]–[15], k-Nearest Neighbour [16], Random Forest (RF) [17], Neural Networks [18], [19]. However, despite their popularity, very few studies tested these classifiers on dataset with amputees [20]–[22], and only few compared their performance in gesture and forces recognition on the same dataset [13], [14], [20].

In order to identify the best performing classifier on both healthy subjects and amputees, in this paper we tested four state-of-the-art classifiers in a hierarchical architecture [13], [14] by decoding seven hand/wrist gestures and three levels of force simultaneously and compared their results between healthy subjects and amputees. The gesture set analyzed in this study included the *rest* condition, four hand gestures (*open hand, bidigital grasp, power grasp, pointing*) and two wrist gestures (*pronation, supination*), while for the two grasps (*bidigital* and *power*) three different levels of force were recorded.

II. Materials and Methods

A. Classification architecture

A hierarchical architecture strategy (Fig. 1) was used to decode gestures and force levels. The structure includes a high hierarchical level that involves a gesture classifier, and a low hierarchical level, which includes two forces classifiers specialized in recognizing three levels of forces from specific types of grasp (*power* or *bidigital* grasp). The force classifiers are activated only when the output of the gesture classifier indicates one of the two grasping classes.

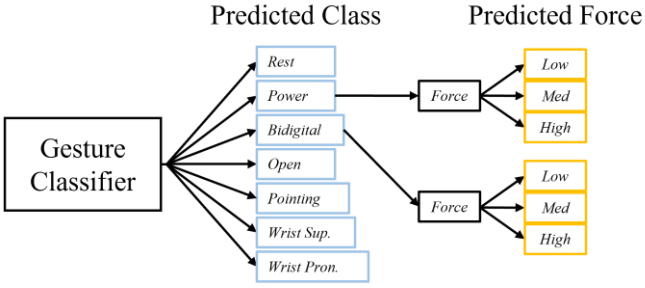

Fig. 1: Hierarchical architecture. The gesture classifier (black box on the left) predicts one of the seven classes (blue boxes). If Power or Bidigital class is predicted, the corresponding force classifiers (black box on the right) predict one of the three level of forces (yellow boxes).

B. Classifiers

The four most used state-of-the-art machine learning classifiers were tested [17]: LDA, SVM, RF with bootstrap aggregation and NLR [13], [14]. Moreover, in order to guarantee an intuitive and natural response of the classifiers with respect to physiological delays of muscle contraction, the signals were divided in time windows of 150 ms of length and 50 ms of overlap [23]. Five commonly used features in the time domain were extracted from the signal: Mean Absolute Value (MAV), Root Mean Square (RMS), Signal Slope Change (SSC), Window Length (WL), Variance (VAR) [24].

C. Experimental setup

Twenty-nine healthy subjects (age: 29.0 ± 7.3 years, 14 F) and fifteen amputees (age: 45.0 ± 13.4 years, 3 F) participated in the experiment. All the subjects signed informed consent for voluntary participation in the study. The studies involving human participants were reviewed and approved by Comitato Etico di Area Vasta Emilia Centro (protocol number: CP-

PPRAS1/1-01; date of approval: 04/10/2018). Muscular activity was acquired through six commercially available sEMG sensors (Ottobock 13E200 - range 0 − 5V, bandwidth 90 − 450Hz), that integrate a pre-processing module which provides a non-negative and enveloped signal as an output. Electrodes were placed equidistantly around the forearm of the participants, about 4 cm below the elbow, accordingly to the common placement in a prosthetic device [25].

For all the subjects (i.e. healthy and amputees), a hand dynamometer (Vernier HD BTA, 46x28x170 mm) was used to acquire exerted forces on the non-dominant/residual hand. EMG and force data were acquired simultaneously with a sampling frequency of 1 KHz, through a LabView interface for DAQ USB 6002 device, connected to a laptop (MSI 86 prestige 15, Intel (R) Core (TM) i7-1185G7 CPU @ 1.80 GHz 2.40 GHz) via USB port.

Prior to the acquisition, the subjects were asked to perform the grasp gestures with three different levels of perceived force (low, medium, high), using both limbs. Thus, EMG data was acquired on the dominant/amputated limb, and the forces with the dynamometers on the non-dominant/residual one. Three repetitions of three seconds were acquired for each force level. The average contraction levels were calculated from EMG signal for each force level, and the low, medium and high levels of force were defined for the two grasps as follows: the low level was set in the range of the average low contraction ± 10%, the medium was set in the range of the average medium contraction ± 10%, while the high level started from -10% of the average high contraction up to the maximum value.

Subsequently, all the subjects performed bi-manually six repetitions for each of the seven gestures, holding the position for 2 s. A rest period of at least 2 s was given after every repetition, and a longer recovery time (>30s) every six repetitions. Two repetitions for each of the three force levels were recorded for each grasp gesture, using the real-time force level and the recorded ranges as visual feedbacks for the users. Gestures were performed in a randomized order.

D. Data Processing and statistics

In order to analyze the steady part of the contraction, for each repetition we kept only the final 800 ms, discarding the rest state preceding the contraction and the subsequent transient state, without any further pre-processing other than the one obtained by the sensors. Thus, for each subject EMG data were organized in a 33600 × 6 matrix (6 repetitions × *7 gestures* × *800 samples* × *6 sensors*), with each column representing a sensor, and divided in time windows of 150 ms. For each subject, time windows were then separated into training and test sets with a 5-fold cross validation, using 30% of the windows for the test and 70% for the training. Features were extracted from each time window. In order to speed up the training process for NLR, a down sampling with a step=10 (keeping the first sample and discarding the following nine) was used on raw data from the time windows without any processing. Both features and raw data were then normalized with respect to their maximum per column (see Eq. (1)).

$$Sn = \frac{S - \min(S)}{Max(S) - \min(S)} \quad (1)$$

where *Sn* and *S* are respectively the normalized and the original signal.

All the classifiers were trained and tested using the same training and test validation sets, which contained a balanced number of observations per class. Since NLR gives one prediction per observation, the final classification output was calculated by using a majority voting (MV) among the prediction of the whole time window. The first-order iterative optimization algorithm "Gradient descent" was used to set the NLR classifier optimal internal hyper-parameters. One Vs. All approach [13] was used for NLR and SVM classifiers to adapt the algorithms to the multi-classification problem. In order to have a balance between classification accuracy and prediction time, RF number of trees was empirically set to 25. Confusion matrices, class accuracy and average accuracy were calculated for all the subjects. Wilcoxon signed rank test for paired samples was applied to the non-normal average accuracies to find significant differences between the classifiers, with a significance level set to $\alpha=0.05$ and applying Bonferroni correction ($\alpha=0.0083$). Wilcoxon rank sum test for independent samples was used to compare the non-normal results from healthy subjects and amputees. Lastly, the execution time for each classifier was calculated in an online test as the time spent from the receipt of 150 ms of signal to the prediction output. The online test simulated the receipt of ten time windows per class for the gesture classifier, and other ten time windows for *power* and *bidigital* grasp respectively. Execution time then averaged over the time windows. The analysis was entirely conducted on a laptop (Lenovo ThinkPad E570, Intel (R) Core (TM) i5 CPU @ 2.50 GHz) with MATLAB software.

III. RESULTS

A. Healthy subjects

The results of the gesture classifier are reported in Fig. *2*. In agreement with previous studies [13], [14], NLR achieved the highest median accuracy among subjects (97.9% ± 4.2), followed by RF (95.9% ± 3.0), LDA (93.9% ± 4.0), and SVM (92.9% ± 6.2). Significant differences were found between NLR and other classifiers, except with RF (p=0.08). All classes of NLR and RF achieved more than 90% of accuracy, while LDA only achieved 89% of accuracy for *bidigital* grasp, and SVM achieved 85% for *power* grasp (Fig. 3).

Force classifiers showed high accuracy for both the *power* grasps classifier (Accuracy NLR = 100% ± 0.0; Accuracy RF = 100% ± 3.0; Accuracy SVM = 100% ± 7.9; Accuracy LDA = 88.9 ± 12.5) and the *bidigital* grasp classifier (Accuracy NLR = 100% ± 6.2; Accuracy RF = 100% ± 6.4; Accuracy SVM = 88.9% ± 11.1; Accuracy LDA = 77.8% ± 14.4). Regarding the *power* grasp, significant differences were found between LDA and NLR ($p<10^{-4}$), LDA and RF ($p<10^{-4}$) and LDA and SVM (p=0.005), while for *bidigital* grasp significant differences between classifiers were found between all classifiers except for RF and NLR (p=0.77) (Fig. *4*).

B. *Amputees*

Similar results were found in amputees (Fig. 2), where NLR achieved the best median accuracy (99.0% ± 7.1), followed by RF (96.9% ± 4.9), SVM (90.8% ± 7.9), and LDA (89.8% ± 8.8). Significant differences were found between NLR and all the other classifiers, except for the RF ($p>0.65$). No significant difference was found between LDA and SVM. All classes of both NLR and RF achieved more than 90% of accuracy, in LDA *power* and *Bidigital* grasp achieved 76% and 78% of accuracy, and in SVM *power* grasp achieved 80% (Fig. 3).

Results from the force classifiers showed high accuracy for both the *power* grasps classifier (Accuracy NLR = 100% ± 4.0; Accuracy RF = 100% ± 9.5; Accuracy SVM = 100% ± 13.7; Accuracy LDA = 83.3 ± 9.5) and the *bidigital* grasp classifier (Accuracy NLR = 100% ± 9.5; Accuracy RF = 100% ± 12.5; Accuracy SVM = 88.9% ± 11.6; Accuracy LDA = 77.8% ± 12.9). A significant difference was found between LDA and NLR for *power* grasp ($p<9*10^{-4}$, while no significant differences between classifiers were found for the *bidigital* force classifier (Fig. 4).

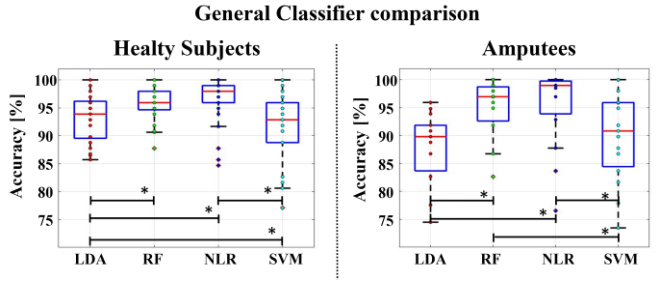

Fig. 2: Gesture classifier healthy subjects (left) and amputees (right). Significant differences are indicated with a star *.

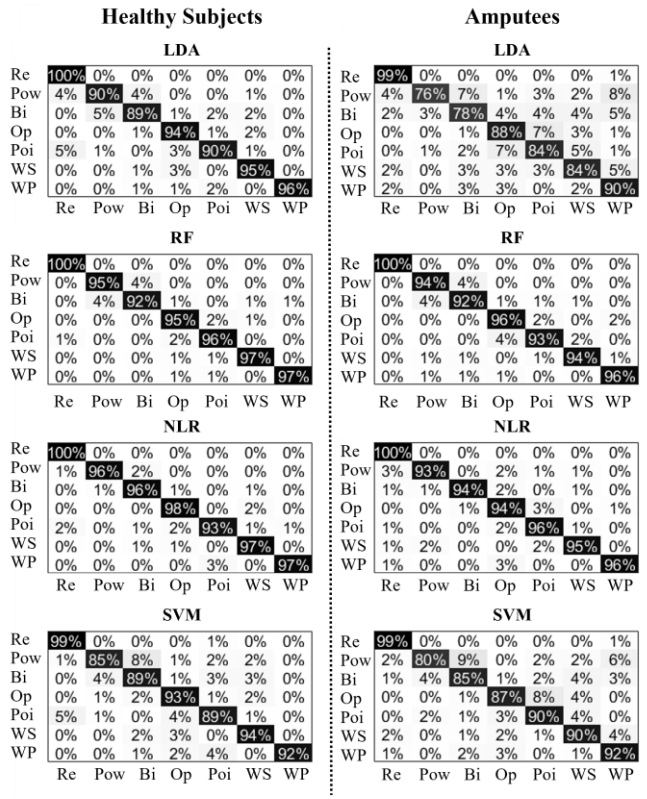

Fig. 3: Confusion matrices for all gesture classifiers and class accuracy for *rest* condition (Re), *Power grasp* (Pow), *Bidigital grasp* (Bi), *Open hand* (Op), *Pointing* (Poi), *Wrist Supination* (WS) and *Wrist Pronation* (WP).

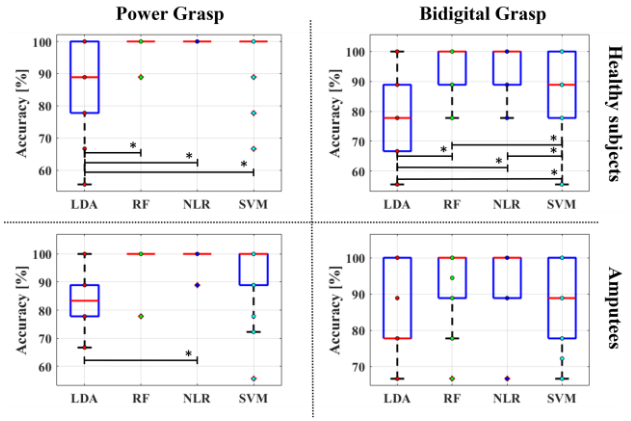

Fig. 4: Force classifier results for *power grasp* (left column) and *bidigital grasp* (right column) in healthy subjects (top row) and amputees (low row).

C. *Healthy subjects vs Amputees*

Despite some differences in the accuracy, Wilcoxon rank sum test showed no significant differences between healthy subjects and amputees, except for LDA classifier.

D. *Online test execution time*

All the classifiers need a time window of 150 ms of signal as an input, except for NLR, that can make a prediction for every new observation (i.e. one prediction per ms for a 1 KHz acquisition). In order to have comparable results, MV was applied to NLR predictions. Execution time reported in Table I shows that LDA has the fastest response in both the general and the force classifiers, followed by NLR, SVM, and RF.

TABLE I: CLASSIFIERS EXECUTION TIME

Classifier	*Gesture Classifier Execution Time*	*Force Classifier execution time – grasps averaged*
LDA	12.5 ± 3.8 ms	11.0 ± 4.7 ms
RF	73.0 ± 8.1 ms	69.3 ± 10.0 ms
NLR	15.9 ± 7.1 ms	13.8 ± 6.8 ms
SVM	34.8 ± 11.3 ms	24.9 ± 18.9 ms

Execution time for LDA, RF, NLR and SVM classifiers. Results were obtained as an average on ten time windows per class (150 ms length).

IV. CONCLUSION

In this paper, four state-of-the-art classifiers in a hierarchical architecture were tested to simultaneously decode seven commonly performed hand/wrist gestures and three levels of force. As expected, results showed high performance for NLR and RF classifiers, while no significant differences were found between the two. On the other hand, LDA and SVM achieved lower performance, suggesting that the nature of the problem of EMG signal decoding is not linearly separable, and thus linear classifiers might not be suitable for facing the problem. All classes of NLR and RF achieved more than 92% of accuracy in both healthy subjects and amputees, contrary to LDA and SVM, that achieved lower performance, in particular with *power* and *bidigital* grasps.

However, these classifiers showed high scalability from healthy subjects to amputees, with no significant differences between the two cases, except for LDA. This highlights the

fact that although amputees might present higher complexity due to their amputations and thus it is important to include them in future studies, high-performing classifiers can overcome this issue. Despite the absence of significant differences between NLR and RF, the online comparison on execution time showed a gap in the performance between the two classifiers, with the NLR being faster responding, and thus, more appropriate for the use in online applications. This is due to the classification algorithm of NLR, which only involves sums and multiplications, and the use of raw data, that eliminates the process of feature extraction. Therefore, results suggest that although NLR and RF may be used interchangeably in an offline scenario, further investigations must be conducted for RF in real time applications. Future studies will evaluate the effects of different features or time windows on classification accuracy or other metrics. Moreover, different under sampling steps and number of trees will be investigated for NLR and RF training, respectively.

ACKNOWLEDGEMENT

This study was supported partly by the European Union's Horizon 2020 Research and Innovation Program under Grant agreement no. 899822 (SOMA project) and partly by the Italian Institute for Labour Accidents (INAIL) prosthetic center with WiFi-MyoHand project (CUP: E59E19001460005).

Abstract - The objective of this study is to design and implement a Neural Network-based model for classifying osteoporotic and non-osteoporotic patients. To accomplish this goal, an echographic scan was conducted on the first four lumbar vertebrae (L1-L4) of 375 patients previously evaluated using Dual Energy X-Ray Absorptiometry (DEXA), which is currently considered the goal standard in the field. The patients were divided into two groups based on their DEXA T-score: those with a T-score lower than or equal -2.5 were classified as Osteoporotic, and those with a T-score higher than -2.5 were classified as non-Osteoporotic. The model developed in this study demonstrates an accuracy value up to 74% as demonstration of the potential Neural Network-based models for the classification of Osteoporotic patients. However, these results are preliminary and require much larger datasets in order to be refined.

Keywords: Osteoporosis diagnosis - Lumbar spine - Neural Network - Ultrasound imaging - Automatic segmentation

I. Introduction

Osteoporosis is a widely prevalent bone disorder characterized by a decline in bone mineral density (BMD) and a degradation of the bone's inner microarchitecture, resulting in increased fragility and a higher risk of fracture [1]. With significant societal and medical costs, osteoporotic fractures are projected to affect nearly 7 million individuals in the European Union alone by 2040 [2]. Spinal and femoral fractures are the most common and debilitating types of osteoporotic fractures, often causing a significant reduction in the affected individuals' quality of life due to high rates of morbidity and mortality [3]; it is estimated that 200 million women worldwide suffer from osteoporosis [4],[5], with 40% of those cases occurring in Europe, United States, and Japan [6]. Unfortunately, many of these cases are undiagnosed due to the lack of accurate diagnostic tools [4]. With the projected increase in the prevalence of osteoporosis, it is imperative to develop more reliable and effective diagnostic and management methods for this disease. In this context, innovative tools for more reliable diagnosis of osteoporosis and more accurate identification of frail patients are needed, promoting public health measures and reducing the consequences of the disease in every aspect. The World Health Organization (WHO) defines osteoporosis as a decrease in BMD of 2.5 standard deviations or more at the lumbar spine or femoral neck compared to young adult reference populations [7]. Currently, dual energy X-ray absorptiometry (DEXA) is the reference method for BMD assessment and osteoporosis diagnosis [8]-[10]. Nonetheless, important intrinsic limitations have been identified for DEXA technology, which hinder its employment for screening purposes [11]. Quantitative ultrasound (QUS) method and others, such as Radiofrequency Echographic Multi Spectrometry (REMS), have been developed and clinically validated as a way to directly investigate the mechanical properties of bone tissue [12]-[18]. Ultrasound (US) waves are naturally suitable for the assessment of the mechanical properties of human tissues, and US devices are typically associated with several advantages such as: absence of ionizing radiation, low cost, small device size, wide accessibility not associated however to DEXA scan [19],[20]. The primary objective of the present research is to explore the correlation between ultrasound signal features and the bone mineral density (BMD) of the human lumbar vertebrae, as measured by Dual-energy X-ray absorptiometry (DEXA), with the aim of creating a Neural Network-based classifier for the diagnosis of osteoporosis. Neural Networks, specifically feed-forward neural networks (FFNNs), are a powerful subset of Artificial Intelligence that enable machines to emulate human cognitive functions. The aim of this study is to develop a diagnostic tool that can accurately classify patients as either osteoporotic or non-osteoporotic with a high degree of accuracy, sensitivity and specificity, investigating the relationships between ultrasound signal features and human lumbar vertebral BMD, as determined by DEXA, in order to implement a Neural Network-based classifier for the diagnosis of osteoporosis. Neural Networks, specifically feed-forward neural networks (FFNNs), are a branch of artificial intelligence that allows

machines to perform human-like cognitive functions. In this study, the FFNNs are implemented as the architecture where information flows in a single direction, from input to output, through layers of interconnected neurons.

The FFNN comprises an input layer one or more hidden layers, and an output layer. Each layer is made up of a set of interconnected "neurons" that process and transmit information to the next layer. In this architecture, the input is passed through the layer of the network and is transformed into the output through a series of linear and non-linear transformations. Through a process of supervised learning, FFNN can be trained to recognize patterns in data, making them a powerful tool for tasks such as classification and prediction. Some examples of machine learning techniques for osteoporosis diagnosis have been already reported in literature[22-23], but none of them has employed ultrasound data derived from vertebral scans. Therefore, the final goal is to develop a diagnostic tool that can accurately classify patients as either osteoporotic or non-osteoporotic with a high degree of accuracy, sensitivity and specificity.

II. Materials and methods

A cohort of 375 Caucasian female patients between the ages of 50 and 80 years (mean age of 60.5±3.0 years) with varying body mass index (BMI) levels (mean of 25.8±4.6 kg/m^2) underwent both DEXA and echographic scans. The acquired data were thoroughly reviewed for scan quality by Echolight Clinical Specialists, who are expert in acquisition control. Only high-quality data were used for the analysis.

In order to assess the osteoporosis status of lumbar spine, echographic scans were performed starting on the L1 vertebra and ending on the L4, with the ultrasound probe held as close and parallel as possible to the sagittal plane on the patient's abdomen. Due to variations in tissue characteristics among patients, the position of the vertebral interface could not be predicted without analyzing the specific ultrasound image.

The ultrasound device used in the study was an EchoStation system developed by Echolight Spa, a clinically-available device used for osteoporosis diagnosis at the axial sites that allows the simultaneous acquisition of both the conventional B-mode echographic images and the corresponding raw RF signals using a central working frequency of 3.5 MHz. The RF signals acquired are sampled with a rate of 40 MHz and a resolution of 16 bits. They are organized into RF frames, each consisting of 253 scan lines. Each scan on the lumbar site requires 80 seconds, corresponding to the acquisition of 100 RF frames (25 per vertebra). The raw data obtained from the scans are segmented using a proprietary algorithm [21], which extracts the Region of Interest (ROI) of the vertebral profile from each RF frame. For each frame, the RF signals are filtered using a band-pass Finite Impulse Response (FIR) filter with a cutoff frequency of 1.0 MHz and 2.5 MHz, respectively. The signal is then converted to its absolute value, filtered with a low-pass FIR with a cutoff frequency of 100 KHz, enveloped and offset to smooth out the top and bottom portions of the image. The image was then processed using luminosity masks, contrast optimization and a 2D Gaussian blurring filter before thresholding to obtain the vertebral profile. The ROI was extracted and represents an RF signal matrix with dimensions of NxM, where M is the number of scanning lines considered in the ROI and N is determined by the signal's information content.

A set of features, were extracted from the signal contained in the ROI. Specifically, the features, extracted from time domain and frequency domain, are computed for each scan lines. After that, in order to obtain a unique value, the mean value for the specific feature is evaluated. This process was repeated for each valid frame (where the vertebral profile is extracted) and the extracted features were previously selected using the "*relief*" method to focus on relevant features and minimize irrelevant and redundant ones [24].

The analysis of the acquired signal was conducted by analyzing one frame at a time, if it was segmentable. Each frame of each patient's scan was associated with a vertebra as follows: frame from 1 to 25 were associated to L1, frames 26-50 were associated to L2, frame 51- 75 were associated to L3 and the last 25 frame were associated to L4. The features that are extracted are considered both from the time domain and the frequency domain, depending on the vertebra under examinations. The group of features were used to train and test a Neural Network classifier for the diagnosis.

Feed-Forward back propagation Neural Networks, with a different number of hidden layers and different activation functions depending on the considered vertebra and based on gradient descent with momentum and adaptive learning rate were used to classify the Osteoporotic patients (labelled with "1") and the Healthy patients (labelled with "0"). Notably, the Neural Network used in the L1 and L3 vertebrae have four hidden layers with sigmoid activation functions. The Neural Network used for L2 has six hidden layers with sigmoid activation functions, and finally the Neural Network used for the last vertebra, L4, has three hidden layers with sigmoid and linear activation functions. The number of features used as input for the neural network varied depending on the vertebrae under examination. Specifically, for the first three lumbar vertebrae (L1, L2, and L3), a total of 20 features were utilized. For the last lumbar vertebra (L4), a total of 10 features were utilized as input for the neural network. To train the Neural Network, the data is partitioned into three groups: 40% for the training set, 30% for the validation set, and 30% for the test set. The amount of data used in each set also varied depending on the specific vertebra being studied. For the L1 vertebra, the neural network model was trained using 111 data, validated using 84 data, and tested using 83 data. For the L2 vertebra, the neural network model was trained using 150 data, validated using 113 data and tested using 112 data. For the L3 vertebra, the neural network model was trained using 145 data, validated using 109 data and tested using 109 data. Finally, for the L4 vertebra, the neural

network model was trained using 122 data, validated using 92 data and tested using 92 data. This distribution of data was implemented with the goal of achieving a balanced proportion of healthy and osteoporotic patients in the data sets for each vertebra, in order to prevent the neural network from becoming skewed towards one class. Moreover, for each patient, the class to which they belong is identified as the average by default of the classification of the individual vertebrae. Specifically, a patient is considered to be osteoporotic if the model classifies at least half of the segmented vertebrae as class "1". The entire workflow can be summarized as follows:

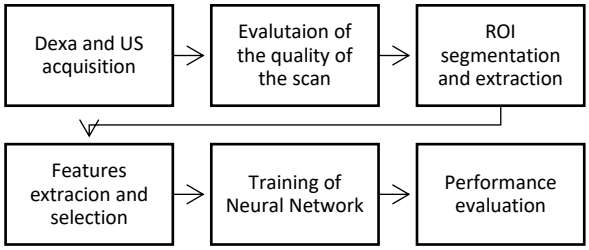

Figure I Flow-chart

In order to assess the efficiency of the implemented model, the following diagnostic parameters were considered:

- $\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}$;
- $\text{Sensitivity} = \frac{TP}{TP+FN}$;
- $\text{Specificity} = \frac{TN}{TN+FP}$;
- $\text{Positive Predictive Value} = \frac{TP}{TP+FP}$;
- $\text{Negative Predictive Value} = \frac{TN}{TN+FN}$;
- Area Under Curve.

In the above formulas: TP, TN, FP and FN indicate respectively the True Positive Class, the True Negative class, the False Positive Class and the False Negative Class.

III. Results and discussion

The study's key findings are summarized in Table I, which illustrates the performance of the classifier on the test set. On a test set of 83 patients, 41 of whom were osteoporotic, the classifier achieved a sensitivity of 62%, specificity of 77% and accuracy of 74%. These results demonstrate the classifier's ability to correctly identify positive and negative case.

Group	Patient	Sensitivity	Specificity	Accuracy
Test	83	62%	77%	74%

Table I Classification performance class accuracy

ROC curve (Figure II) has been plotted to further highlight the classifier's performance. The area under the curve (AUC) of the ROC is 0.70, which indicates the classifier's overall capability in distinguishing between the two classes.

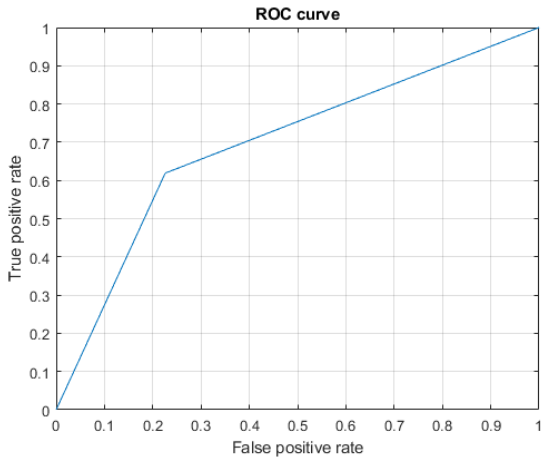

Figure II ROC curve

Finally, the Positive Predictive Value (PPV) and Negative Predictive Value (NPV) turned to be respectively 48% and 86%.

IV. Conclusion

This study utilizes a set of features extracted from in-vivo echographic scans of the lumbar spine to train a neural network-based classifier. The goal is to achieve a high level of accuracy in identifying osteoporotic patients. The trained classifier demonstrated an accuracy of 74% on the test set, with an AUC of 0.70, indicating a good performance of the classifier in distinguishing between osteoporotic and non-osteoporotic patients.

A potential next step for this study could be to expand the dataset with the aim of creating a classifier that has more robust performance. Furthermore, the extension of the dataset will make it possible to extend the age limits thus classifying more patients. Finally, it would be interesting to use other machine learning techniques in future studies.

***Abstract*— Reliable assessment of fetal health in pregnancies complicated by maternal diabetes is still challenging, but fundamental to reduce risks. Cardiotocography (CTG) is the most common tool in electronic fetal monitoring, but its utility in the management of diabetes-complicated pregnancies is still debated. Here we present some preliminary findings of a study aimed towards better defining the role of CTG in the management of pregnancies complicated by maternal diabetes by investigating the relation of CTG parameters with glycemic levels and pregnancy outcomes. A comprehensive set of standard and non-standard parameters was computed from the CTG traces collected at multiple gestational ages of 61 women with gestational diabetes, 25 with pregestational diabetes and 66 controls and related to pregnancy outcome and glucose levels. We identified an increase in the relative spectral power in the MF band and in the ternary Lempel Ziv Complexity in the diabetes-complicated pregnancies, as well as a week negative association between glucose level and signal variability. Associations with pregnancy outcomes are weak and call for further investigation.**

***Keywords*—Cardiotocography, Diabetes, Fetal Monitoring.**

I. INTRODUCTION

Diabetes Mellitus is one of the most common conditions in pregnancy and is known to increase risks for both the mother and fetus. It can be divided into Pregestational diabetes (PGDM) (i.e., diabetes of type 1 and type 2) and Gestational diabetes (GDM), a transient and generally milder form of diabetes that develops during pregnancy. The risks, which primarily depend on the level of glycemic control, include excessive fetal weight (LGA) and fetal hypoxia [1] [2].

To minimize the risk of adverse outcomes, various forms of antenatal fetal surveillance are usually recommended for pregnant women affected by PGDM and GDM with poor glycemic control [3][4]. The main goal is to reduce stillbirth, primarily by helping the clinicians identify as early as possible catastrophic events and informing for the optimal time of delivery. However, reliable assessment of the health of the fetus in diabetes-complicated pregnancies is still challenging. Ultrasonography is a useful tool but provides only anatomical information and cannot consistently diagnose macrosomia [3]; and doppler velocimetry does not appear to be a good predictor of adverse outcomes [5]. The most frequently used form of electronic fetal monitoring in diabetes-complicated pregnancies is Cardiotocography (CTG) [3], which consists of the simultaneous acquisition of the fetal heartbeats, uterine contractions, and fetal movements. In clinical practice, CTG tracings are classified as “reassuring” or “non-reassuring” based on signal characteristics such as the presence of accelerations and episodes of high variability [6], either by visual inspection or using computerized systems [7]. Despite its popularity, its utility is disputed [8]. One reason is that while reassuring CTG tracings can be reliably used to rule-out fetal compromise, especially when caused by hypoxia, the examination has low positive predictive value [3], [8]. In the work presented in [9], we used a large database of CTG recordings to investigate the impact of GDM on an extensive set of standard and non-standard parameters and we identified significant differences which we believe are indicative of variations in the autonomic control of the fetal heart rate (FHR) that are usually overlooked in standard analysis of CTG traces. However, we did not have information about the pregnancy outcome or the level of glycemic control. Here, we present preliminary results from a prospective observational study aimed at better defining the role of these non-standard CTG parameters in monitoring diabetes-complicated pregnancies. In particular, we investigated their variation in the diabetic population with respect to controls and their relation with glycemic levels and the pregnancy outcome.

II. METHODS

A total of 152 pregnant women were enrolled at Federico II University Hospital, Naples, Italy. 25 women had a diagnosis of diabetes that predated pregnancy and 61 were diagnosed with gestational diabetes following a 1-step glucose tolerance test. The remaining 66 women are healthy controls. All participants read and signed an informed consent for participation in the study.

Participants were subject to multiple CTG examinations at different stages of pregnancy. A total of 744 recordings distributed as depicted in Fig 1 was obtained. The recordings include: the FHR and a signal quality index, the uterine contraction signal, and the fetal movements series (FM), which is set to 1 when the mother presses a button to indicate a perceived movement and 0 when she does not. For each recording we consider here only the first 20 minutes, which is the minimum length available for all the recordings.

The fasting glucose levels were measured for all subjects during routine blood test performed at the third trimester.

We retrospectively divided the diabetic population into two groups on the basis of data at delivery. Group 1 includes pregnancies with good outcomes (i.e., no admission in neonatal intensive care units, Apgar scores at 1 and 5 minutes higher than 7, weight below the 90th percentile for gestational age) while Group 2 includes all pregnancies that did not respect at least one of the aforementioned criteria.

The purpose of the analysis is three-fold. Firstly, we tested for variations in CTG parameters between the three groups defined before the CTG examination (Controls, GDM and PGDM). Secondly, we tested for variations between two

groups retrospectively defined on the basis of data at delivery to assess the usability of CTG parameters as predictors of pregnancy outcomes. Lastly, we looked for relations between CTG parameters and glucose levels.

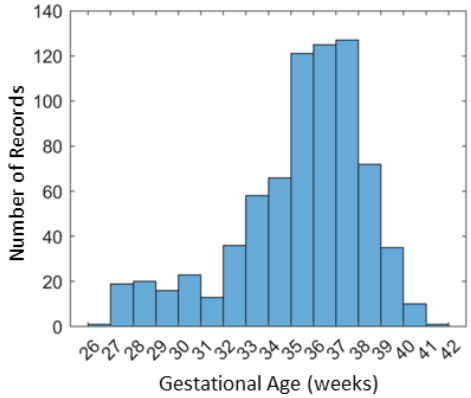

Fig 1. Distribution of CTG recordings by gestational age

A. *Feature computation*

For each recording, we identified the baseline, accelerations, and decelerations using the Mantel algorithm [10]. We then selected and computed a set of parameters belonging to different domains on the basis of the results obtained in [9]. The mean of the FHR baseline (MeanFHR), the number of accelerations per hour (#Acc) and the Short Term Variation (STV) [11] were chosen because they are widely used in clinical settings. We also included the Sample Entropy (SampEn), which was computed using x = 1, m = 0.1 and r = 1, and the ternary Lempel-Ziv complexity (LZ3), which was computed as explained in [12]. Both these features quantify the signal complexity. We then applied the Phase Rectified Signal Averaging (PRSA) technique [13] setting L=40, T=1 and s=2 and computed the Deceleration Reserve (DR) [14]. The continuous wavelet transform was applied at the centre of the signal obtained from the application of the PRSA and used to evaluate its power in Low Frequency (0.03-0.15Hz), Movement frequency (0.15–0.5Hz) and High Frequency (0.5-1Hz) ranges. We then normalized their values by the total power of the PRSA signal. More details on this procedure and its advantage over classical spectral analysis can be found in [13].

B. *Statistical analysis*

To address the dependency on the gestational age (G.A.) of the CTG parameters we divided the recordings into 3 groups: weeks 34 to 35, 36 to 37 and 38 to delivery. We excluded recordings from weeks prior to 34 due to the small sample size (in particular in the control group, that have no indication to undergo a CTG examination at this G.A.). Within each window, we employed the Mann-Whitney U-test to evaluate differences in median values of each feature among the considered populations. To ensure the independence of the samples inside each window, for the subjects who had multiple recordings we considered the median value of each feature.

When testing for differences between Group 1 and Group 2, we did not consider the group of weeks from 38 to delivery because caesarean sections before that G.A. were performed in several high-risk pregnancies.

To identify relations between CTG parameters and blood glucose levels we computed the Spearman's rank correlation between each CTG feature obtained at 36-37 weeks of gestation (one value per subject) and the blood glucose level.

Results are considered significant if p-value < 0.05.

III. RESULTS

The glucose levels in Controls, GDMs and PGDMs are reported in Fig 2. Unsurprisingly, the diabetic populations have higher blood glucose levels ($p<0.01$ for all comparisons). It is worth noticing however that, with the exception of a small number of cases in PGDMs, the values are good or excellent and there is a substantial overlap between Controls and GDMs, probably due to the success in diet control.

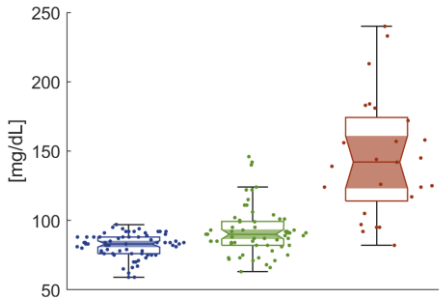

Fig 2: Blood glucose concentrations at the third trimester in Controls (blue), GDMs (green) and PGDMs (red).

The distribution of the features in the three populations discussed and significant variations are reported in Fig 3.

Regarding the comparison between physiological and GDM-complicated pregnancies, the results of this study largely align with the findings reported in [9].

Specifically, an increase in relative power in the MF band (even though here we considered the value obtained after the application of the PRSA and in [9] we employed classical spectral analysis) and an increase in ternary Lempel Ziv complexity. However, we were unable to replicate the results concerning the DR. Despite the difference in blood glucose levels reported in Fig 2 and the higher incidence of unfavourable outcomes in PGDMs (which is reported in Table I) we did not identify significant differences between GDM and PGDM in terms of CTG parameters.

TABLE I SIZE OF SELECTED GROUPS

	Group1	Group2
GDM	43	18
PGDM	12	13

Number of diabetic subjects divided per diagnosis and pregnancy outcomes as explained in Section II.

Fig 4 reports the comparisons between Group 1 and Group 2. The mean FHR, STV and the distribution of power in the PRSA spectrum varied significantly between pregnancies complicated by diabetes that had favourable and not favourable pregnancy outcomes. Concerning the last two features, the directions of the significances are the opposite of what we expected: diabetic pregnancies with unfavourable pregnancy outcomes had values more like those of the healthy controls.

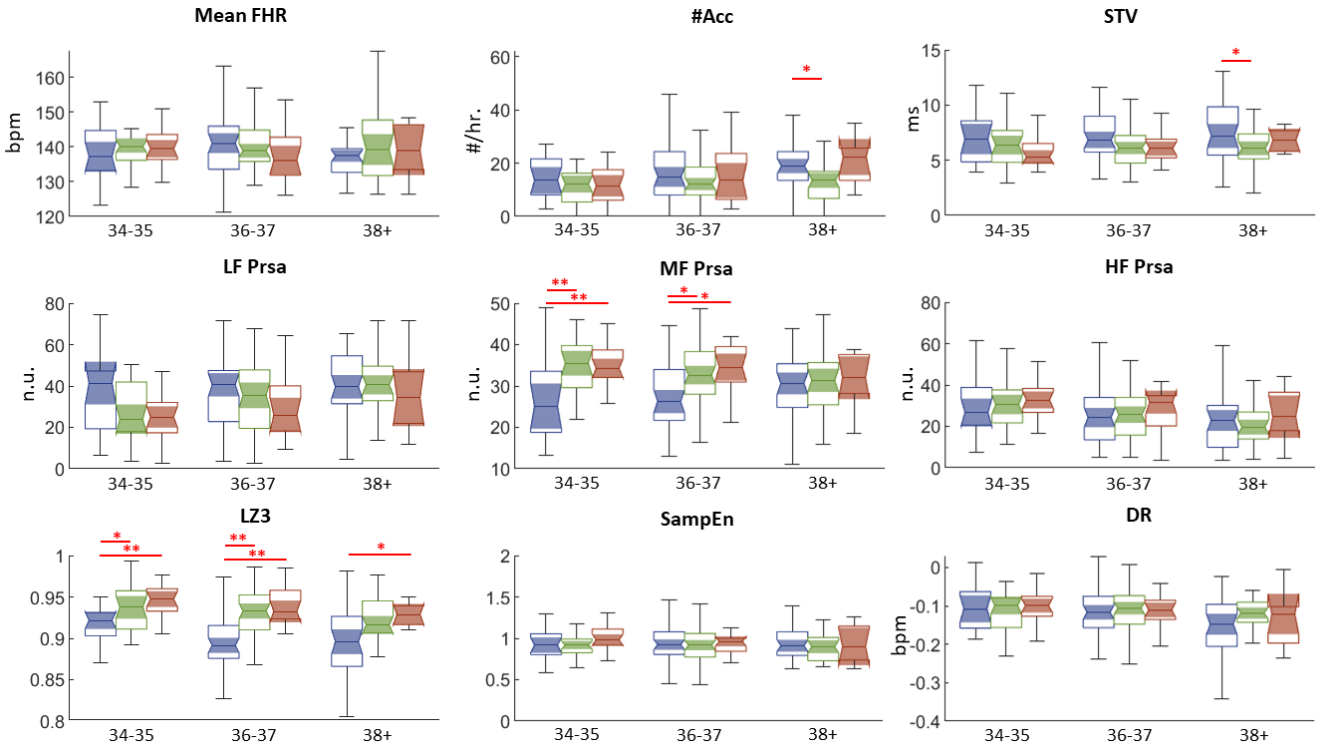

Fig 3: Boxplots are color coded: Controls in blue, GDM in green and Pregestational diabetes in red. Significances are represented with red lines. * indicates p<0.05 and ** p<0.01

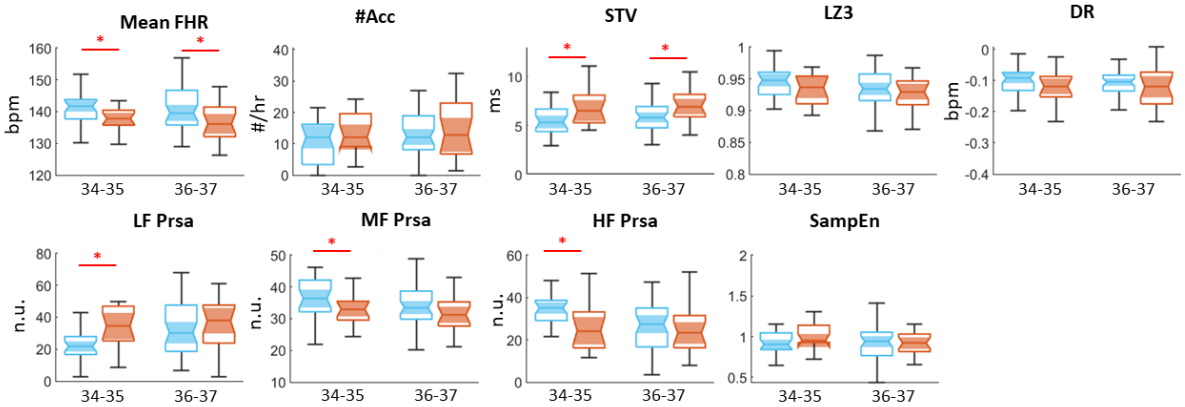

Fig 4: Group 1 (unfavourable pregnancy outcome) is in red and Group 2 is in blue.

TABLE 1I CORRELATIONS BETWEEN CTG PARAMETERS AND GLUCOSE

	r	p-value
MeanFHR	-0.09	0.316
#Acc	-0.20	0.032
STV	-0.26	0.005
SampEn	0.11	0.247
LZ3	0.27	0.003
DR	0.22	0.022
LF Prsa	-0.28	0.002
MF Prsa	0.19	0.039
HF Prsa	0.24	0.008

Spearman's rank correlations between fasting maternal blood glucose levels and CTG parameters

Regarding the relation with fasting glucose levels (measured during routine exam, and not at the time of the CTG examination) we found some significant results, even though the correlation coefficients are small or very small. Results are reported in Table II. Maternal glucose levels are associated with reduced variability of the FHR (lower STV and number of accelerations per hour) especially in the LF band, which is associated to a relative increase in the power in HF. These results are consistent with values found in adults [15], suggesting that maternal hyperglycemia is transferred to the fetus and has an impact on the FHR series at least to some extent comparable to the effect it has on adults.

IV. DISCUSSION

Research on CTG has been focused primarily on the identification of fetal hypoxemia and intra-uterine growth restriction, while its role in the management of pregnancies complicated by maternal diabetes, despite being very common in clinical practice, is still less clear. Traditional parameters appear to have little value in this application, while more interesting results have been obtained in the frequency domain and with non-linear analysis.

The results obtained in the comparison of CTG parameters between pregnancies with good and unfavourable pregnancy outcomes in the diabetic population are unexpected and require further research for proper interpretation. Specifically, a reduction in STV is usually considered a sign of fetal distress, but we observed higher values in pregnancies with unfavourable pregnancy outcomes. It should be noted, however, that most of the cases of bad outcomes were due to LGA and not hypoxemia, which is arguably the most common cause of fetal distress and is known to reduce STV [7]. We acknowledge as a limitation to the present study that we did not differentiate between pregestational diabetes of type 1 and type 2 and between subjects undergoing or not insulin therapy.

We believe it would be an interesting future development to add these distinctions, as well as dividing the causes of bad pregnancy outcomes. This is a goal for which, however, a larger population sample is necessary. The association between CTG parameters and maternal blood glucose levels also warrants further research, as we believe it could help towards a better understanding of fetal physiology in conditions of chronic hyperglycemia.

ACKNOWLEDGEMENT

The authors are grateful to Dr S. Tagliaferri from Federico II University, Naples, Italy for the collection of the data and his continuous support during the study. The work was carried out with the support of the MIUR PRIN Project Call 2017 “ICT4MOMs” 2017RR5EW3.

Abstract — Control theory represents a new frontier in the study of the human connectome as it offers the possibility of introducing new explainable features with the potential of binding neural connectivity to its pathological alterations. Starting from resting-state functional MRI (rs-fMRI) data sets, we estimate the functional connectivity for a given brain parcellation, thus deriving the system matrix that can be studied with network control theory. We assess the energy efficiency of large-scale brain network dynamic reconfigurations occurring at rest as well as the extent to which the transitions between and across distinct dynamic states are not just random but preferentially follow energetically efficient trajectories. In addition, we derive novel dynamic features of system controllability, distinguishing between average and modal controllability. The application of these concepts is illustrated on real rs-fMRI data sets acquired in four adult subjects, highlighting the range of variability of these features, in relation to the analysis settings, and discussing their potentials for possible use in future studies.

Keywords—Neuroimaging, Human connectome, Functional MRI, Network Control Theory.

I. INTRODUCTION

In recent decades, non-invasive neuroimaging techniques have been growing and resting-state functional MRI (rs-fMRI) has emerged as one of the most widely used techniques for investigating the functional connectivity of the human brain (human connectome) [1]. Particularly, the complex neurophysiological dynamics underlying the large-scale brain reconfiguration mechanisms can be addressed with rs-fMRI, in both healthy and disease conditions. In this work, we focus on the calculation of specific dynamic features of the human connectome that can be obtained from the analysis of rs-fMRI time series using control theory [2] and have recently gained special attention for their possible benefit in the discrimination of health and disease conditions [3]. For illustration purposes, we apply these concepts to real rs-fMRI data sets acquired in four adult subjects and discuss the outcome of this approach. We resort to Schaefer's parcellation to pinpoint regions of the human cerebral cortex that can be nominally grouped into seven large-scale brain networks [4]. In this context, and with reference to [5], we present the concepts from control theory [6] that provide the mathematical framework for this type of human connectome analysis. We first introduce the interaction matrix, which describes how the whole brain evolves as a dynamic linear system from a given (current) state to another (future) state. Then, we characterize the dynamic reconfiguration mechanism of large-scale brain networks in terms of Energy Efficiency and Average and Modal Controllability. To derive control theory measures, we contrast the parameters derived from the static functional connectivity (sFC), i.e., by evaluating the average synchronization of fMRI time series between all pairs of regions over the entire interval of observation, to those derived from the dynamic functional connectivity (dFC), i.e., by evaluating the time-varying aspects of brain dynamics across several consecutive time windows and eventually using a sliding window approach.

II. METHODS AND MATH EQUATIONS

We model the brain state transitions through the classical linear dynamical system formulation:

$$\dot{x} = A(t) \cdot x(t) + B \cdot u(t) \quad (1)$$

Where **x**(t) is a N x 1 vector representing the brain states over time (t) and space (N regions). **A**(t) is the N x N interaction matrix, which we estimate from the static or dynamic functional connectivity analysis (or FC matrices). The static functional connectivity is calculated as the Pearson correlation between all pairs of regional fMRI time-courses and is kept constant over time in the model (1). Instead, the dynamic functional connectivity is estimated by dividing the signal into M windows and then calculating the Pearson correlation for each window. **B** is the control input matrix (N x m) obtained from the identity matrix, from which we select the m columns associated with the set of control nodes (regions) into which we wish to inject inputs, whereas **u**(t) is the input energy vector over time (m x 1). The interaction matrix is obtained via the following normalization with the weighted Laplacian matrix derived from the (dynamic or static) functional connectivity matrix:

$$L_{ij}(t) = \delta_{ij}\Sigma_k |FC_{ik}(t)| - FC_{ij}(t) \quad (2)$$

$$A(t) = \frac{-L(t)}{\lambda_{max}(L(t))} \quad (3)$$

In the control analysis with a static interaction matrix, for a given initial state $\boldsymbol{x_0}$ and a given target final state $\boldsymbol{x_f}$, the optimal control energy principle allows us to calculate the static energy as:

$$E_s(x_0, x_f) = \frac{1}{2} d^T W^{-1} d \quad (4)$$

Where:

$$d = x_f - e^{A\tau_s} x_0 \quad (5)$$

is the difference between the target final state and the hypothetical final state that the system can reach without control and **W** is the so-called controllability Gramian matrix. When selecting a single node *i* as control node (i.e., $B = B_i$) the controllability matrix is obtained via the Lyapunov equation as:

$$W_i = \int_0^{+\infty} e^{At} B_i B_i^T e^{A^T t}\, dt \quad (6)$$

From the trace of this matrix, it is possible to obtain a measure of Average controllability, i.e., the input energy that is to be applied to the selected control node to drive the state transition towards all possible target states:

(7) $\psi_i = Trace\ (W_i)$

We also calculate the Modal controllability that is the ability to control each evolutionary mode of the network:

(8) $\phi_i = \sum_{j=1}^{N}(1 - \lambda_j^2(A))v_{ij}^2$

According to the definition of temporal networks [6], for the dynamic analysis, we end up with having M time windows and for each one we define an interaction matrix:

(9) $A(t) = A_K$

Thus, under optimal control conditions, we define the dynamic energy as:

(10) $E_d(x_0, x_f) = \frac{1}{2} d^T W_{dyn}^{-1} d$

Where:

(11) $d = x_f - e^{A_M \tau_M} e^{A_{M-1}\tau_{M-1}} \dots e^{A_1 \tau_1} x_0$

And:

(12) $W_{dyn} = SWS^T$

is the dynamic controllability Gramian matrix, S given by:

(13) $S = (\prod_{i=M}^{2} e^{A_i \tau_i^d}, \dots, \prod_{i=M}^{m+1} e^{A_i \tau_i^d}, I)$

III. ENERGY ANALYSIS

We first estimate the energy cost for the series of transitions across brain states as driven by the interaction matrix (see section IV for mathematical details). We achieve this by selecting each group of brain regions assigned to a large-scale network as input (control) nodes. Assuming that the instantaneous brain state is represented by the (z-scored) rs-fMRI signal at each time point and that the control signal implements an optimal control strategy [7], we estimate the energy cost in case of a constant interaction matrix (i.e., derived from sFC values) as well as in the case of a time-varying interaction matrix (i.e., derived from dFC values). We hypothesize that the extent to which a dynamically updated interaction matrix reduces the energy cost, compared to a constant interaction matrix, can provide a useful measure of energy efficiency for the system.

A. Energy Efficiency

The choice of the interaction matrix to characterize the transition between states affects the efficiency of energy expenditure. We evaluate two hypothesis about the energy efficiency of the system. First, we explore how the control time interval τs is related to the estimated control energy and then calculate a measure for the energy cost. In fact, referring to [6], we expect that the control trajectory implied by the (time-varying) dFC should be energetically more efficient in driving the systems across states, compared to the (time-constant) sFC. We applied these concepts to a data set of 100 real rs-fMRI time-series (from 100 cortical regions) representing the evolution of the system across 600 brain states during an observation time of 10 minutes (sampling frequency = 1 Hz). In our Matlab analysis, using modified code from [6], we perform 50 computer simulations where the pair of initial and target states are randomly chosen from the first 25% of the time-series and the remaining interval, and set the Default Mode and Visual network regions as control nodes. We report the values of dynamic and static energy as a function of the control time τ_s resulting from all simulations. The control time defines the interval of decay of the input energy [6] and therefore the observed temporal window between the application of the input energy to the control regions and the reach of the final state from the initial state under optimal control conditions. In Fig 1, the energy cost is reported when using either dFC or sFC for the interaction matrix and we can easily observe a substantially reduction of energetic cost between dynamic and static conditions mainly at shorter control intervals, for $\tau_s < 50\ s$, while, e.g., for $\tau_s > 100\ s$ the difference between energy values is blurred. Hence, over shorter control times, a dynamic analysis seems to better emphasize the energetic advantage of the system in evolving between two states with a time-varying interaction matrix. Along this line, we evaluated the quantity $\log\frac{E_S}{E_D}$, i.e., the logarithm of the ratio between static and dynamic energy, as a heuristic measure of energy saving when the control time ranges between 10 s and 100 s. Referring to Table I, we show how the median of this quantity is significantly above zero (signed rank test, $p<0.05$) for the default-mode network in three (out of four) subjects and for the visual network in all four subjects. This underscores that the relationship between energy saving and control times might be peculiar in brain functioning and future studies on large samples of healthy control and pathological subjects might reveal whether this approach can yield a promising candidate marker for assessing the energetic (in)efficiency of brain large-scale networks evolving between two random states during rest.

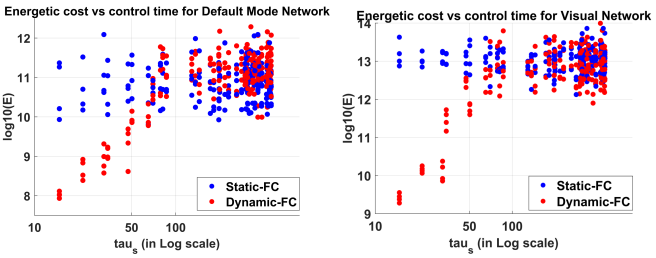

Fig. 1: Right Log of static (blue) and dynamic (red) energy estimates for all simulations (with random initial and final points) and subjects as a function of the log of the control time for default mode network as control nodes. Left: Log of static and dynamic energy estimates for all repetitions and subjects as a function of the log of the control time for visual network as control nodes.

TABLE I: EVALUATION OF THE MEDIAN OF THE LOGARITHM RATIO BETWEEN STATIC AND DYNAMIC ENERGY AT SHORTER CONTROL TIMES FOR EACH SUBJECTS IN DEFAULT MODE AND VISUAL NETS AND P VALUE WITH BONFERRONI'S CORRECTION

Subject	*Default Mode Network Median (p value)*	*Visual Net Median (p value)*
Subject 1	0.849 (2.88e-08)	0.577 (6.92e-07)
Subject 2	0.166 (2.25e-03)	0.724 (4.29e-07)
Subject 3	-0.060 (0.05)	0.486 (1.73e-06)
Subject 4	0.155 (2.40e-04)	0.451 (5.42e-06)

B. Energy Shuffle

In the previous analysis, the order of intermediate states is not taken into account. However, if we assume that a series of dynamic states is energetically more favorable, and if these transitions are effectively supported by a neurophysiologically meaningful dynamic evolution, the actual trajectory (i.e., the

exact sequence) should also be relevant. Thus, another analysis has been conducted to assess the relative energy cost corresponding to the observed order of dFC matrices compared to a randomly permuted order of dFC matrices. For this "shuffled state analysis", we perform additional 50 repetitions (with permuted orders) and evaluate the p-value of the comparison of the energy ratio $log\left(\frac{E_{shuffle}}{E_d}\right)$ against zero. Here we expected that, no matter which network (i.e., group of control regions) is set, the reconfiguration of connectivity matrices along the truly observed order of states should cost less energy to the system compared to the random reconfiguration across the same states if the brain network really followed physiologically driven state transitions, i.e., a non-random trajectory [2]. In contrast, if the median of the logarithm of the ratio between shuffled and dynamic energy results below zero, this would suggest that the brain might not have followed the most favorable trajectory of pattern reconfiguration. For example, in our analysis, we observed how a subject showed such a ratio significantly above zero for the default mode *(p=5.45e-19)* and for the visual network *(p=1.08e-29)*, but not for the limbic network *(p=0.99)*, suggesting that maybe for the limbic network energetic inefficiency exists in the dynamic transitions across brain states, at least within the selected range of control times. Thus, this parameter could yield another candidate marker of network energetic (in)efficiency that might deserve an extended investigation in future human connectome studies.

IV. CONTROLLABILITY

Controllability of the network refers to the possibility to manipulate the energy at certain nodes to drive the system along a pre-defined (desired) trajectory from an initial state to a target state. In this context, controllability could, e.g., usefully describe the mechanism of cognitive control where particular brain regions are forced (e.g., via neural stimulation) to act as drivers and facilitate the brain transitions to specific states or neural processing modes that would better support cognitive functions [7]. By again referring to control theory [6], we can distinguish between average and modal controllability, to respectively indicate an ability of the brain to reach more and less consolidated states (see section IV for mathematical details). A consolidated state would be one which is well-established from previous recurrent experiences (and therefore expected to occur very frequently during rest). In contrast, a non-consolidated state would be one which can be reached upon very specific conditions and task demands (and therefore expected to occur less frequently during rest). Thus, we first compare dFC vs. sFC derived controllability values across different time window sizes, to underscore the variable gain in terms of controllability from the dynamical observation of the fMRI time courses. Then, by using a sliding window approach, here we introduce a few novel measures from the analysis of the trends of dynamic vs. static controllability as a curve across time to better characterize the dynamic controllability of the system: the total time during which the dynamic controllability is above the static controllability, the area under this curve and the number of crossings. Finally, we report the variations of these measures in relation to the approach used for the dynamic analysis (i.e., overlapping vs. non-overlapping windows and fixed vs. variable window sizes).

A. Average Controllability

We evaluate the average controllability for a given network, i.e., the input energy needed to drive the system to a specific target state. This allows us to identify brain areas that steer the system towards easy-to-reach states, i.e., those that require shorter paths and less state transitions (e.g., to support internal thinking during resting conditions, see, e.g., [7]). For brevity, here we report the values obtained for the default-mode network as it is well known that this network connects areas that are more active when the brain goes through its baseline cognitive states (e.g., during the resting state), from which the brain transiently moves back and forth to/from a multitude of more task-oriented states [7]. As shown in Table II, dynamic average controllability is always higher than the static one for three out of four subjects. But this analysis also allows us to detect when and how the average controllability value changes, i.e., when the network is more (or less) dynamically controllable. We thus observe that reducing the window size increases the dynamic controllability and this is in line with the fact that reducing the control time has benefits in terms of energy cost, as we observed in the energy analysis. Indeed, in Table II, we can observe an increment of average controllability in all subjects at a window size of 30 s but not 60 s. A further analysis allows us to observe variations in the trends of controllability between non-overlapping and overlapping sliding window analysis (Fig 2). In the first case, each window is separated from another one, while in the second case a window slides continuously along the time course. The last option introduces more variability in the trends but also higher values of controllability. In this way, we could observe the evolution of the brain across many more controllability conditions and we could eventually be able to better control the network at specific times of high controllability.

TABLE II: COMPARISON BETWEEN VALUE OF STATIC AVERAGE CONTROLLABILITY AND DYNAMIC ONE WITH DIFFERENT WINDOW SIZE

Subject	*Static*	*Dynamic ws = 60 s*	*Dynamic ws = 30*
Subject 1	1.111	1.154	1.165
Subject 2	1.146	1.166	1.184
Subject 3	1.173	1.176	1.179
Subject 4	1.168	1.161	1.188

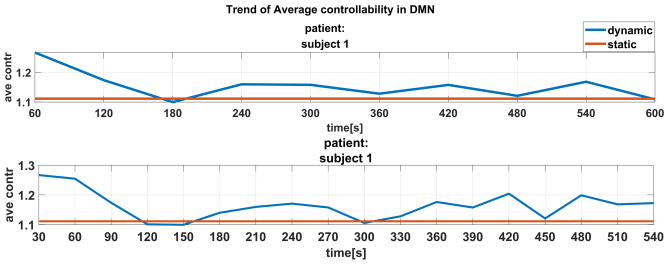

Fig. 2: On the top, dynamic average controllability trend against static average controllability value without overlapped analysis, while below we have the same trends but with overlapped analysis

Moreover, to underscore how window size affects the average controllability, we repeated the overlapping window analysis with two different window sizes (30 s and 60 s). In addition, we also evaluated the number of crossings of dynamic average controllability trends across the (constant) static value, the area under the curve and the time when the dynamic trend is above the static constant trend. As shown in Table III, the increment of controllability is strictly associated to the increment of these parameters. In particular, we can observe an increment of the number of crossings associated to more variability in the trend due to the reduction of the window size. The increment of area values can be another measure for the increment of average controllability while the increment of the time indicates that

longer time intervals would be available to control the network more efficiently. Therefore, alteration or reduction of these parameters could be yet more candidate markers of an altered mechanism of functional connectivity, e.g., due to a disease condition.

TABLE III: COMPARISON BETWEEN PARAMETERS FOR ONE SUBJECT IN CASE OF OVERLAPPED DYNAMIC AVERAGE CONTROLLABILITY IN DEFAULT MODE NETWORK BY VARYING WINDOW SIZE

Analysis	*No of Crossing*	*Area*	*Time*
Overlapping ws = 60 s	4	25.34	457 s
Overlapping ws = 30 s	11	44.33	513 s

B. Modal Controllability

Modal controllability identifies brain areas that can push the brain into states that require substantial input energy. From a cognitive perspective, it reflects the capacity of the brain to adapt to novel cognitive conditions but also to execute more complex cognitive functions, such as top-down regulation or control of mental operations in response to environmental changes or external stimuli [7], [9]. Indeed, modal controllability depends on the eigenvectors of the interaction matrix, which describes all possible dynamic modes of the system. The previous approach can be similarly applied to the modal controllability, but in this case, we report the results for the fronto-parietal network as it is known that this network functionally connect regions that are responsible for the execution of complex cognitive tasks [7], [9]. Comparing static and dynamic controllability values in Table IV, we again note, in three out of four subjects, the increase of modal controllability values in the dynamic vs. static configuration. This increment is also larger when reducing the window size. Thus, we could still suppose that the advantages of controlling specific dynamic modes of the system can be assessed using these measures.

TABLE IV: COMPARISON BETWEEN VALUE OF STATIC MODAL CONTROLLABILITY AND DYNAMIC ONE FOR FRONTO-PARIETAL NET WITH DIFFERENT WINDOW SIZE

Subject	*Static*	*Dynamic ws = 60 s*	*Dynamic ws = 30*
Subject 1	0.890	0.895	0.913
Subject 2	0.887	0.910	0.925
Subject 3	0,894	0,895	0,910
Subject 4	0,937	0,932	0,928

TABLE V: COMPARISON BETWEEN PARAMETERS FOR ONE SUBJECT IN CASE OF OVERLAPPED DYNAMIC AVERAGE CONTROLLABILITY IN FRONTO-PARIETAL NETWORK BY VARYING WINDOW SIZE

Analysis	*No of Crossing*	*Area*	*Time*
Overlapping ws = 60 s	8	-4.733	175 s
Overlapping ws = 30 s	18	4.250	364 s

Furthermore, as shown in Table V, for the overlapping window analysis, we can observe the same parameters and their increment by reducing the window size. In fact, we move from a negative area to a positive area and the time during which the dynamic behavior is favorable increases. This highlights the importance of the choice of the window size for the dynamic analysis because a negative area and a lower value of this time do not allow the possibility to control efficiently the brain regions and its dynamic modes. Overall, we have observed that modal controllability values are lower than average controllability ones, as expected, because it is easier to reach states across short paths associated with basal cognitive function rather than states across paths requiring more transitions. Anyway, higher controllability (either modal or average) indicates a better ability of the brain in reaching efficiently the target state.

V. CONCLUSION

Control Theory analysis is being presented as an innovative way to model the functional connectivity of the human brain, as it offers a new framework to investigate diseases and assess the consequence of lesions on behaviors and cognitive performances [10]. We highlighted some possible features that can become useful to describe the variability of the human functional connectome and possibly inspire new markers to address the alterations secondary to a disease, but also to open toward the design of novel paradigms of targeted external stimulation of the brain [10]. Starting from rs-fMRI data sets, we have obtained the interaction matrix in different ways in order to underscore the advantages in terms of energy and controllability when we model the brain as a temporal (dynamic) network. Through the energy analysis, we point out how the ratio of static and dynamic energetic cost could provide markers of energetic (in)efficiency of a specific brain region or network, albeit the control time appe ars to be a crucial parameter in the setting up of the control theory analysis. Then, with the analysis of average and modal controllability, we highlight some possible surrogate measures that can support an evaluation of the ability of the brain to respond to externally timed stimulations. In conclusion, we expect that further research into this kind of analysis can lead to introduce other features. Nonetheless, any of the illustrated features will require proper experimental validation to relate these candidate markers to the acquisition parameters settings. This will require the careful design of proper test-retest studies to assess the robustness of the features and proper cohort studies to address the relation with clinical features.

***Abstract*—Severe acquired brain injury often leads to a disorder of consciousness (DoC) which can be classified as vegetative state (VS) or minimally consciousness state (MCS) according to its severity. The golden standard for DoC diagnosis is currently represented by the standardized Coma Recovery Scale Revised which, due to fluctuations in DoCs' vigilance, can lead up to 40% of misdiagnosis. EEG-based analyses have demonstrated promising results in DoC patients' assessment and quantitative EEG measures are candidates as a reliable instrument to support clinical diagnosis with high accuracy. Methodologies for spectral analysis and connectivity estimation were applied to EEG resting state data from 58 DoC patients clinically assessed as VS or MCS. Indices describing the global properties of the resting networks and the characteristics of power spectra resulted significantly different between the two groups of patients. The significant indices were used as features to train a classifier able to discriminate VS from MCS with performance metrics equal to 67% for accuracy and 85% for precision. These findings boost the promising role of EEG-based indices as valuable and reliable tool to support DoC clinical diagnosis.**

***Keywords*—Diagnosis, disorders of consciousness, connectivity analysis, spectral analysis.**

I. Introduction

PEOPLE who survive a severe brain injury, can suffer from disorders of consciousness (DoC), a clinical condition characterized by alteration in arousal (eye opening), and awareness (defined as the presence of nonreflexive behavior). Three main states can be included in DoC: coma, vegetative state (VS) and minimally conscious state (MCS). Coma is characterized by the total absence of both arousal and awareness, while VS patients show arousal, but they are unresponsive to external stimuli and only show reflexive behavior. MCS subjects, on the other side, demonstrate signs of awareness of themselves and the environment, but this condition is characterized by strong fluctuations [1]. The European Task Force has introduced the definition of "unresponsive wakefulness syndrome" (UWS) [2] to replace the term "vegetative state," although it has not been universally accepted [3]. For this reason, in this work we will use the double term VS/UWS for referring to that condition.

DoC classification is based on standardized neurobehavioral rating scales, among which Coma Recovery Scale Revised (CRS-R) is the most widely diffused and consists in 6 subscales evaluating auditory, visual, motor, oromotor, communication and arousal processes. Clinical scales represent the gold standard for DoC assessment. Although they represent a consistent and sensitive standard, clinical scales depend on behavioral responses, that can be affected by a multitude of factors, such as fluctuation of arousal, fatigue, pain, spasticity, to cite just few of them. Thus, the misdiagnosis rate is high and attested around 40% [4]. However, an accurate assessment is fundamental for DoC's diagnosis, prognosis and monitoring of treatment and rehabilitation effects [5].

The absence of quantitative measures for the diagnosis of DoC patients has motivated many researchers to find objective measures derived from brain signals as support for the clinical evaluation. Previous studies have performed EEG analyses of resting state acquisitions to investigate connectivity characteristics in DoC patients, but mainly using neuroimaging techniques (i.e., functional magnetic resonance imaging, fMRI). Results of this kind of studies demonstrated the correlation between the level of consciousness and the connections weight in the Default Mode Network (DMN), a circuit composed by specific brain areas active during rest condition and deactivated in attention-demanding tasks [6].

EEG shows invaluable advantages in comparison to other neuroimaging techniques, both at the theoretical and at the practical level: it allows to capture the dynamics of brain connectivity and its spectral distribution, by keeping it viable to handle severely disabled patients even with bedside testing, being therefore eligible for routine clinical application.

Previous studies have identified markers derived from a combination of connectivity estimators and graph theory able to classify MCS patients from VS/UWS and healthy subjects with an accuracy slightly above chance [7],[8].

Indeed, in this study a quantitative analysis of EEG recorded in resting condition was conducted to calculate spectral and connectivity indices that could be a reliable instrument to perform diagnosis in patients with disorders of consciousness.

II. Materials and Methods

A. Participants

The study involved 58 patients admitted at the Post-Coma Unit of Fondazione Santa Lucia of Rome and diagnosed with DoC (29 males/29 females, mean age 45±16 yr, CRS-R score: 11±5, etiology: 22 TBI, 6 anoxic, 27 vascular, 3 other). According to their CRS-R scores, 40 out of 58 patients were assessed as MCS (19 males, 21 females, mean age: 46.85±16.03 yr, CRS-R score: 14±3), while the remaining 18 were diagnosed with VS/UWS (10 males and 8 females, mean age: 39.67±15.38 yr, CRS-R score: 5±2). No significant differences were found between the two groups both in terms of age (unpaired t-test, p-value = 0.1157) and gender (χ-squared test, p-value = 0.5702). The present study protocol was approved by the local Ethics committee of Fondazione Santa Lucia (Prot. CE/PROG.603). Written informed consent

was obtained by the patients' legal surrogates.

B. EEG recordings

EEG signals were acquired by means of 19 bridge electrodes (Micromed) positioned over patients' scalp according to 10-20 International System (reference on Fpz, ground on Oz). EEG was acquired in resting state condition for approximately 5 minutes with a sampling frequency equal to 250 Hz.

C. Pre-processing

Raw signals were band-pass filtered (1-20 Hz) to select the frequency band of interest and to remove the contribution of muscular artefacts. Independent Component Analysis (ICA) was used to remove ocular artefacts when eye-blinks were recognizable on the traces. Subsequently signals were segmented in epochs of 1 second duration. A threshold approach for artefacts removal was then applied to exclude trials exceeding in absolute value the amplitude of 100 μV. A random sample of 100 trials was extracted for each subject to provide an equal amount of data for each patient to perform further analyses.

D. Spectral Analysis

Spectral analysis was executed on pre-processed data of the midline electrodes (Fz, Cz, Pz) computing Power Spectral Density (PSD) by means of Welch periodogram (Hann windows of 1 second duration with no overlap). Five out of 58 patients were excluded from spectral analysis due to residual muscular component. Relative Power (RP) was calculated to evaluate the contribution of the single frequency bands (delta: 1-3 Hz, theta: 4-7 Hz, alpha: 8-13 Hz) to the global power.

E. Connectivity Analysis

Connectivity analysis was conducted estimating functional resting state network using Partial Directed Coherence (PDC) [9], a multivariate spectral estimator providing weight and direction about functional links connecting different time-series in specific scalp positions. PDC values were averaged in delta (1-3 Hz), theta (4-7 Hz) and alpha (8-13 Hz) bands and asymptotic statistics validation method was applied to assess the significance of each connection against chance level [10]. Four out of 58 patients were excluded from connectivity analysis since estimated networks showed density values inferior to 10%.

To evaluate global properties of the estimated networks, the following indices were calculated: clustering coefficient, path length and small-worldness. Clustering coefficient is a segregation index that quantifies the presence of functionally specialized clusters in the estimated network and investigates the prevalence of clustered connectivity around individual nodes. Path length is a measure of integration of the network and reflects the distance between nodes. Small-worldness describes how well the properties of segregation and integration are combined to create a network that presents both segregated modules and intermodular (integrating) links [11].

F. Statistical Analysis and Classification

Basing on the exclusion criteria applied to spectral and connectivity analyses that were mentioned before, spectral indices were evaluated for 14 out of 18 UWS patients and 39 out of 40 MCS, while connectivity indices were calculated for 18 UWS and 36 out of 40 MCS. Afterwards the spectral and connectivity indices evaluated for the two groups were statistically compared using an unpaired t-test (alpha equal to 0.05).

Measures that resulted statistically different between the two groups were deployed as features to train a Supported Vector Machines (SVM) classifier with linear kernel able to discriminate MCS and UWS classes. Data augmentation was applied to numerically inferior class to compensate for unbalanced dataset. Leave-one-subject-out was used as validation approach and for each subject classification performance indices were calculated (i.e., accuracy, precision, specificity, sensitivity, area under curve).

III. Results

A. Comparing spectral and connectivity indices between VS/UWS and MCS

Relative powers in all the three bands considered (delta, theta and alpha) resulted significantly different between the two groups of patients on Pz channel. Moreover, relative power evaluated in delta and theta bands obtained a significant p-value (<0.05) also on Fz channel. As shown in Fig. 1, relative power in delta band on Pz channel is significantly higher in VS than in MCS patients. Conversely, relative power in theta and alpha bands showed the opposite trend, being lower in VS/UWS patients than in MCS. No significant differences were found in relative powers evaluated on Cz channel for all the three bands.

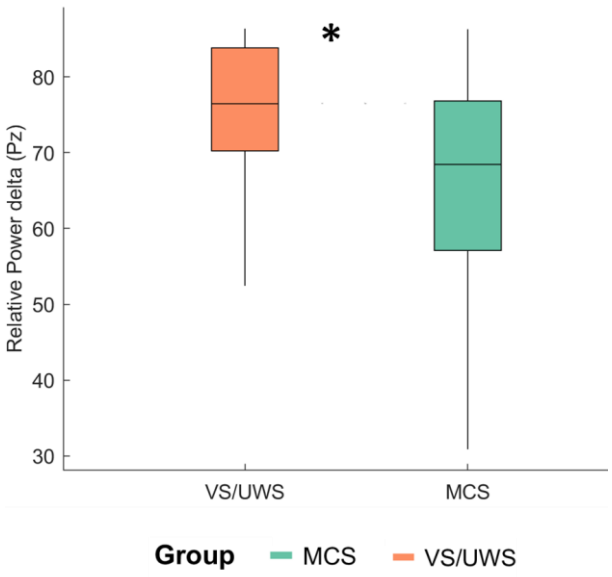

Fig. 1: Box plot representation of the statistical comparison of the relative power in delta band on Pz channel for VS/UWS group (in orange) and MCS group (in green). Statistically significant differences between the two groups are marked with the symbol *.

Statistical analysis applied to connectivity indices evidenced significant differences between the two groups for clustering coefficient and small-worldness, both in delta band.

As reported in Fig. 2, path length (Fig. 2, panel a) shows

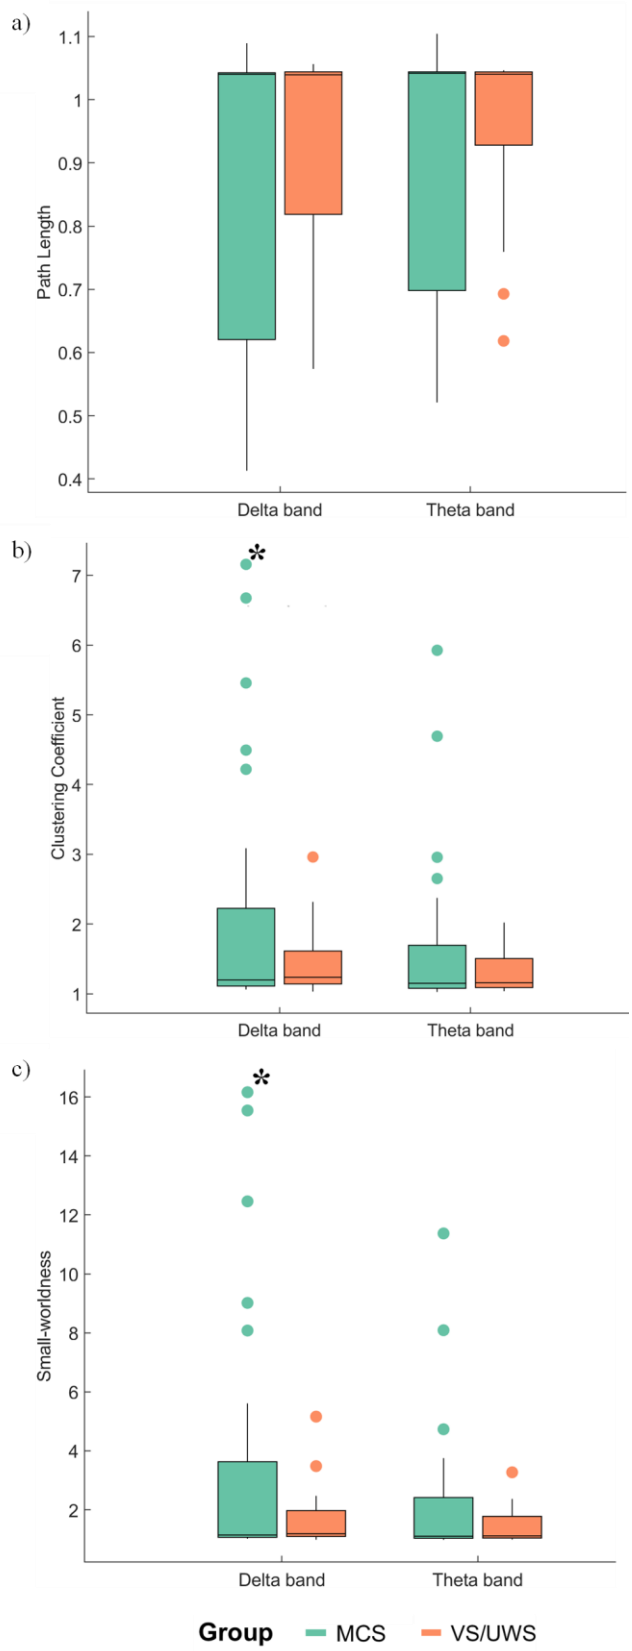

Fig. 2: Box plot representation of the statistical comparison of the connectivity indices distributions in delta and theta bands for VS/UWS group (in orange) and MCS group (in green): path length (panel a), clustering coefficient (panel b), small-worldness (panel c). Statistically significant differences between the two groups are marked with the symbol *.

significant differences between the two groups neither in delta nor in theta band, while both clustering coefficient (Fig. 2, panel b) and small-worldness (Fig. 2, panel c) evaluated in delta band are significantly lower in VS group. No significant p-values were obtained from statistical analysis of connectivity indices evaluated in theta and alpha bands.

B. EEG-based Classification of VS/UWS – MCS patients

Relative power on Pz channel, clustering coefficient and small-worldness, all evaluated in delta band and resulted as significant indices from statistical analysis, were used as features to train the SVM classifier. Figure 3 shows the values of the performance indices calculated for the classifier trained: the accuracy value obtained is equal to 67.35% with an AUC equal to 75%.

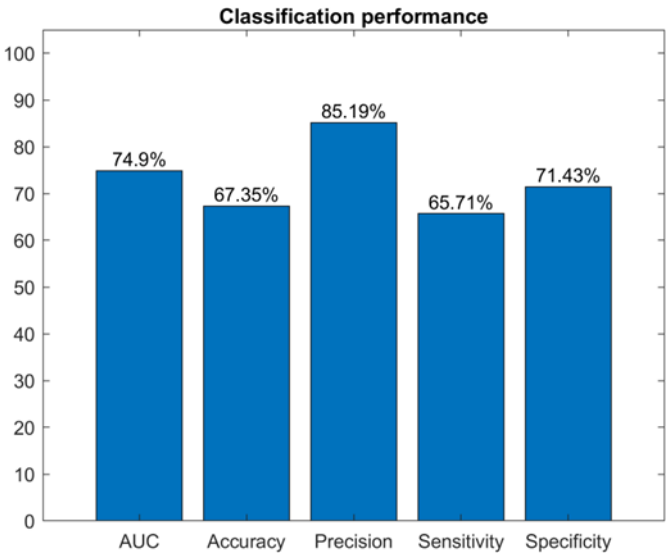

Fig. 3: Histogram reporting the performance of the SVM classifier with linear kernel trained using as features the following indices: relative power in delta band on Pz channel, clustering coefficient in delta band, small-worldness in delta band.

IV. Discussion

In this paper we aimed at providing quantitative and reliable indices, extracted from EEG resting state networks, to discriminate VS/UWS from MCS in order to corroborate the clinical/behavioral diagnosis of DoC patients.

Among the indices calculated small-worldness, clustering coefficient and relative spectral power on Pz channel, all evaluated in delta band, resulted as quantitative measures able to distinguish the two classes of patients. Indeed, these indices resulted significantly different between UWS/VS and MCS patients.

Previous EEG studies, based on graph theory indices extracted from connectivity networks at rest, have already pointed out the distinctive aspects of brain networks that characterize the DoC in comparison with healthy subjects and the correlations with their degree of behavioral responsiveness or hidden awareness [12].

According to the results obtained, clustering coefficient is significantly higher in MCS patients. This index quantifies the property of segregation of the estimated network. Segregation

measures describe the presence in the network of densely interconnected groups of brain regions that are specialized in fulfilling common functions. Higher values of clustering coefficient witness the presence of clusters in functional networks [11]. Therefore, the results obtained evidence that resting state networks in MCS were characterized by higher communication efficiency and higher tendency to organize their structure in clusters in comparison with UWS/VS. Previous studies already evidenced the correlation between the re-emergence of strong connectivity hubs in brain network and increasing levels of consciousness [13].

Integration measures are the other important category of indices that describe the global properties of the estimated network and that represent the ability of the brain to integrate the information deriving from distributed regions. Lower values of path length represent a major functional integration among different brain regions and an efficient propagation of information in the network [11]. Although MCS patients showed lower values of path length, the difference between the distribution of values was not significant between the two groups, so this measure was not considerate crucial to discriminate the two classes.

An optimal network needs to balance functional integration and segregation and this capacity is described by small-worldness. Small-world networks can simultaneously support segregation (high clustering coefficient) and integration (low path length) and are characterized by small-worldness index values superior to 1 [11]. The analyses conducted evidenced higher values of small-worldness in MCS group. The presence of highly inter-connected hubs in patients with increasing level of consciousness are believed to contribute to create a small-world functional network in the brain [14].

Several prior studies already stated the ability of spectral indices to distinguish between UWS and MCS patients. UWS/VS patients have shown increased delta power but decreased alpha power, compared to the values calculated in MCS [15]. Theta power is not so well studied, but it was found to be higher in UWS patients compared to healthy controls [16], moreover a study reported that UWS patients had lower theta power when compared to MCS patients [17]. These results are all consonant to the ones obtained in the current study.

Since connectivity indices showed significant differences only in delta band, the significant spectral index chosen to train the classifier was relative power in delta band. Albeit the accuracy of the classifier implemented has margins of improvement, it nevertheless exceeded the accuracy of clinical assessment methods. This finding further strengthens the potential and the relevance that such surrogate measure of the consciousness disorders might have to improve clinical diagnosis of DoC patients.

V. Conclusion

This study suggests how quantitative EEG measures could be a valid instrument to support clinical diagnosis in patients suffering from disorders of consciousness. The analyses conducted indicate how surrogate measures of consciousness disorders based on EEG might allow to improve the accuracy of the gold-standard clinical instruments for diagnosis. This can be achieved with just few minutes of EEG signal recording without requiring any voluntary contribution by the patient.

In order to better the classification performance obtained, this study can be considered as a preliminary one, with the purpose of investigating more specific indices describing resting state networks and to test alternative classification approaches.

***Abstract*—In the framework of security, biometrics proved to be the new frontier for human identification/authentication. It is more and more easy to find system exploiting fingerprint, voice or face recognition in application ranging from forensic to smartphone unlocking. In this paper the possibility of considering hand gesture for authentication purposes is explored. Hand gesture Doppler signatures are extracted by means of an ultrasound prototype and a deep learning based detector is considered. The system is cheap, reliable and, based on the complexity of the gestures, allows different security level. The prototype performances have been evaluated in a one-vs-all authentication scenario with the help of a testing population of 25 subject. The feasibility of the system is confirmed by promising results.**

I. Introduction

The importance of biometrics in security applications is exponentially growing in the last years. The idea of exploiting peculiarity in human morphology or habits for identify people is progressively replacing classic procedures like complex passwords or smart cards since biometrics do not involve in something related to knowledge and/or possess [1]. For example, in most of modern devices fingerprint, voice and face are exploited in order to unlock files or services [2] replacing passwords.

A biometric trait must satisfy constraints related to robustness, availability, universality, specificity and stability to be considered as a good candidate in identification purposes. Moreover, these types of system should be cheap and the related measures should be easy to be taken.

Based on literature studies, there are two major biometric families based on the nature of the trait: the former, morphological traits, is related to some physical feature of the user. Behavioural systems, conversely, exploit some peculiarity of the user while he/she does some tasks. This latter family present the advantage of being more robust to spoofing attacks compared to the morphological one [3] since, based on their nature, their are typically changeable in case of being compromise.

Many research groups focused their attention in finding appropriate behavioral traits and developing the related systems. For example, in [4] and [5] cardiac and brain electrical activity, respectively, are measured in order to identify person. Both systems present good results, but due to uncomfortable acquisition these systems are not feasible in most of the security applications. The possibility of exploiting gaits for identification task is explored in [6] where the gait Doppler spectrum is extracted by means of an FMCW radar. Main limitation of the system is related to the wide area required for the correct functioning.

A new frontier of behavioural biometrics is hand gesture. Gestures represent a trait easy to compute, change and reproduce and hand are already exploited by person in a normal conversation, as matter of the fact, studies have shown that, during a conversation, about 55% of information is provided by attitude and gestures [7]. Some examples of identification systems based on hand gestures are provided by [8] where smartphone accelerometers and gyroscopes are exploited to recognise people or by [9] where the touch screen of smartphones is considered for the same task. In [10], conversely, person are distinguished based on mouse gestures. All of these systems share the same requirement of contact whit some sensors limiting their usage in some context.

Contact-less gesture identification system have been, so, proposed in order to combine the advantage of exploiting gestures avoiding, at the same time, the limitation of the need of contact. For example, in [11] hand gesture are acquired by means of a Kinect system. A limitation, in this case, is represented by the sensibility the light changes and privacy issues may occur. Additionally, in [12], hand gesture are acquired due to a Wi-Fi system. In this case the criticism is related to low accuracy of the proposed solution.

In this paper an Ultrasound (US) prototype is proposed in order to extract hand gesture signatures for person authentication. The idea is to exploit the Doppler effect that affects the US reflected signal. Such incoming signal contains information related to several part of the hand movements.

Ultrasounds have been already exploited for both hand gesture detection [13] as well as in other biometric systems [14] but, based on the author's knowledge, this is the first approach to use ultrasound for sensing hand gesture in an identification/authentication scenario.

The basic idea of the proposed approach is that peculiarities in gesture execution should be reflected in some differences in the scattered signal extractable by a proper processing algorithm and discriminated by an ad-hoc deep learning based detector. In order to test the feasibility and evaluate the discrimination properties of the proposed system, a one-vs-all authentication scenario test with the help of 25 volunteers has been conducted obtaining promising results.

The remainder of the paper is the following: in Section II,

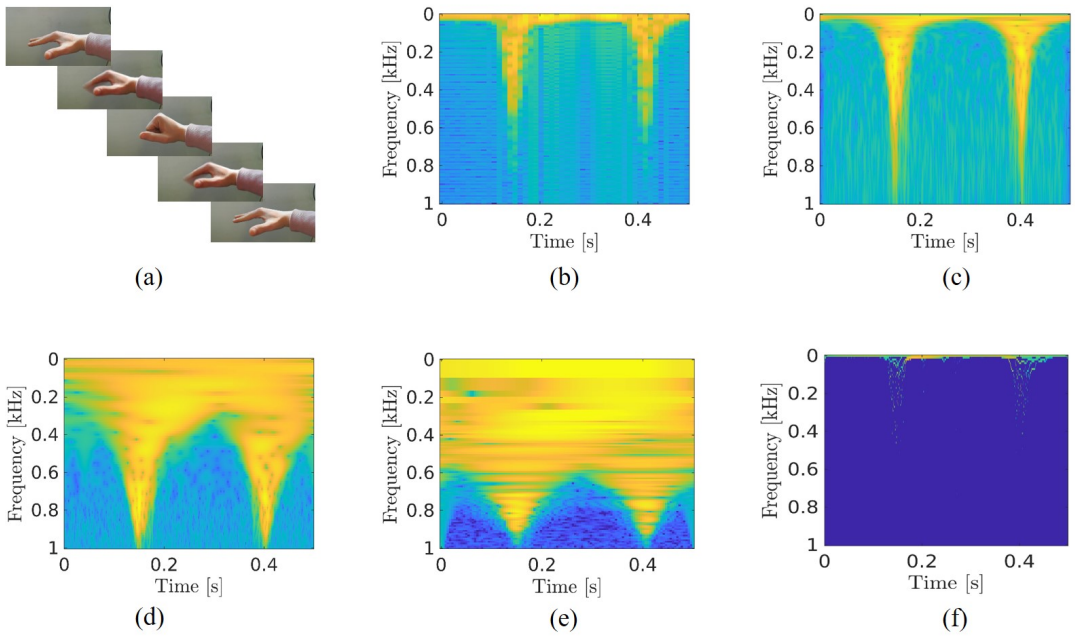

Fig. 1: Visual comparison of the considered time/frequency transforms. In (a) is shown the considered hand gesture, (b) shows STFT related to the its received signal, ST is shown in (c). (d) (e) and (f) show, respectively the WT, CQT and HHT of the gesture in (a).

the hand-gesture person authentication prototype is presented. Section III contains the description of the testing scenario and the related performances, finally, in Section IV, conclusions are drawn.

II. Proposed Method

Considering a principle similar to Sonar object speed detection, the proposed system exploit Doppler effected induced to the reflected US wave by the target motion impinged by the US transmitted wave. For this purpose, a prototype composed of an US transmitter, an US receiver, a waveform generator and an analog-to-digital acquisition board is proposed (a more rigorous prototype description can be found in [15]).

More in detail, considering a monochromatic source, the backscattered wave is the result of relationship among different contribution related to several parts of the target (e.g. human hand). By a multiplication between transmitted and received signals followed by a low pass filter (2 kHz of cut-off frequency for a 40 kHz sine wave source) it is possible to retrieve a beat signal manly related to the target motion.

Such signal is non-stationary and, therefore, a proper signal processing algorithm must be considered in order to preserve information in both time and frequency domains. In this framework 5 different time-frequency (t-f) have been considered [16], [17]: *Short-time Fourier Transform* (STFT), *Stokewell Transform* (ST), *Wavelet Transform* (WT), *Constant Q Transform* (CQT) and *Hilbert-Huang Transform* (HHT).

An example of the time-frequency matrix resulting from the considered algorithms is shown in Fig.1. All the figures refer to the same hand gesture (e.g. a closing-opening movement of the hand). From the images is possible to note evident differences among the approaches although they exhibit similar features clearly related to the considered gesture (two frequency spikes related to the time instant in which the hand is opened and successively closed).

The idea of the proposed system is that, even if two distinct user compute the same hand gesture, the resulting t-f matrix show differences due to peculiarities in the gesture execution. In order to detect and associate a t-f matrix the to corresponding user a deep learning based detector has been implemented. Such choice is motivated by the fact that such family of algorithms has been already successful exploited in many classification tasks.

Considering an authentication task, where the author of the gesture is known and system is asked to accept or deny a gesture sample, the proposed detector is shown in Fig. 2. The input is one of the considered t-f matrix. Such image is sent to a cascade of three convolutional layers (3×3 filters with 64 features) and, successively, to a fully connected layer with two nodes. The output of the network represent a similarity score between the feature extracted from gesture sample under test and those related to the user declared as genuine. Based on a threshold such sample is accepted or denied.

III. Results

In order to evaluate the performance of the proposed system, a one-vs-all authentication scenario is considered. For this purposes, a dataset of gestures have been acquired and exploited for training and testing the detector. More in detail, to a population of 25 volunteers have been asked to repeat 90 times 3 different gestures: *Closing and opening the hand*

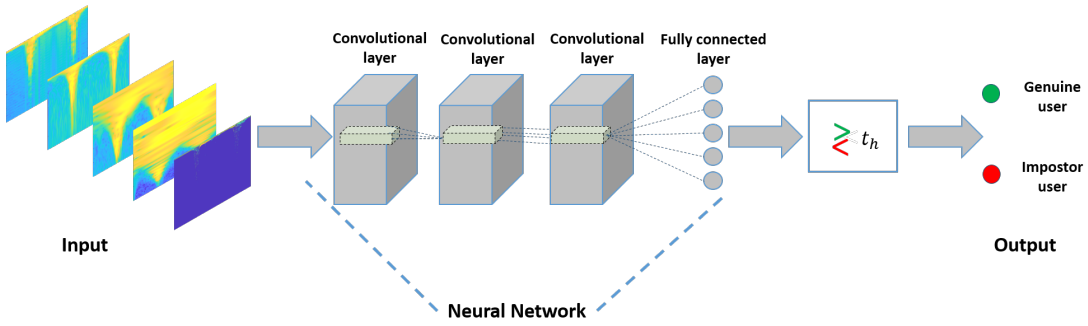

Fig. 2: Block diagram of the detector. The considered time/frequency transform is fed as input of a cascade of convolutional layers ended by a fully connected layer. The corresponding output (membership score) is compared with a threshold in order to accept or deny the gesture.

(Gesture 1), *shifting the hand from left to right* (Gesture 2) and *key-tapping* (Gesture 3).

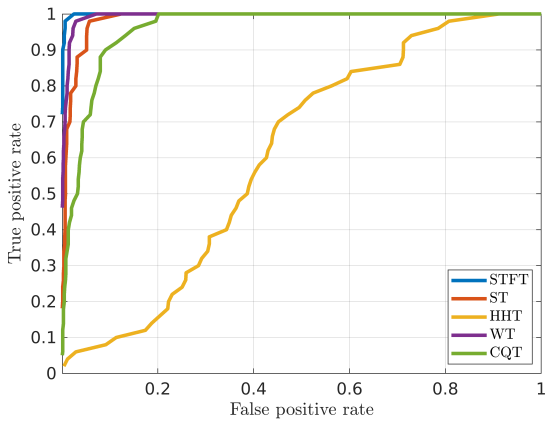
For all the subjects and gestures the 90 repetitions have been divided into into two sets; 40 repetitions have been used for training the network and the remaining 50 for testing. In order to increase the number of training sample an augmentation strategy has been considering. Specifically, each gesture sample has been time shifted 4 times. In this way the detector has been trained to recognize the Doppler features independently from their time position in the time window of observation.

As mentioned in the previous section, a crucial parameter of the detection algorithm is the threshold t_h. If the similarity score provided by the network is greater of t_h such sample is considered as genuine if, conversely, is lower, such sample is rejected. By changing the value of t_h is possible to obtain different working point.

Under the assumption of defining the subject to be authenticate as *Genuine* and all the others as *Impostor*, for each working point the *True Positive Rate*, defined as the ratio between the correct *Genuine* assignment against all the *Genuine* testing samples and the *False Positive Rate*, that is the ratio between the incorrect *Genuine* assignment against all the *Impostor* gesture samples, are computed. Considering the true positive and false positive rates for different values of t_h it is possible to draw the Receiver Operative Curve (ROC) of the detector.

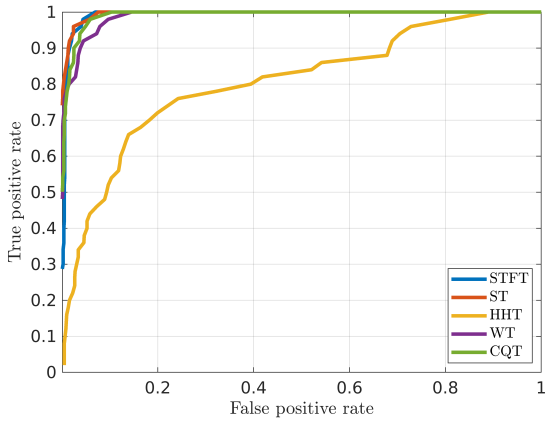
For each gesture and t-f algorithm it is possible to compute the corresponding ROC curve. In Fig. 3 for example, the ROC curves related to each one of the three considered gestures are shown (Gesture 1 is shown in Fig. 3(a), Gesture 2 in Fig. 3(b) and Gesture 3 in Fig. 3(c)). The curves in each graph represent the results of considering a different t-f algorithm as input of the detector. All the curves refer to the same subject to be authenticate.

By looking at the curves, it is possible to note that the behaviour of the system is related to the considered gestures and, in particular, Gesture 3 present worst performances compared to the other 2 gestures. This result can be motivated by the fact that Doppler spectral bandwidth related to gesture 3 is lower with respect to Gesture 1 and 2 and, so, the amount of "features" useful to the detector is lower. From Fig. 3 it is also possible to note that the system produce worst performances if the HHT is considered as t-f input matrix independently from the considered gesture.



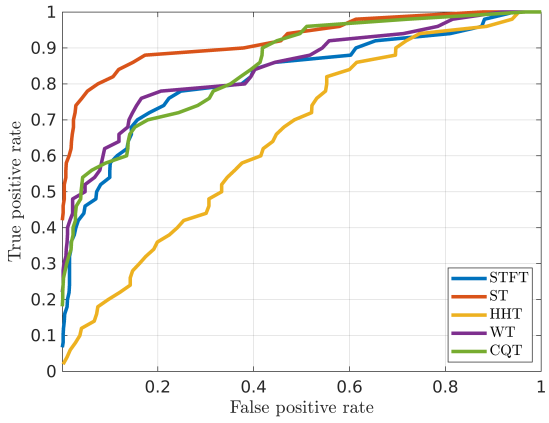
For generalizing the previous statements, the system have been also trained in order to authenticate each one of the 25 volunteers in a one-vs-all authentication scenario. From each obtained ROC curves two synthetic metrics have been extracted. In particular, the first, Area Under ROC (AUR), represents the overall performance of the receiver, the closer this value is to 1 the better the receiver has to be considered; the second, the Equal Error Rate (EER) is defined as the threshold which gives an FPR equal to 1-TPR. In this case, values closer to 0 represent better performance.

In Tab. I mean values of AUR and EER related to each t-f algorithm and gestures, averaged with respect to the 25 subjects, are shown. From the table it is possible to confirm what resulting from the Fig. 3 and, additionally, it is possible to observe promising performances specifically in case of Gesture 1 and STFT algorithm.



It is worth to note that all the proposed tests refer to the worst case scenario where the impostors know perfectly the correct gesture to compute.

IV. Conclusion



This paper presented a novel biometric approach in the framework of authentication. Ultrasound Doppler signatures are exploited for training a deep learning based detector. in this framework an ad-hoc prototype have been designed and tested and the Doppler spectrum information related to the hand gesture have been extracted by means of different time-frequency transform. The system have been tested in an one-vs-all authentication scenario showing promising result. The proposed solution is cheap, portable and robust to environmental noise. Additionally, is presents the advantage of changing the gesture if it is compromised. Moreover, in situation where an high degree of security is needed, more complex gestures can be considered. A further possibility is to consider such system also in multi-biometric configuration in combination with other biometric systems in order to increase the performance of the overall system.

***Abstract*— Fetal Magnetic Resonance Imaging (MRI) is a non-invasive method for neurodevelopment evaluation. In clinical settings, MRI of the fetal brain typically involves the acquisition of fast anatomical sequences such as T2-weighted Spin Echo or Gradient Echo, over different planes on which several biometric measurements are manually extracted. Recently, some automatic toolkits that use the acquired two-dimensional (2D) images to reconstruct a Super-Resolution (SR) isotropic volume have been developed, thus enabling three-dimensional analysis of the fetal central nervous system.**

In this study, we characterized the reliability of the Super-Resolution (SR) images reconstructed via NiftyMIC and MIALSRTK toolkits over a common clinical fetal MR dataset (20 - 21 weeks of gestation). We compared 15 biometric measures derived from the acquired 2D images with those extracted from the SR brain volumes. Furthermore, we examined two different acquisition sequences (TSE Vs. b-FFE) to evaluate which of them lead to more reliable measures and high-resolution reconstructions. Our findings strengthen the adoption of SR toolkits for fetal brain reconstructions to perform biometric evaluations, suggesting the acquisition of TSE sequences because of their robustness against intensity artifacts.

***Keywords*— Fetal brain, Magnetic Resonance Imaging, Super-Resolution Algorithm, Fetal biometry**

I. Introduction

FETAL MRI is a non-invasive exam used for diagnostic purposes via morphologic and biometric evaluations. In clinical practice, brain biometry relies on the comparison of measurements manually derived from MRI images to normative ranges and it is a good approach to assess fetal brain development [1,2].

Recently, new advanced image processing techniques based on Super-Resolution (SR) algorithms have been developed [3,4]. These techniques can handle multiple 2D fetal scans, even those corrupted by motion artifacts, and generate a high-resolution reconstruction of the fetal brain with isotropic voxel size. This enables the morphologic and biometric evaluation of the fetal brain, allowing for navigation of the reconstructed image in any plane, and to perform quantitative analysis of tissue volume development. Modern available tools for fully automatic brain reconstruction from fetal T2w-TSE MRI scans are NiftyMIC [3] and MIALSRTK [4].

In this study, we characterized qualitatively and quantitatively the reliability of the fetal brain images reconstructed by these tools. We collected a heterogeneous dataset of fetal MRI images and we compared the biometric measures derived from the 2D images to those obtained from the 3D reconstructions. Finally, we examined TSE and b-FFE sequences to determine which led to more reliable reconstructions.

II. Materials and Methods

A. Dataset

17 fetal brain MRI examinations of singleton pregnancies (20.24 ± 0.44 gestational weeks) were collected via a 3T Philips scanner at the IRCCS Fondazione Ca' Granda Ospedale Maggiore Policlinico. The protocol included T2w-TSE and/or b-FFE sequences, acquired with different set-ups due to the clinical context. The procedures were approved by the institutional ethical review boards of the hospital, and all women signed informed consent for the research use of data.

B. Super-Resolution Reconstruction

Fetal brains were reconstructed into SR volumes with an isotropic spatial resolution matching that of input sequences via NiftyMIC [3] (v0.8) and MIALSRTK [4] (v2.03). Acquired images were visually inspected to discard sequences with artifacts [5]. On average, 3 out of 6 sequences per subject were used for the reconstruction.

C. Qualitative evaluation of the SR brain volumes

The quality of the SR images was evaluated in a blinded protocol by two MR pediatric experts with a Likert scale [6] rate score between 1 and 4. A rating of 1 indicates a *bad* quality reconstruction that is not suitable for biometric purposes due to significant motion distortion and blurring effects. A rating of 2 indicates a *poor* quality reconstruction that may be useful for obtaining one reliable biometric measure, but the overall quality is still poor, with persistent motion distortion and blurring effects. A rating of 3 indicates an *acceptable* quality reconstruction that can be used for biometric purposes, despite some remaining blurring effects. A rating of 4 indicates an *excellent* quality reconstruction that is free of any blurring effects (Figure 1).

Figure 1: Example of fetal brain reconstructions obtained via NiftyMIC and MIALSRTK. The reconstructed brain quality was rated from bad to excellent.

D. Biometric measurements

The biometric measures were assessed manually via 3D Slicer [7] by one expert in pediatric image analysis, both on the 2D images and on the 3D reconstructions. In accordance with previous studies [1,8-10], we selected the biometric measures represented in Figure 2. Each measure was taken two times and then averaged on the subject.

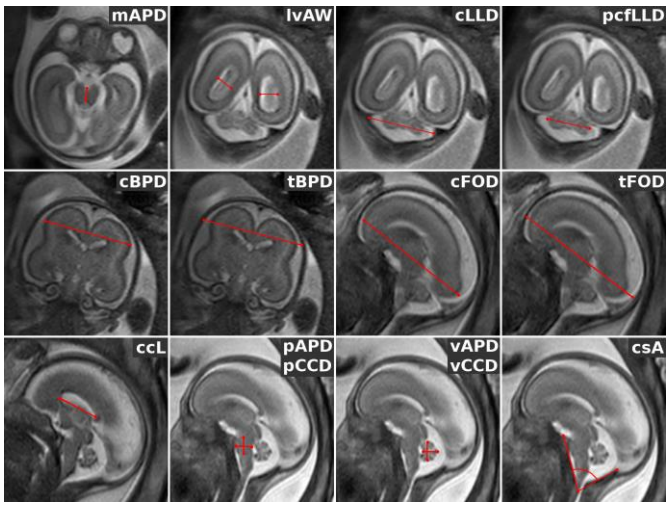

Figure 2: Biometric measurements (marked in red) representation in each orthogonal orientation. Axial orientation: the mesencephalic Antero-Posterior Diameter (mAPD). Coronal orientation: the lateral ventricles Atrial Width (lvAW), the cerebellar Latero-Lateral Diameter (cLLD), the posterior cranial fossa Latero-Lateral Diameter (pcfLLD), the cerebral BiParietal Diameter (cBPD), the thecal BiParietal Diameter (tBPD). Sagittal orientation the cerebral Fronto-Occipital Diameter (cFOD), the thecal Fronto-Occipital Diameter (tFOD), the corpus callosum Length (ccL), the pontine Antero-Posterior Diameter (pAPD), the pontine Cranio-Caudal Diameter (pCCD), the vermian Antero-Posterior Diameter (vAPD), the vermian Cranio-Caudal Diameter (vCCD), and the clivo-supraoccipital Angle (csA). For a more detailed description of how to perform the measurements please refer to [1].

E. Analyses

Three analyses were performed with R software v4.0.5:

- tools evaluation: we performed an agreement analysis between the biometric measures on each 2D acquisition and on the SR brain using Passing-Bablok regression with the Person's correlation coefficient [11], and Bland-Altman plot [12]. The reliability of the measurements obtained from the reconstructed volumes was evaluated by calculating the intraclass correlation coefficient (ICC) as a measure of correlation and agreement with those obtained from the 2D sequences. The criteria established by [13] was used to interpret the ICC magnitude. Finally, the mean values and the standard deviations of biometric measures were compared with the paired two-tailed t-test and F-test. The Shapiro-Wilk method [14] was used to test the normality of the biometric measures distribution.
- tools comparison: we performed a qualitative (Likert score) and quantitative (percentage error and Passing-Bablok regression) comparison between the fetal brain reconstructed images obtained via the tools investigated. The consistency of the quality assessment of brain volume reconstruction between raters was evaluated using Gwet's agreement coefficient (Gwet's AC1). To evaluate the magnitude of this coefficient, the Altman's benchmarking was adopted [15]. The slope coefficient and intercept of the Passing-Bablok regression line were compared using paired two-tailed t-test and F-test.
- sequences evaluation: we performed a qualitative and quantitative comparison, as introduced in previous steps, between TSE and b-FFE sequences to investigate differences in the SR images.

III. Results

A. Tools evaluation

Forty fetal brain volumes were reconstructed via NiftyMIC and MIALSRTK. Out of the reconstructions obtained via NiftyMIC and MIALSRTK, seven of them were found to be of bad quality and were therefore not considered in the subsequent analysis. Thus, 33 fetal brain images reconstructed via NiftyMIC and MIALSRTK were considered for the biometric analysis (Figure 3).

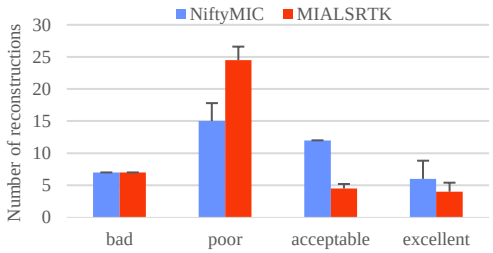

Figure 3: NiftyMIC and MIALSRTK comparison in terms of reconstruction quality. Each bar and whisker represent the average and standard deviation consensus among the two raters' assessment for each quality scale.

The statistical comparisons identified no significant differences between measures derived from reconstructed volumes and 2D images, with the only exception for the cLLD measures ($p = 0.01$ and $p < 0.001$ for NiftyMIC and MIALSRTK, respectively).

The Passing-Bablok test and the Bland-Altman plots confirm the significant agreement between the biometric measures derived from 2D images and reconstructed volumes ($r_{min} > 0.74$ and $r_{min} > 0.71$ with both $p < 0.003$, for each measure Pearson's correlation coefficient derived on NiftyMIC and MIALSRTK reconstruction, respectively).

The reconstruction reliability of both tools was assessed as Moderate to Good [13] (averaged ICC with 95% CI was 0.82 [0.62 - 0.92] for NiftyMIC, and 0.79 [0.57 - 0.90] for

MIALSRTK). The ICC results are reported for each biometric measurement in Table 1.

Table 1: Intraclass Correlation Coefficient (ICC) between biometric measurements derived from reconstructed fetal brain and 2D images. The ICC is reported for both toolkits, NiftyMIC and MIALSRTK.

Orthogonal Orientation	Biometric Measure	ICC	
		NiftyMIC	MIALSRTK
AX	mAPD	0.85	0.86
COR	r-lvAW	0.87	0.88
	l-lvAW	0.87	0.84
	cLLD	0.77	0.80
	pcfLLD	0.84	0.85
	cBPD	0.74	0.57
	tBPD	0.84	0.78
SAG	cFOD	0.75	0.70
	tFOD	0.73	0.74
	ccL	0.92	0.90
	pAPD	0.64	0.50
	pCCD	0.82	0.91
	vAPD	0.87	0.89
	vCCD	0.88	0.79
	csA	0.87	0.79

B. *Tools comparison*

The estimated agreement coefficient (GWet's AC1) between the two raters was 0.74 and 0.78 for NiftyMIC and MIALSRTK, respectively, based on the visual inspection and scoring of the reconstructed images. Using Altman's benchmarking scale, the magnitude of the estimated coefficient was considered to be *Good*, with a probability of 95.1% and 99.2% for NiftyMIC and MIALSRTK, respectively.

Results of the estimated biometric measurements percentage error (Table 2) showed an overall average error rate of -0.1% ± 4.9% and -0.7% ± 5.1% for NiftyMIC and MIALSRTK, respectively. Out of 15 measurements, NiftyMIC had a smaller magnitude of mean percentage error in 11 measures and a smaller standard deviation in 9 measures compared to MIALSRTK.

The two-tailed t-test showed no significant differences between the toolkits' Passing-Bablok regression slope and intercept values.

Table 2: Toolkits comparison in terms of biometric measurements percentage error. The error is calculated between the measurements derived from the reconstructed fetal brain and those derived from 2D images. The percentage values are discussed in terms of mean and standard deviation (SD).

Orthogonal Orientation	Biometric Measure	SR reconstruction	
		NiftyMIC	MIALSRTK
		Mean ± SD	Mean ± SD
AX	mAPD	0.53% ± 4.64%	0.12% ± 5.51%
COR	r-lvAW	-0.74% ± 7.51%	0.85% ± 4.76%
	l-lvAW	-0.9% ± 7.05%	1.36% ± 6.71%
	cLLD	-1.51% ± 2.86%	-3.31% ± 3.05%
	pcfLLD	-1.32% ± 4.08%	-1.53% ± 4.08%
	cBPD	0.4% ± 3.92%	-0.95% ± 3.92%
	tBPD	0.91% ± 3.45%	-0.01% ± 3.95%
SAG	cFOD	-1.12% ± 3.28%	-1.46% ± 4.38%
	tFOD	0.4% ± 3.22%	-0.08% ± 3.92%
	ccL	0.98% ± 5.45%	-2.46% ± 5.7%
	pAPD	0.5% ± 5.63%	-0.54% ± 6.36%
	pCCD	-0.95% ± 4.59%	-0.16% ± 4.45%
	vAPD	-0.36% ± 4.65%	0.66% ± 5.51%
	vCCD	1.18% ± 7.74%	-3.53% ± 7.66%
	csA	0.2% ± 5.62%	0.68% ± 6.88%

C. *Sequences evaluation*

The results of the visual quality assessment for SR images revealed that TSE sequences were rated lower than b-FFE sequences (Figure 4).

The agreement coefficient between the two raters for the visual quality assessment of the reconstructed images was estimated to be 0.89 and 0.64 for TSE and b-FFE reconstructions obtained via NiftyMIC, respectively, and 0.77 and 0.78 for TSE and b-FFE reconstructions obtained via MIALSRTK, respectively. The magnitude of the estimated coefficient was determined to be *Very Good* with a probability of 99.9% for TSE reconstructions via NiftyMIC, *Moderate* with a probability of 98.9% for b-FFE reconstructions via NiftyMIC, *Good* with a probability of 93.6% for TSE reconstructions via MIALSRTK, and *Good* with a probability of 93% for b-FFE reconstructions via MIALSRTK.

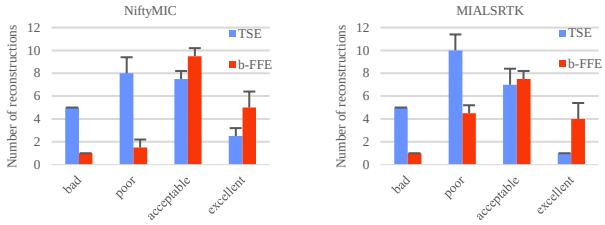

Figure 4: MRI sequences (T2w- TSE and b-FFE) quality comparison of the reconstructed fetal brain obtained via NiftyMIC and MIALSRTK. Each bar and whisker report the quality average and standard deviation consensus among the two raters' assessments for each quality scale.

Moreover, b-FFE sequences were usually characterized by the presence of intensity artifacts [16] affecting both the acquired 2D and reconstructed images, independently from the toolkit adopted (Figure 5).

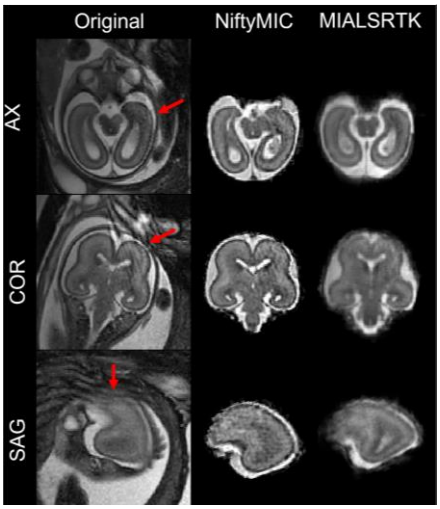

Figure 5: Examples of b-FFE acquisition artifacts. The artifact is reported on 2D images and reconstructions obtained via NiftyMIC and MIALSRTK. The artifact, pointed out by the red arrow, is shown in each orthogonal plane (axial, sagittal, and coronal).

The estimated biometric measurements percentage error showed an average error rate of 0.3% ± 4.9% and -0.4% ± 4.8% for NiftyMIC TSE and b-FFE reconstructions, respectively; -0.75% ± 5.37% and -0.61% ± 4.8% for MIALSRTK TSE and b-FFE reconstructions, respectively. The percentage error of different measurements was significantly different from 0 for ccL in b-FFE and vCCD in

TSE reconstructions via NiftyMIC; for cLLD in b-FFE and TSE, and vCCD in TSE reconstructions via MIALSRTK.

The Passing-Bablok regression slope coefficient of the MIALSRTK-TSE reconstructions showed significant ($p = 0.02$) differences with respect to a null distribution. The paired two-tailed t-test exhibited no significant differences between the two sequences' slope and intercept values. The F-test showed significant differences ($p = 0.03$) for the intercept values between NiftyMIC TSE and b-FFE reconstructions.

IV. Discussion

Automatic brain reconstruction methods from fetal MRI scans are crucial to perform quantitative volumetric studies of neurodevelopment. The publicly available modern toolkits which include a full pipeline for fetal brain MRI reconstruction are NiftyMIC and MIALSTRK. These toolkits were each proposed and validated on T2w spin echo sequence, but were not evaluated on a heterogeneous dataset (i.e., different acquisition set-ups and MRI sequences). In this study, we firstly validated the aforementioned methods, then we conducted a qualitative and quantitative comparison among them over a heterogeneous dataset including TSE and b-FFE sequences.

The results showed that the reconstructed volumes were geometrically reliable and, in 80% of the cases, clinically useful for biometric measurements. In detail, NiftyMIC reconstructions were qualitatively rated higher than MIALSRTK reconstructions since the latter were more blurred and less anatomically defined. Nevertheless, the measurements were very similar between the two methods, suggesting a good agreement between them.

Only the cLLD measure was found to be significantly different between measurements obtained from reconstructed volumes and 2D images. This may be due to the larger partial volume affecting the acquired 2D images.

The fetal brain reconstructions obtained from b-FFE sequences were rated higher than TSE ones. However, the presence of intensity bands on both the b-FFE images and derived volumes may be an important source of errors, suggesting that TSE sequences are more reliable for the 3D reconstruction and the possible subsequent volumetric measurements.

The main limitations of this method-comparison study are the reduced number of acquired subjects as well as the amount of sequences per orthogonal orientation adopted for the reconstructions, the narrow range of subjects' gestational age, and the use of the toolkits with default settings.

V. Conclusion

We compared two toolkits on a set of common clinical fetal MR scans acquired around the 21st gestational week. We found that NiftyMIC and MIALSRTK provide reliable reconstructed volumes, which can be used for biometric measurements. Moreover, the availability of SR images with an isotropic voxel size allows for conducting volumetric-based analyses, which may provide more faithful indices for assessing brain development. Finally, we disclosed that TSE sequences should be recommended for this aim as they are less affected by intensity artifacts.

***Abstract*— Brugada syndrome (BrS) is an inherited cardiac disorder at high risk of sudden death. There are two ECG patterns for BrS: Type 1 (coved-type), representing the only diagnostic pattern for BrS (BrS1), while type 2 (saddle-back type) is only suggestive of BrS (BrS2). The QT interval on surface ECG, known to be heart-rate (HR) dependent, characterizes ventricular activity and is associated with the risk of ventricular arrhythmias. Aim of this study is to investigate the role of QT-interval and QT-interval-segment correction in subjects with BrS1 and BrS2, compared to controls (CTR). Open-access "Brugada ECG Database" by Zenodo was considered, containing HR, QT interval and its segments (QJ, JT_p, and T_pT_e) of 60 subjects with BrS1, 27 subjects with BrS2 and 51 CTR. Time intervals and segments were corrected according to nine correction formulae. Feature distributions of BrS1, BrS2 and CTR were compared by unpaired Wilcoxon rank sum test. All BrS1 and BrS2 features were statistically different from CTR. QT interval and corrected QT interval were significantly longer in BrS1 and BrS2 than in CTR, mainly due to longer QJ and T_pT_e, while JT_p was significantly shorter in BrS1 and BrS2 than in CTR. No significant differences were observed in QJ and JT_p between BrS1 and BrS2, whereas five correction formulae revealed that BrS1 had significantly longer T_pT_e interval than BrS2, suggesting physiological differences between BrS1 and BrS2 in late repolarization phase. In conclusion, major differences exist between BrS patients and CRT in QT-interval duration, mainly due to longer QJ and shorter JT_p duration in BrS patients, while differences may exist between BrS1 and BrS2 patients in the late repolarization phase, highlighting the need of proper QT-HR correction to better characterize BrS patients.**

***Keywords*—QT Interval, Brugada Syndrome, QT Correction, Digital Cardiology.**

I. Introduction

BRUGADA syndrome is an inherited cardiac disease, defined also as sodium channelopathy [1,2], characterized by a prevalence of 1-5/10000 individuals; it is responsible for 4% of all sudden cardiac deaths [3-5]. Diagnosis of Brugada syndrome is also based on electrocardiogram (ECG) analysis. ECG is the measurement of cardiac electrical activity, that is composed of three wave patterns (Fig. 1): the P wave reflects the atrial depolarization; the QRS complex reflects the ventricular repolarization and covers the atrial repolarization and, finally, the T wave reflects the ventricular repolarization [6]. Considering the standard ECG pattern, diagnosis of Brugada Syndrome occurs if the precordial V1-V3 leads are characterized by ST-segment elevation of at least 0.2 mV. [1]. Brugada Syndrome is classified according with the topology of the T wave: if the T wave results to be negative, the Brugada Syndrome is of Type 1 (BrS1, Fig. 2a), while if the T wave results to be positive or biphasic (saddleback pattern), the Brugada Syndrome is of Type 2 (BrS2, Fig. 2b).

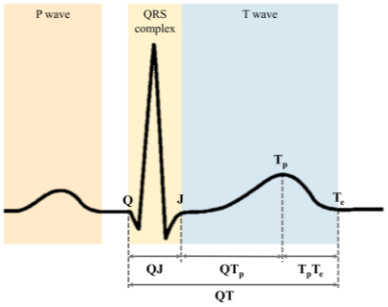

Fig. 1: Electrocardiogram (ECG) pattern, characterized by P wave, QRS complex and T wave. Measurement of QT and its fragmentation into QJ, QTp and TpTe segments is also depicted.

Subjects affected by BrS1 appear to have higher probability to suffer from malignant ventricular arrhythmias [7]. SCN5A gene mutations, occurring in about 25-30% of BrS cases, have been associated with a worse prognosis [8].

The most important ECG feature for the characterization on ventricular activity (depolarization and repolarization) is the QT interval (Fig. 1), defined as the time interval between the beginning of the QRS complex and the end of the T wave [6]. It can be also characterized by its composing segments (Fig. 1), that are the QJ segment (also called QRS duration), the JT_p segment and T_pT_e segment. QJ segment reflects the timing of ventricular depolarization, JT_p segment reflects the timing of early ventricular repolarization and T_pT_e segment reflects the timing of late ventricular repolarization.

It is widely known that QT interval is heart-rate (HR) dependent [9,10]. Specifically, an increase/decrease of the heart rate provokes a decrease/increase of the QT interval. Thus, the measurement of QT interval should be normalized according with HR. In the literature, nine QT-interval corrections have been proposed in order to adjust the QT-interval measure [9-19]. Despite the wide use of QT-interval correction, no studies investigated the role of correction in Brugada Syndrome and, specifically, in the correction of the different segments constituting the QT interval. Thus, aim of this study is to investigate the role of the correction of QT-interval segments in subjects affected by Type 1 and Type 2 Brugada Syndrome.

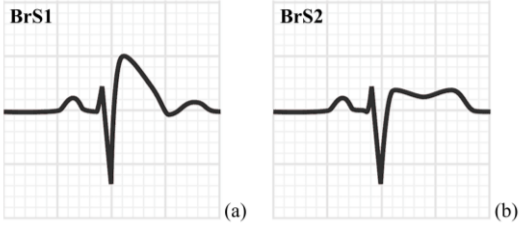

Fig. 2: Electrocardiographic pattern of Brugada Syndrome Type 1 (BrS1, panel a) and Brugada Syndrome Type 2 (BrS2, panel b).

II. Materials and Methods

A. Database

Open-access "Brugada ECG Database" by Zenodo was considered in this study [20-21]. The database contains ECG features of 60 subjects affected by Type 1 Brugada Syndrome (BrS1), 27 subjects affected by Type 2 Brugada Syndrome (BrS2) and 51 control subjects (CTR). Specifically, ECG features were extracted from 3 precordial leads, that are V1, V2 and V3. In this study, the heart rate (HR), the QT interval, the QJ segment, the JT_p segment and the T_pT_e segment of three leads were considered for each subject.

B. QT-Interval and QT-Interval-Segment Correction

QT interval and QT-interval segments (QJ, JT_p and T_pT_e) of three V1-V3 leads of BrS1, BrS2 and CTR were corrected according with the formulae [9,10] reported in Table I.

TABLE I: Formulae for QT-interval and QT-interval-segment correction.

Ref.	*Correction*	*Formulae*
[11]	Bazett	$\begin{cases} QTc=\frac{QT}{\sqrt{60/HR}} & JT_pc=\frac{JT_p}{\sqrt{60/HR}} \\ QJc=\frac{QJ}{\sqrt{60/HR}} & T_pT_ec=\frac{T_pT_e}{\sqrt{60/HR}} \end{cases}$

C. Statistics

Normality of HR, QT-interval, QT-interval-segment, corrected QT-interval and QT-interval-segment distributions was assessed by Lilliefors test. Not normal distributions of BrS1, BrS2 and CTR were reported as $50^{th}[25^{th};75^{th}]$ percentiles and compared using the unpaired Wilcoxon ranksum test for median values.

III. Results

HR distributions of BrS1, BrS2 and CTR were 73[66;81]bpm, 65[62;73]bpm, and 69[65;79]bpm, respectively; median HR of BrS1 and BrS2 were statistically different (p=0.04). QT-interval, QT-interval-segment, corrected QT-interval and QT-interval-segment distributions are reported in Table II. QT interval and corrected QT interval were statistically longer in BrS1 and BrS2 than in CTR, mainly due to longer QJ and T_pT_e durations, while JT_p was significantly shorter in BrS1 and BrS2 than in CTR. Regarding the comparison BrS1 and BrS2 (Fig. 3), BrS1 presents median value of JT_p in V3 lead statistically lower than BrS2 (BrS1:164 ms, BrS2:174 ms, p=0.04). Differently, BrS1 presents median value of JT_pc segment not statistically different than BrS2 in all corrections (Table II, p>0.05). Median value of T_pT_ec of BrS1 and BrS2 are statistically difference in V3 lead if considering correction by Framingharm, Hodges, Schlamowitz, Rautaharju and Sarma [15-19] and in V2 lead if considering correction by Rautaharju and Sarma [18,19].

IV. Discussion

This study aimed to investigate the role of the QT-interval and QT-interval-segment correction in subjects affected by BrS1 and BrS2. Evaluating the QT interval in BrS is essential because it may be a prevention tool against sudden death [7].

It is widely known that QT interval is HR dependent, *i.e.*, QT interval modulates according to the HR (lower HR associates to longer QT interval; higher HR associates to shorten QT interval). In the literature, several QT-interval corrections were proposed [9-19] to investigate HR-QT association and to normalize QT interval, avoiding misinterpretation. Despite the many studies, none of them evaluated the effect of HR on QT-interval segments, that are depolarization (QJ segment), early repolarization (JT_p segment) and late repolarization (T_pT_e segment).

According with our results, the effect of HR on QT-interval segments appears extremely important. Indeed, statistical difference of JT_p in V3 between BrS1 and BrS2 subjects might be misinterpreted, although it is the consequence induced by HR (same statistical significance). Thus, QT-interval and QT-interval-segment normalization is essential when discriminating Brugada Syndrome. Of note, five QT-interval corrections reveal that BrS1 and BrS2 presents statistically different T_pT_ec in leads V2 and V3. These results highlight a possible difference between BrS1 and BrS2 in the late repolarization phase, at a difference with what is shown by the uncorrected measurements, showing differences in the early repolarization phase. These results need to be confirmed by further clinical studies, possibly including patients with known genetic background.

TABLE II: QT-INTERVAL AND QT-INTERVAL-SEGMENT DISTRIBUTION OF SUBJECTS AFFECTED BY BRS1, BRS2 AND CTR.

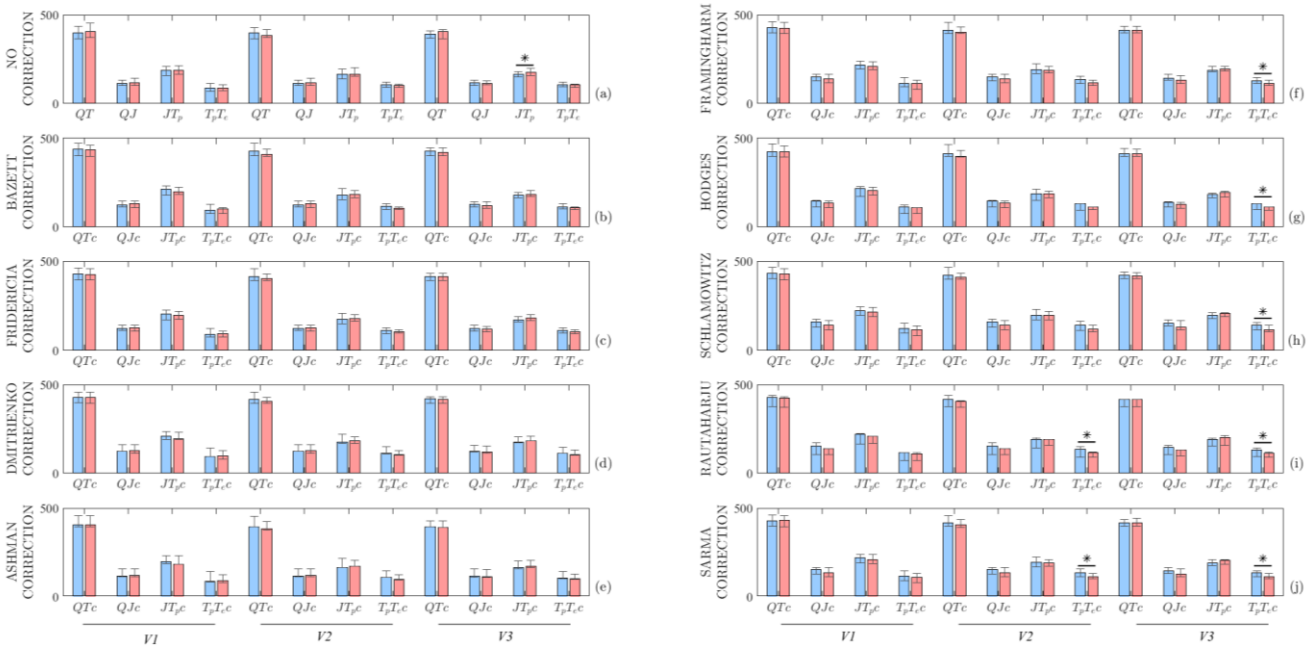

Fig. 3: QT-interval and QT-interval-segment distribution (in ms) of subjects affected by BrS1 (in blue) and BrS2 (in red). Different panels depict QT interval and QT-interval segments of (a) no correction, and corrections by (b) Bazett [10], (c) Fridericia [11], (d) Dmitrienko [12], (e) Ashman [13], (f) Framingharm [14], (g) Hodges [15], (h) Schlamowitz [16], (i) Rautaharju [17] and (j) Sarma [18].

V. Conclusion

QT-interval and QT-interval segment corrections are essential in Brugada syndrome. Future studies will investigate the difference in late depolarization between subjects affected by Type 1 and Type 2 Brugada Syndrome.

***Abstract*— Resting state networks (RSNs) were most studied using functional magnetic resonance imaging (fMRI). Interhemispheric functional connectivity (FC) appears mostly supported by the corpus callosum (CC) and several studies have investigated this aspect, still not providing conclusive evidence. In this context, patients in whom the CC was resected for therapeutic reasons (split-brain patients) provide a unique opportunity of research. The purpose of this pilot study is to investigate, with resting state fMRI, the interhemispheric FC in two callosotomized patients operated in adult age, and in four healthy control subjects with intact brain. The analysis was performed with fMRI of the Brain (FMRIB) Software Library (FSL); the evaluation of interhemispheric FC and the recognition of the RSNs were performed by using the probabilistic independent component analysis (PICA). The multi-subject analysis on control subjects allowed the identification of three RSNs: medial visual, default mode, and sensory motor. Both patients showed a bilateral brain activation in the medial visual network, comparable with the controls; in the sensory motor and the default mode networks the activation was unilateral, at variance with controls. These results seem to suggest that the brain, during its maturation, builds new subcortical communication pathways, alternative to the CC, which might support interhemispheric FC in case of callosotomy. Further studies are needed to confirm the observations obtained and reported in this preliminary research.**

I. Introduction

THE resting state brain activity refers to spontaneous activity without deliberately given stimuli. Such activity shows relatively consistent distributed patterns and can be used to characterize network dynamics without needing an explicit task to drive brain activity [1]. Indeed, in resting conditions, left and right hemispheric regions are not silent but are active and show reciprocal high correlation suggesting ongoing information processing and functional connectivity (FC) between these regions during rest [2]. Although the relation between structural and FC has profound implications for our understanding of cerebral physiology and cognitive neuroscience, it remains incompletely understood.

The brain seems to be mainly driven by its intrinsic activity and possible external stimulations can modulate, rather than determine, its activity. The brain is always active, even in the absence of a specific task being performed or of a particular stimulus [2]. Moreover, one of the most striking features of resting state FC is symmetry about the midline. Resting state correlations tend to be particularly strong between corresponding loci in each hemisphere (homotopic FC) [3], [4]. Resting state networks (RSNs, *i.e.*, anatomically separated, but functionally linked, brain regions) show a high level of FC during rest. The most common RSNs were discovered and described by Beckmann and coworkers [5], and, more recently, by Smith and coworkers, who identified 10 networks of the state of rest studying 36 healthy patients during resting state [6].

The corpus callosum (CC) is the major commissure connecting the two hemispheres structurally and functionally. Accordingly, the CC is supposed to accounts for the prominent symmetry of FC. Patients in whom the CC was resected for therapeutic reasons (split-brain patients) provide a unique opportunity to study this question. However, data pertaining to this question are mixed and partially contradictory. Previous observations made in patients with intractable epilepsy, who have undergone therapeutic section of the CC, report conflicting results [7–9]. Specifically, a study on a 6-years-old boy before and after a complete callosotomy reports that FC was normal before surgery but largely lost afterward [7]. On the other hand, a partially intact interhemispheric FC was found four decades after total callosotomy [8]. A more recent study, carried out on young epileptic patients, followed up until 2 years after surgery, affirms that CC resection reduces interhemispheric FC [9].

The present study is a preliminary analysis considering two adult patients, operated in adult age to resect the CC. The aim is to evaluate their interhemispheric FC, analyzing functional magnetic resonance imaging (fMRI) data acquired in resting state condition. A healthy population, whose fMRI data were acquired in the same resting conditions, is used as control population.

II. Experimental Procedure

A. Participants

The data were obtained from two epileptic patients (42 and 52 years; males) who underwent complete callosal resection about 20 years before the study, and four healthy subjects (31-64 years; M/F=1/4), all right-handed. The fMRI data were acquired between June 2018 and September 2022. All participants gave their informed consent to the experimental

procedure, approved by the Ethical Committee of Università Politecnica delle Marche. Details of healthy subjects (controls) and callosotomized patients are reported in Table I.

TABLE I: DATA OF PARTICIPANTS

Participants	*G*	*AT*	*CR*	*Y2S*
		Controls		
S1	F	31	na	na
S2	M	56	na	na
S3	F	52	na	na
S4	F	64	na	na
		Callosotomized patients		
P1	M	42	Total	19
P2	M	52	Total	24

AT: age at testing; CR: callosal resection; G: gender; Y2S: years after second surgery.

B. Functional MRI data acquisition

Both controls and patients were instructed in advanced to lie down and remain still as much as possible during the fMRI acquisition, to keep their eyes open, to relax without falling asleep and without focusing on anything. Resting-state BOLD fMRI data and T1-weighted structural images were acquired using a 1.5 Signal HDxt GE Medical System MRI scanner.

Functional images were acquired with an echo planar image (EPI) gradient-echo sequence, with the following parameters: echo time (TE)=50 ms, repetition time (TR)=3000 ms, flip angle=90°, field of view (FOV) of 240×240 mm, matrix size of 64×64, number of volumes=300, number of axial slices=35, slice thickness=5 mm in controls and 4 mm in patients, with no gap between slice acquisition, voxel resolution 3×3×(slice thickness) mm. The duration of resting state fMRI was 15 min and 10 s. The T1-weighted structural images (3D; high-resolution whole-brain images, also called structural image) were acquired with a MPRAGE sequence with TE= 6.7 ms, TR=14.7 ms, FOV of 290×290 mm, matrix size of 288×288 mm, number of sagittal slices=158, slice thickness=1 mm with no gap between slice acquisition, voxel resolution 0.5664×0.5664×1 mm. The duration was 8 min and 8 s.

C. Data analysis

The structural and functional images were analyzed by means of the fMRI of the Brain (FMRIB) Software Library (FSL). [10]

A preprocessing procedure was performed on the raw data. The procedure includes several steps, as follows: (1) brain extraction, (2) motion correction, (3) slice time correction, (4) spatial smoothing, (5) temporal filtering and (6) registration. The step of brain extraction was performed using the brain extraction tool (BET) [11]. BET removes non-brain tissues (*e.g.*, skull and meninges) from the T1-weighted structural images according to the fractional intensity threshold parameter, which was set to 0.2. The remaining steps were performed within the Multivariate Exploratory Linear Optimized Decomposition into Independent Components (MELODIC), a FSL tool [5]. The slice time correction was performed on the functional images treating them as acquired sequentially in ascending order from bottom to top. The spatial smoothing was applied by setting the full width at half maximum at 5 mm. Finally, for temporal filtering, a high-pass filter was used, with a cutoff frequency of 0.01 Hz. The step of registration was performed using the FMRIB's Linear Image Registration Tool (FLIRT) [12]. By means of FLIRT, the co-registration of the T1-weighted structural image with the functional image was performed, as well as the normalization respect to a standard brain used as template to allow multi-subject analysis. The co-registration was different for controls and patients. In controls, it was performed with the 12 degree of freedom registration method; in patients, it was performed with the boundary-based registration method. For the normalization phase, the Montreal Neurological Institute (MNI) approach was used as template.

After pre-processing, independent component analysis (ICA) decomposition allowed to discriminate the data of functional images into non-Gaussian sources to improve the specificity and sensitivity of results derived from blood-oxygen-level-dependent (BOLD) signal evaluation. Specifically, with FSL the probabilistic ICA (PICA) model proposed by Beckmann and Smith was used [5]. At variance with the standard ICA, the PICA model quantifies the statistical significance for estimated spatial maps of brain activity and includes a noise/error term added to the source.

The spatial maps of brain activity estimated by PICA model show the active voxels, to which is associated a statistical significance. The activated voxels were not considered necessarily associated to a neural activity of interest, since the activation might also have been an artifact. In the implementation performed through MELODIC tool, the threshold defining the voxel activation was set to 0.5 and the number of independent components was automatically estimated by the tool. This analysis was performed on both patients through two single sessions and on all controls through a multi-session. This last procedure, by temporally concatenating the functional images of all controls in a data matrix, allows to identify common spatial maps of brain activity, which can be compared with the spatial maps obtained in both patients.

The information defined in the PICA decomposition is employed to discriminate noise independent components (characterized by noise/artifacts) and neural independent components (of interest), holding for the evaluation of brain activation patterns only the last ones. Specifically, these two classes of components were identified examining the respective differences in terms of spatial, temporal, and spectral characteristics. Because of the small number of controls, and because of the presence of patients with pathological characteristics, a visual inspection of the components was preferred, which represents, when possible, the gold standard technique [13]. Neural independent components are then classified according to the RSNs identified by Smith [6].

D. Results

The multi-subject analysis on controls allowed the identification of three activation networks attributable to Smith's RSNs: the medial visual network (MVN), the default mode network (DMN), and the sensory motor network (SMN). Both patients showed activation in these networks, although with different degree of bilaterality. Results from multi-subject analysis on controls and single subject analysis on patients are shown in figures 1-3, where panels in row A refer to the controls, in row B to P1, in row C to P2; the activations are shown, in sagittal, coronal, and axial planes, respectively. In particular, figure 1 shows activation reported in the MVN, figure 2 shows the DMN and figure 3 shows the SMN. The coordinates identifying the specific anatomical planes considered are indicated in the figures. In all panels, the lighter the color the more intense the activation. According to the radiological convention, the left hemisphere is on the right side of the figures. Both patients showed a bilateral cerebral activation in MVN, comparable with that of controls (Fig. 1). The activation in the DMN is bilateral in P1, although more pronounced in the right side (Fig. 2, B3) and only in the left hemisphere in P2 (Fig. 2, C3); the activation in the SMN is evident in the right hemisphere only in P1 (Fig. 3, B3), and in both sides in P2 (Fig. 3, C2 and C3).

III. Discussion and Conclusion

The aim of this study was to investigate the FC in the brain of patients undergone callosal resection to alleviate severe intractable epilepsy. These patients offer a unique opportunity for neuroscientists to examine the mechanisms of interhemispheric interactions, neuroplasticity, and compensatory reorganization [8]. The results are based on the analysis of resting-state fMRI data using the PICA method implemented in FSL.

Among the neural independent components identified on the multi-subject activation patterns of controls, only three networks of the Smith's resting state classification could be identified. This result could be due both to the small number of controls and to the individual variability of their brain activity in absence of intentional stimuli.

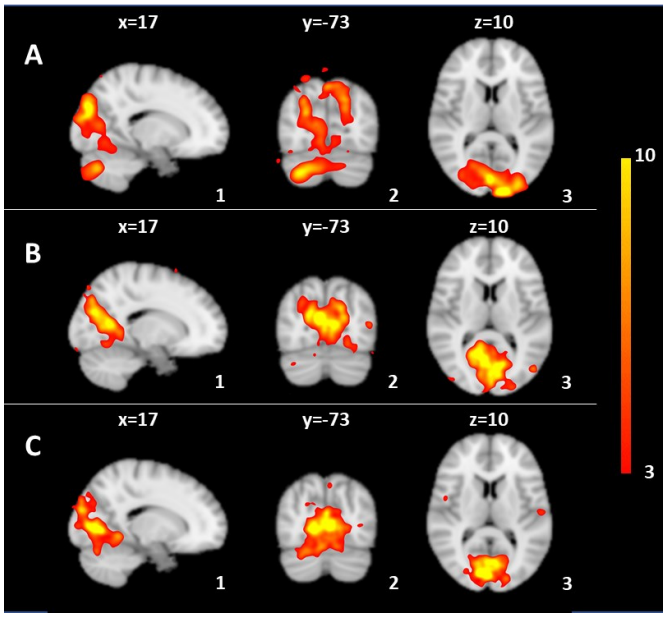

Fig. 1: Medial visual network (MVN) visualization on sagittal (1), coronal (2) and axial (3) planes. Panels show the results of multi-session analysis on controls (A), and single-session analysis on patients (P1 in B, P2 in C).

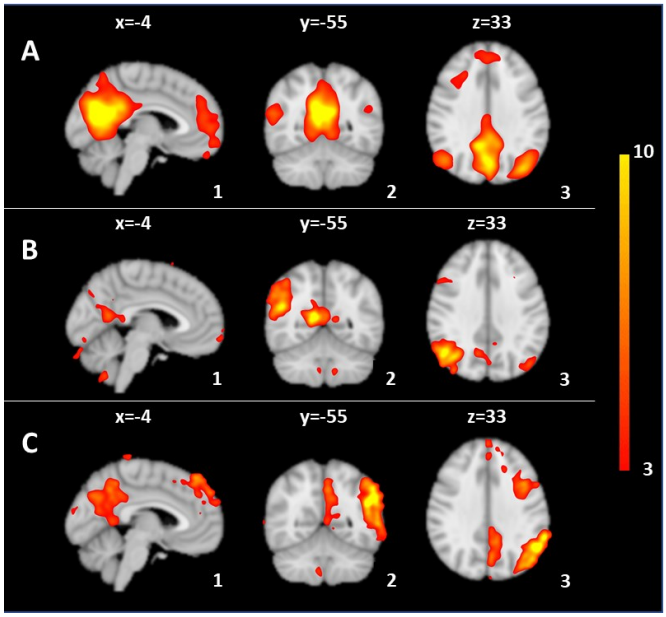

Fig. 2: Default mode network (DMN) visualization on sagittal (1), coronal (2) and axial (3) planes. Panels show the results of multi-session analysis on controls (A), and single-session analysis on patients (P1 in B, P2 in C).

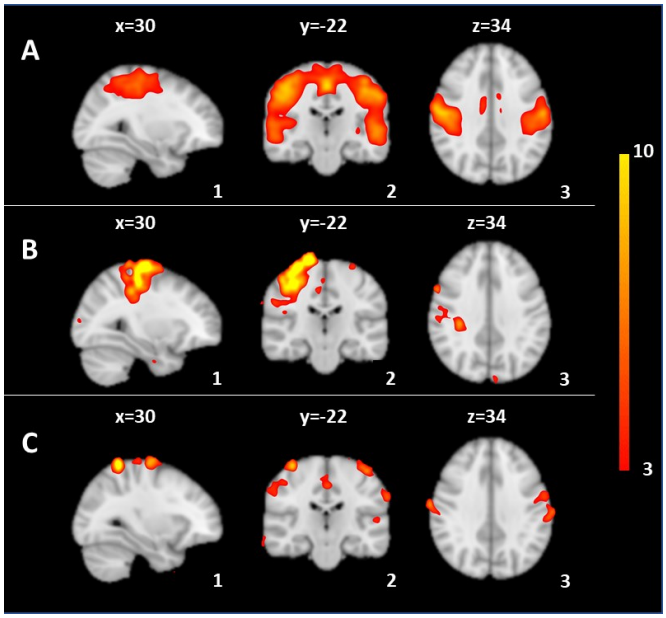

Fig. 3: Sensory motor network (SMN) visualization on sagittal (1), coronal (2) and axial (3) planes. Panels show the results of multi-session analysis on controls (A), and single-session analysis on patients (P1 in B, P2 in C).

Results from patients' analysis show a low degree of bilateral activation in most RSNs, probably due to callosotomy or pharmacological treatment of epilepsy. In both patients, the more unilateral networks were the DMN (figure 2), and the frontoparietal, both right and left, networks (not reported because they were not identified in controls' multi-subject analysis). Only the first could be compared with the population of controls considered in the present study. Thus, the FC of the networks resulted slightly altered. On the other hand, a high

degree of bilateral activation is shown in visual areas in both patients (figure 1).

Present results agree with those reported in a previous study, in which some bilateral activation was observed in occipital visual area and in fronto-parietal networks [8]. Both patients showed bilateral activation in the MVN network, patient P1 also in the DMN network, and patient P2, on the other hand, displayed bilateral activation in the SMN. In agreement with the results of Uddin and coworkers [8], it can be speculated that some degree of FC survives after callosotomy when this surgery is performed in adult age. This fact can be explained by considering that the brain, during its maturation over the years, usually builds other subcortical communication pathways, alternative to the CC, which were then reorganized and exploited once the callosotomy occurs. Through these alternative pathways the right hemisphere would be able to communicate with the left one, and thus maintain a possible interhemispheric communication even after callosotomy.

The brain reaches its maturity around 20 years of age and, once this maturity is reached, the communication routes between the two hemispheres, alternative to the CC, are fully developed. Thus, it is possible that, in callosotomized patients, alternative neural pathways to the CC for interhemispheric connections, prior to total callosotomy, have developed.

On the other hand, present results contrast with those reported in a more recent study in young patients [9]. In these patients, operated during the infancy or early adolescence, the FC was dramatically reduced after callosotomy. In this case, it can be suggested that the brain development was not completed yet at the time of callosotomy, and alternative routes, other than CC, did not have the time to be built. The comparison with intact brains suggests that in healthy subjects' brain a possible dual mechanism does exists, meaning that cortical and sub-cortical mechanisms work together to coordinate networks. The persistence of some bilateral networks in patients seem to suggest that the CC is not the only pathway involved in the connections between the two hemispheres. Further studies involving larger populations could help to confirm the results obtained in this preliminary study and the observations deduced.

A. Limitations of the study

The manual classification of components is certainly a limitation of the study, but also a necessity, given the peculiarity of the patients studied. Although the visual inspection implies a time consuming and non-automated analysis procedure, in conditions as those described in the present study, *i.e.*, when the data set analyzed comes from patients with altered neural activity and altered structural connectivity, this procedure becomes necessary. Moreover, the automatic classification may be more difficult when noise/artifacts are present, which can be incorrectly interpreted as signal of interest if not carefully visualized and classified. Thus, some components corresponding to valid RSNs, may not be recognized, and classified as noise.

Moreover, the registration phase of preprocessed controls' data may have been affected by the lower quality of functional images in controls than in patients. This issue may be the cause of activations of some voxels out of the brain template and/or interested area (indeed, it was more evident in results related to controls than in those related to patients). Nevertheless, derived errors can be considered neglectable. Future studies will consider an optimization of the registration procedure to manage low-resolution functional images.

The small number of controls (4) of the present analysis constitutes a limit in the identification of the different areas of activation. Considering a greater number of controls in the study would allow to recognize a greater number of components corresponding to Smith's RSNs.

Another limitation of the study is the small number of patients, which however is justified by the fact that the patients undergone callosotomy are rather few; this type of operation, being a solution carried out in the past to treat drug-resistant epilepsy, is at present performed very seldom.

ACKNOWLEDGEMENT

The Authors are especially grateful to Prof. Giorgio Innocenti, recently deceased, for initial stimulating suggestions, to the patients for participating in the study, to Gabriella Venanzi for scheduling the patients' exams, and to the radiology technicians Luigi Imperiale, Lucio Montesi and Alessio Canari for their invaluable help in collecting data during and soon after the volunteers' fMRI sessions.

***Abstract*—This paper presents a preliminary study addressing the application of convolutional neural networks (CNN) for diagnosing of osteoporosis using a non-invasive ultrasound technology that can be used to predict bone fragility and fracture risk. Our method uses only raw RGB images, obtained from ultrasonic scans of 5,170 subjects on the femoral site as input to the CNN, and outputs a binary class in terms of healthy or osteoporotic. It is shown that semi-supervised learning performance reach 81% in terms of sensitivity and 76% of global accuracy, thus improving classification capacity with little effort in data annotation. These preliminary results highlight promising results that can be improved in future developments and by increasing the size of the dataset.**

***Keywords*—Osteoporosis, CNN, Semi-supervised learning**

I. INTRODUCTION

Recent research demonstrated that learning from data provides additional means to infer a diagnosis by automatically building accurate models of the specific phenomena described in the data. The statistical inference of a model strongly depends on two main factors: 1) the learning algorithm, and 2) the data used to build the model. While learning algorithms are well established in research, data collection, annotation and processing are still relevant for the resulting model. Clearly, the more the data, the better the result, but having big, well-annotated, dataset is not always achievable, particularly in the medical field in which data annotation is an extremely resource consuming task.

The idea of semi-supervised learning is to leverage knowledge capability using unlabelled data. Initially, the algorithm uses traditional supervision to update the model weights; then, it minimizes the difference in predictions between other similar unlabelled training examples. In our case, the pseudo-labels are data not annotated with *Dual Energy X-ray Absorptiometry* (DEXA) T-score (that is the gold standard for labels in osteoporosis), but with a fictitious label generated through the neural network.

The model used in this research is a convolutional neural network (CNN) [1] trained on RGB raw radiofrequency (RF) data to classify patients into two classes: healthy and osteoporotic. According to the clinical standard for femoral neck (extended also to entire femur and lumbar spine), a patient is considered as "osteoporotic" when the T-score is below the threshold of -2.5, as "osteopenic" when the T-score is between -2.5 and -1.0, and as "healthy" when the T-score is higher than -1.0. For simplicity, healthy and osteopenic are joint in the same class and labelled as "healthy".

The main purpose of this work is to introduce an innovative approach to osteoporosis diagnosis using a Deep Learning method applied to echographic scans, using pseudo-labels to enhance the performance of a statistical model, taking advantage of a semi-supervised approach.

II. RELATED WORK

From its development, quantitative ultrasound has been considering a potential technique for osteoporosis screening [2], [3] offering several advantages such as absence of ionizing radiation and portability when compared with DEXA scans [4], [5]. Traditional bone densitometry uses DEXA as the reference test for diagnosing osteoporosis, which is based on the well-known X-ray analysis. The exposition of subjects to X-rays over time constitutes a risk factor for humans as they produce ionizing radiations [6]. In contrast, the innovative *Radiofrequency Echographic Multi-Spectrometry* (REMS) is a non-invasive technology that uses ultrasonic imaging instead of X-ray to identify any changes in the human bone structure [7], [8].

The ultrasonic signals are widely used as a safe diagnosis tool; thus, the idea of this work is to define a learning system that, after being trained according to semi-supervised approach, is able to classify subjects characterized by a different degree of osteoporosis resembling DEXA [9], looking for obtaining the same performance in terms of sensibility, specificity and accuracy.

Several studies suggest that features in time and frequency domains are important to build a machine learning classifier to determine the class of a subject [9]. The first step in this procedure is the feature extraction from the RF signal. Feature extraction constitutes an extensive engineering work, and the choice of which features are relevant is an important problem to solve [10]. To overcome this limitation, deep learning methods based on CNN are built on the idea of automatic feature

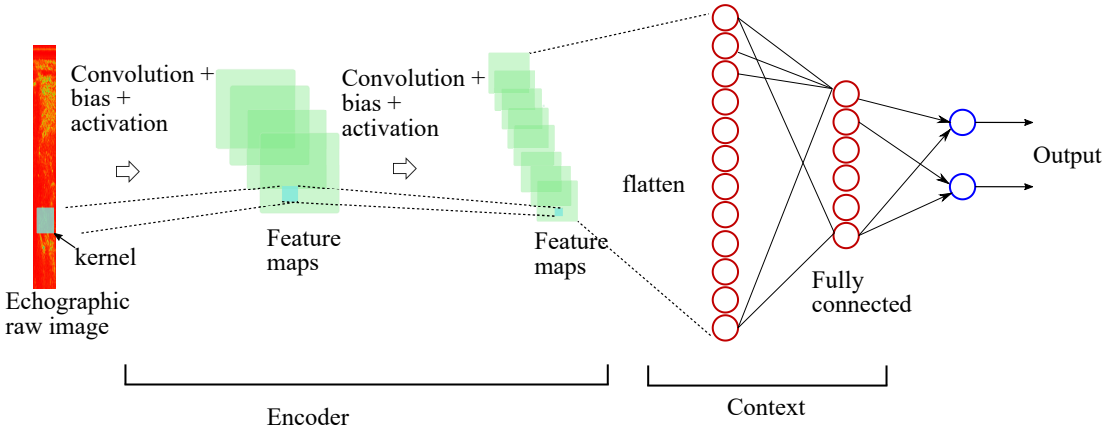

Fig. 1: Architecture of proposed CNN. The input is the raw RGB echographic image, the CNN is a multilayer convolutional network and each layer contains several convolutional kernels, bias and activation function. The flattened operator connects the convolutional network to the fully connected layer to classify the image. The output contains two neurons representing each class: healthy and osteoporotic.

identification [11]. According to the most recent literature, CNNs are considered an effective tool for pattern recognition, and widely used in many different clinical fields including ultrasound signals [12]. Several studies indicate that the use of CNNs with ultrasound signal as input data is a promising technique for the osteoporosis diagnosis, offering relevant scores about sensitivity, specificity and accuracy [13], although the size of the dataset constitutes the most relevant criticality to train the network and improve performance.

III. Materials and Methods

A. CNN architecture

The CNN structure used in this work is represented in Fig. 1, and it resembles the well-known AlexNet-type architecture [1] that was implemented using PyTorch and adapted to our use case. Each layer of the network contains several convolutional kernels (ranging between 2 and 128), bias and activation function. The activation function is the standard Rectified Linear Unit (ReLU). The final layers are built using a series of fully connected neurons, the output contains three neurons representing each class: healthy or osteoporotic. An additional softmax function to the output is used to represent the values in terms of the probability of each class.

The input is an ultrasonic frame containing raw radio frequency (RF) data. Such RF data, encoded as an RGB image, and used as input to the neural network, are acquired on the femoral site, the target used as annotation corresponds to the DEXA T-Score on the femoral neck. The RGB encoding reveals to be an effective and efficient way to integrate existing CNN implementations with our own dataset. This implies a massive amount of work of data gathering and analysis as each subject was scanned using both DEXA and REMS technology. Each ultrasonic acquisition on femoral site collects 50 frames, which are individually analyzed. The data is divided into subgroups: Training set, data used to train the network; Validation set, data used to validate the network; and Test set, data used to measure the abstraction capacity of the network.

B. Dataset construction

REMS scans of proximal femur were performed employing a dedicated echographic device (EchoStation, Echolight Spa, Lecce, Italy), equipped with a convex transducer operating at the nominal frequency of 3.5 MHz and used by clinical operator as recommended by the manufacturer [14]. The total of subjects is 5,170: of which 3,170 are paired with a DEXA measurement, the remaining 2,000 scans were not annotated with DEXA due to many technical reasons. The idea of using pseudo-labels was introduced in order to make use of these 2,000 subjects. Each subject is composed several images as one ultrasonic scan records up to 50 frames.

Information about the dataset is reported in Table I: the CNN used in this work was trained using roughly 2,300 annotated subjects, of which 450 are used for validation. Please note that the validation dataset is taken from the train set which is randomly split into five groups to carry out cross-validation. Due to the randomization in the selection of subjects in each group, the size of each set has roughly 1% variation along the cross-validation procedure. Furthermore, it is worth mentioning that all frames of each scan fall into the same group, either train, validation or test.

Furthermore, 870 patients are also randomly selected at the beginning of the operation and left aside. This group is used for testing only, thus not involved in the cross-validation procedure. The test corresponds roughly to 28% of all DEXA-annotated available patients. Lastly, additional 2,000 patients are annotated via pseudo-labels using the best performing model, and used to run an additional training cycle. It is worth mentioning that the learning flow relies only on the ultrasonic scan: in fact, no additional information about the subject (i.e., anthropometric data) is used in the learning algorithm, thus providing an agnostic approach.

All the patients used in this study are Caucasian women living in European countries, and signed an informed consent, though personal information are anonymized.

TABLE I: Number of subjects per dataset split. The dataset is divided in train, validation and test subsets, which constitute respectively the 72%, the 20% and the 28% of entire dataset. The data are shifted between data with T-score DEXA (annotated) and data with pseudo-labels. Please note that the validation set is a subset of the training set

Dataset split	# Subjects	% Subjects
Train	∼2300	∼72%
Validation	∼450	∼20%
Test	870	∼28%
TOT – DEXA annotated	3170	-
Pseudo-labels	2000	-

TABLE II: Number of subjects per each class (healthy and osteoporotic) and respective percentage. The classes are strongly unbalanced: the amount of osteopenic and healthy subjects is the majority of the dataset, while osteoporotic subjects are only about the 15% of dataset.

FSL	# Healthy	# Osteoporotic	# TOT
# Subjects	2700	470	3170
Percentage	∼85%	∼15%	-
# Test set	670	100	870
Percentage	∼89%	∼11%	-

C. Loss function

According to the trend in the general population, the classes are strongly unbalanced as only about 15% of the subjects in the dataset present a T-score lower than -2.5, and thus classified as osteoporotic. This underlines the difficulty in construction of an optimal dataset, due to a lack of availability of subjects with confirmed osteoporosis. What has been described so far is an additional complication for the problem as it is more important for the network to learn how to recognize the less-represented class in the data, that is "osteoporotic". This effect is also considered during the design of the loss function, weighed cross entropy for our case, through the definition of specific weights on the errors for each class.

The weights have been set to ensure class balancing, and optimize the knowledge abstraction capacity. The classical supervised learning technique uses a cycle of training and validation on well-annotated data, minimizing the loss function along the training.

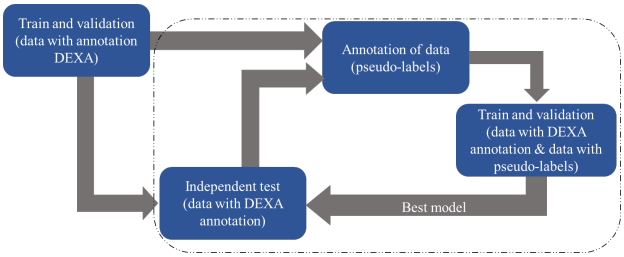

Fig. 2: Semi-supervised learning workflow. The procedure starts with supervised learning training cycle on subjects with DEXA annotations; then, synthetic annotations on unlabelled data are generated, using the minimum loss model. The training is repeated on all subjects (data with DEXA annotations and pseudo-labels). The performance of best model is evaluated on independent test.

D. Workflow

The entire workflow is shown in Fig. 2, and it implements the steps explained as follow:

- Step 1: Supervised learning on 2,300 data annotated with DEXA T-score;
- Step 2: Generate pseudo-labels (T-score diagnostic output) on 2,000 non-annotated data;
- Step 3: Re-training the neural network using all data (roughly 4300 subjects);
- Step 4: Evaluation of diagnostic performance on independent test data with DEXA annotation;

E. CNN setting

Training — An epoch of the training phase provides the random selection of all the subjects divided into subgroups: each frame of the single subject, also randomly selected, crosses the CNN correlated with its annotation as a function of the DEXA T-score.

Validation — During the validation phase, subjects are sequentially passed through the CNN (no randomization is applied), selecting only the first valid frame for each subject. The validation phase is designed in such a way to evaluate the effectiveness of the training while compromising between overfitting and underfitting, and to reduce the computational burden of analyzing all the frames for each patient. The validation is performed for each training session on one of the batches in the list, which is excluded from the training phase.

Test — The test phase can be carried out in two distinct ways: Frame test: only a single frame (the first in the list for each subject) is used for diagnosis inference. Patient test: all the frames of a single subject are analyzed, and the subject's diagnosis is obtained as the arithmetic average of the diagnosis on each single frame.

Model average — This probably represents the optimal method for combining learned models, exactly which have reached the best accuracy and the lowest value of loss function. The use of model averaging can improve the robustness of the system, stabilizing the imbalance of the classes that could occur in some models [15].

IV. Results and Discussion

The results were analyzed taking into account the models that obtained the best performance in terms of:

- Best global accuracy;
- Minimum loss value.

After each training session, both frame test and patient test were conducted, using the models that have reached the best accuracy, and the minimum value of the loss function.

A. Best accuracy Vs. Best loss

Comparing the results obtained using these different convergence criteria, one can see that: 1) the best accuracy case provides improved results on the class of interest, and the less represented in the dataset, due to data imbalance (performance on the osteoporotic class is of about 54%); 2)

TABLE III: Performance comparison of best accuracy Vs. best loss in terms of sensibility, specificity and global accuracy. The value are calculated using the average estimation over five models trained in a cross-validation setting.

	Sens	*Spec*	*Acc*
Best Acc	75%	54%	73%
Best Loss	81%	42%	76%

TABLE IV: Performance comparison between FSL and SSL in terms of sensibility, specificity and global accuracy.

	Sens	*Spec*	*Acc*
FSL	71%	66%	69%
SSL	73%	67%	71%
Gain (SSL-FSL)	2%	1%	2%

the best loss criterion provides higher global accuracy, that is 76% against 73% calculated as the weighed average for each class. However, the global accuracy value is biased by the high number of subjects in the osteopenic class, thus resulting in a low accuracy in the class of interest.

On one hand, the best accuracy model provides better performance on the osteoporotic class of about 54%, which represents the class of interest, and the less represented in the dataset due to data imbalance. On the other hand, the best loss model provides higher global accuracy, that is 76% against 73% calculated as the weighed average for each class. It is important to emphasize that the misclassification healthy to osteoporotic and vice-versa are very limited (6-7% for the best accuracy model and 9-6% for the best loss model). We conclude that the best accuracy critierion better fits the dataset used for the aim of this study.

B. FSL Vs. SSL

The results of the test patient for the fully supervised learning (FSL) case and semi-supervised learning (SSL) are reported in Table IV in terms of sensibility, specificity and global accuracy on the average estimation between five distinct models trained in a cross-validation setting thus using different data. Particularly in Table IV one can see that the SSL case consistently overperforms the FSL by a few percentage points. Clearly, this effect can be counted as an increase in the knowledge abstraction capacity gained using additional data points. The gain is consistent, 2% on sensibility, 1% on specificity and 2% on global accuracy. From this result it is possible to conclude that it is possible to leverage classification accuracy exploiting big quantities of unlabelled data.

V. Conclusion

In this study a CNN was trained as a classifier to infer the osteoporosis diagnosis for patients on a strongly unbalanced dataset. To enhance the classification performance, and make use of big unlabelled data, a semi-supervised learning technique was used, providing to algorithm annotated data and also pseudo-labels. It is shown that semi-supervised learning consistently increases global classification performance.

The major limitation and challenge to be addressed to further improve this method is data annotation, that is a labour-intensive process, but strongly required as CNN-based models learn from data and, though semi-supervised learning helps, most of the work is done in the fully-supervised setting, thus using DEXA annotated subjects. CNN systems are promising as they can provide high classification performance that could be reached through an increase of the dataset size. Further studies, and a bigger dataset, are required to support clinical application.

***Abstract*—In this work, we investigate the feasibility of classifying physiological states including conditions of postural and mental stress using heart rate variability (HRV) and pulse rate variability (PRV) time-, frequency- and information-domain indices. The performance of four different machine learning algorithms, i.e. Linear Discriminant Analysis (LDA), Support Vector Machines, Neural Networks (NN) and k-Nearest Neighbors, were compared, with and without prior applying the minimum Redundancy Maximum Relevance (mRMR) algorithm for feature selection. Analyses were conducted on 76 young healthy subjects under three different conditions (supine rest, orthostatic and mental stress). Results evidence higher accuracy for HRV indices if compared to PRV and better classification performance of orthostatic stress. The highest accuracy has been achieved by the NN algorithm on HRV time series, with a value of 90.9% after feature selection, while LDA is the best algorithm for PRV features (81.8%).**

***Keywords*—Heart Rate Variability (HRV), stress classification, feature selection, Machine Learning (ML).**

I. Introduction

In recent years, the application of machine learning (ML) techniques to medical data analysis has significantly increased in the research field and healthcare industry. ML has been especially exploited to help to classify various autonomic nervous system states related to different types of stress [1], their excess being considered one of the most important pathogenic factors of the modern life [2].

Usually, noninvasive stress assessment is carried out by studying Heart Rate Variability (HRV), i.e. the beat-to-beat variation of heart rate (HR), and its indices represent the most reliable markers of mental and physical stress [3]. HRV reflects the complexity of the cardiovascular regulation and, given the inhibition of parasympathetic accompanied by the activation of the sympathetic branch of the autonomous nervous system during stress conditions, can reflect the body's ability to respond to various (e.g. environmental and psychological) stimuli [3]. Short-term HRV is usually assessed by measuring the time interval between consecutive heartbeats (i.e. R-R intervals) from 5-minute recordings of electrocardiographic (ECG) signals (i.e. short-term HRV) and computing time-, frequency- and information-domain measures [3], [4]. Recently, there has been an increased interest in studying whether and to what extent HRV can also be studied from photoplethysmographic (PPG) or blood pressure recordings, providing the so-called Pulse Rate Variability (PRV). PPG is an optical technique able to detect changes in microvascular blood volume in tissues and is widely used in wearable devices, being simple, low-cost, safe and minimally invasive [5]. Even if the two techniques (PPG and ECG) are often considered interchangeable to measure HRV, several reasons suggest that the beat-to-beat variability recorded with the PPG is somewhat different from HRV [5], [4], [6]. PPG and blood pressure recordings can be affected by physiological factors related to the transmission of the pulse wave through the vascular system and measurement errors due to motion-induced signal corruption, lowering the peak detection accuracy and thus reducing the agreement between PRV and HRV.

Applying machine learning techniques to HRV and PRV features to classify the stress level thus represents nowadays an important challenge for researchers. In particular, various studies have focused on classifying physiological states using HRV [7], [8] or PRV [1] time- or frequency-domain indices. However, to the best of our knowledge, no works have carried out stress classification applying ML techniques to both HRV and PRV indices on the same data, using entropy measures and a feature selection phase as well.

The goal of this work was thus to compare the performances of four classic ML algorithms for classifying different physiological states in healthy young subjects. This study was aimed as well to investigate the reliability of using PPG in place of ECG signals and to evaluate the most suitable PRV features. Furthermore, a feature selection phase has been applied before classification to check whether this step improves the classification accuracy.

II. Materials and methods

A. Subjects and experimental protocol

The data used for this study belong to a historical dataset previously used to assess cardiovascular variability [4]. ECG and blood pressure signals were collected from 76 young, healthy, and normotensive subjects with normal body mass index (32 males; age: 18 ± 2.7 years; BMI = 21.3 ± 2.3 kg/m^2). All the procedures were approved by the Ethical Committee of the Jessenius Faculty of Medicine, Comenius University, Martin, Slovakia, and the participants signed a written informed

consent. The signals were acquired simultaneously (sampling rate: 1 kHz) using horizontal bipolar thoracic leads for ECG and the volume-clamp method for blood pressure. For this study, three different conditions of the experimental protocol fully described in [4] have been taken into account: (a) REST: subjects resting in the supine position on a motorized bed for a period of 15 minutes (baseline); (b) HUT: 8-minute-lasting head-up tilt state induced by tilting the bed to a 45° upright position to produce orthostatic stress; (c) MA: subjects lying in the supine position and undergoing a mental arithmetic test (consisting in performing of a 3-digit number and indicating whether the number obtained was even or odd) for 6 minutes to induce cognitive load (this phase was preceded by another resting state for a full recovery of parameters [4]).

B. Preprocessing and features extraction

Starting from the acquired signals, HRV and PRV indices were computed from time series of 300 consecutive heartbeats (~5 min) respectively extracted from ECG and PPG signals, i.e. R-R intervals (RRI) and pulse-pulse intervals (PPI). In a previous study [4], 12 HRV and PRV features belonging to three different domains were calculated and demonstrated to be useful for discriminating among different stress conditions. In the time domain, the mean (MEAN), the root mean square of the successive differences (RMSSD), and the standard deviation of the normal-to-normal intervals (SDNN) of RRI and PPI series were calculated. The frequency domain indices were the absolute power in the Low Frequency (LF, 0.04-0.15 Hz) and High Frequency (HF, 0.15-0.4 Hz) bands, the normalized powers (respectively LFn and HFn), the ratio traditionally used as the sympathovagal balance index (SVB, i.e. LF/HF ratio), and finally the frequency of the peak in HF band (f_{HF}, i.e. the respiratory peak). In the information domain, three entropy measures were computed: the entropy (H), the conditional entropy (CE), and the self-entropy (SE) of RRI and PPI time series. We refer the reader to [4] for further details on the computation of the above-mentioned features.

C. Classification algorithms

Four classic ML classifiers were selected to evaluate and compare their performance in discriminating between rest and orthostatic/mental stress, determining which one is most effective for the given task. The classifiers, hereinafter briefly introduced, were chosen given their widespread use for a variety of classification tasks, including those involving ECG signals [9]. By choosing common classifiers, it is easier to compare the obtained results with other findings in the literature, focusing on the performances of the proposed approach rather than on the characteristics of the classifier itself.

1) Linear Discriminant Analysis. The Linear Discriminant Analysis (LDA) is a supervised learning method that relies on classifying data into K classes based on K discrimination functions. Being a linear method, it assumes that the classes can be separated by a linear boundary. LDA has several advantages, such as its simplicity and computational efficiency, robustness to overfitting and good generalization performance, as well as the ability to provide a clear interpretation of the results. Nonetheless, it requires features normally distributed within the classes [9].

2) Support Vector Machines. The Support Vector Machines (SVMs) are a type of supervised learning algorithm that exploit either a linear or quadratic decision rule and work by finding the hyperplane in a high-dimensional feature space that maximally separates the classes [9]. SVMs have several advantages, including their ability to handle high-dimensional data. However, they are sensitive to the choice of kernel function and the values of the hyperparameters and may be computationally expensive to train on large datasets.

3) k-Nearest Neighbors. The *k*-Nearest Neighbors (kNN) is considered the most straightforward classification algorithm, classifying unknown data into a class closer to the data and having higher majority [9]. When using kNN, the user specifies the value of *k*, i.e. the number of nearest neighbours that the model uses to make a prediction. kNN has several advantages, i.e. simplicity, flexibility, and no *a priori* training, but it can be computationally expensive for large datasets and sensitive to the chosen distance metric and *k* value.

4) Neural Networks. A Neural Network (NN) is a machine-learning model consisting of multiple layers of interconnected nodes resembling the human “neurons” [9]. A NN is trained using a dataset and an optimization algorithm, which updates the weights and biases of the neuron interconnections to minimize the error between the predicted output and the true output. NNs are particularly useful for tasks involving complex patterns and connections, but as a drawback they could be computationally expensive to train, requiring a large amount of data to achieve good performance.

The analyses carried out in this work were aimed to compare the performances of the four above-mentioned algorithms to classify data into the three classes corresponding to different physiological states, i.e. REST (rest), HUT (orthostatic stress) and MA (mental stress), investigating as well whether the PRV features calculated from PPI time series can achieve results comparable to HRV indices computed from RRI series. The MATLAB Classification Learner app was used to train the various models. For each classifier and each set of features, the "Optimized version" has been chosen, allowing automatic parameter tuning. To carry out the training, validation, and testing of each classifier, a *k*-fold cross-validation (*k*=5) was used. This process was repeated *k* times, so each fold serves as the test set once. The model performance has then averaged across all *k* iterations. Each classifier was trained by giving as an input the HRV or PRV features described in section II.B, setting the same model parameters to allow for a comparison of the results. The performance of the classifiers was evaluated mainly through accuracy, but also calculating metrics by class, i.e. recall, specificity and precision [10].

D. Feature selection

Usually, using a feature selection approach for selecting a subset of features rather than all the available ones allows for improving classification accuracy and limiting the problem of

overfitting [11]. In this work, we have first used all the 12 extracted features, also considering them separately according to their domain; afterwards, the Minimum Redundancy Maximum Relevance (mRMR) [12] feature selection algorithm was used to rank the 12 features. The mRMR is a widely employed feature selection method in machine learning, being simple to implement and particularly useful when the goal is to identify the most important features for predicting the target variable. The mRMR algorithm uses mutual information (MI) to select the subset of features that exhibit the maximum correlation (denoted with D) with the target, alongside the minimum redundancy (denoted with R) between them. MI can be computed using the following equation [12]:

$$MI(X;Y) = \sum_{x\in X}\sum_{y\in Y} p(x,y)\log\frac{p(x,y)}{p(x)p(y)} \tag{1}$$

where X and Y are variables with joint probability density function $p(x,y)$ and marginal probability density functions $p(x)$ and $p(y)$, respectively. The mRMR features set is obtained by simultaneously optimizing the parameters D and R in terms of the Mutual Information Quotient (MIQ) criterion[12]:

$$\text{MIQ} = \max\left(\frac{D}{R}\right) = \max_{S\in\Omega}\left\{\frac{\sum_i MI\,(c;X_i)}{\left[\frac{1}{|S|}\sum_{i,j\in S} MI\,(X_i;X_j)\right]}\right\} \tag{2}$$

being X_i and X_j the features, Ω the feature set and c the classes (REST, HUT, MA) vector. The MATLAB implementation of the original mRMR algorithm by Peng was used, considering the HRV/PRV features as input structure which has been discretized with a 3-states quantization [12].

III. Results and Discussion

In this section we first investigate the performance of the four ML algorithms in classifying the different physiological states, using either RRI or PPI features, all together or grouped according to the domain of calculation of the feature (time, frequency or information). Subsequently, a feature selection phase through mRMR was performed, in order to assess how the classification accuracy varies by removing one by one feature according to the order established by the feature selection algorithm, once again comparing the use of either RRI or PPI indices.

1) Classification results without feature selection: Figure 1 shows the classification accuracy of the four ML algorithms (LDA, SVM, kNN, NN) in classifying the physiological state (rest, orthostatic or mental stress) when using all the 12 HRV or PRV features, or using only a group of features according to their domain (time, frequency and information). The accuracy values computed using PRV features extracted from PPG signals are overall slightly lower than those achieved obtained with HRV indices. This behaviour suggests that the difference between RRI and PPI affects the capability of discriminating among classes, even if it does not happen in all cases. Results also evidence that using only information-domain indices produces a lower accuracy for both RRI and PPI (almost always below 60%), and not allowing correct classification of

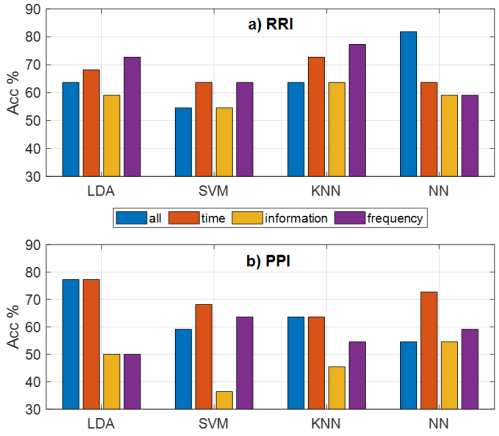

Fig. 1: Classification accuracy of the four ML algorithms for (a) RRI and (b) PPI indices, considering the features altogether (blue), or grouped according to their domain (orange: time; yellow: information; purple: frequency).

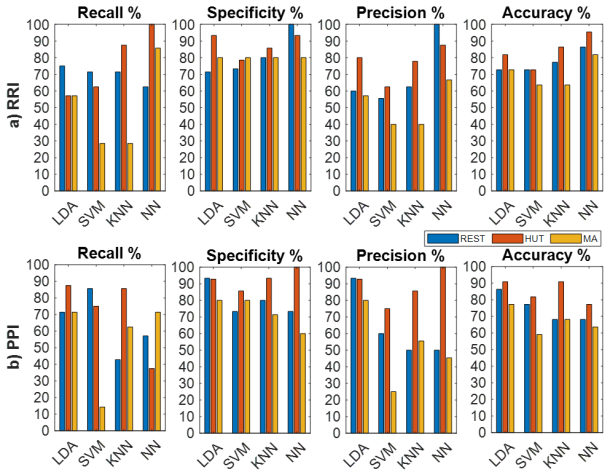

Fig. 2: Recall, specificity, precision and accuracy metrics by class (blue: REST; orange: HUT; yellow: MA) computed on (a) RRI and (b) PPI features

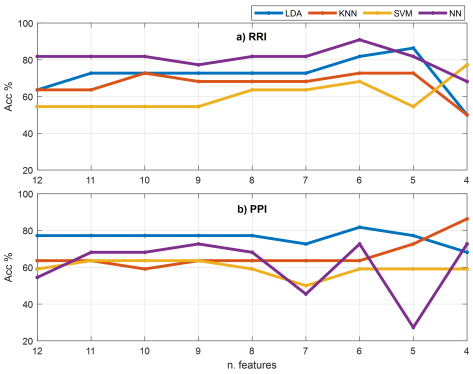
the three physiological stages. On the other hand, time- and frequency domain indices allow to achieve higher values of accuracy, the former performing always better in the case of PPI, the latter overall better in the case of RRI features (apart from NN). Considering all the HRV features together and comparing the ML classifiers, NN achieves the best results, performing however worse when considering only certain groups of features. This behaviour is expected, given that NN needs a larger amount of data and this need is not met when the features are considered separately by domains. The accuracy obtained by LDA classifier on PPI features was similar to that achieved by NN using RRI indices, thus supporting the use of PPG for identifying stress. Figure 2 depicts the results in terms of metrics by class, including recall, specificity, precision, and accuracy, to understand which stress state is best classified by each ML algorithm considering all the 12 features together. Overall, recall values are lower for PPI than RRI, with the maximum value obtained in the case of HUT class (100%). With regard to PPI indices, the highest recall value (87.5%) is obtained with LDA classifier again for HUT class. Analysing the other metrics, we highlight that higher values of specificity,



precision and accuracy are achieved with the NN classifier for RRI and with LDA for PPI. Nonetheless, the NN classifier is able to reach the maximum specificity and precision (100%) also for PPI with regard to HUT class. Summarising, the HUT class is classified by all the ML algorithms and for both RRI and PPI indices better than MA that in turn achieves lower values on average. This may be ascribed to the fact that orthostatic stress produces a stronger sympathetic activation and/or parasympathetic inhibition if compared to the mental one, in agreement with previous findings in the literature [4].

2) Classification results with mRMR feature selection: Figure 3 depicts the results in terms of accuracy obtained through the 4 ML classifiers performing first a feature selection phase using the mRMR algorithm. The table (Fig. 3c) lists the feature importance ranking according to mRMR (in descending order) for RRI and PPI indices, i.e. the order of minimally redundant and maximally relevant features. Fig.3(a) and (b) show the accuracy of each classifier, respectively for RRI and PPI indices, as the input features, starting from all 12, are gradually removed one by one, as in the table in inverse order (less important features are removed first). Also in this case, NN is the classifier with the best results for RRI (with a maximum accuracy of 90.9%), while LDA is the best for PPI (81.8%). For most classifiers and for both RRI and PPI indices, there is a slight increase in accuracy when reducing the features, with a peak around 6 or 5 features (apart from NN for PPI which presents an irregular trend). Overall, the maximum accuracy achieved with feature selection is higher than without (cf Fig. 1), with a more marked increase for RRI than PPI. For instance, for NN applied to RRI features the maximum accuracy increases from 81.8% to 90.9%, while for LDA applied to PPI the increase is from 77.2% to 81.8%. In [8] authors applied 3 out of 4 classifiers used in this work (kNN, LDA, SVM) and mRMR feature selection algorithm on RRI data in various conditions of stress corresponding to a range of everyday life conditions, obtaining accuracy values of 66.7% (kNN), 65.6% (LDA) and 73.6% (SVM) without pairwise transformation method. Even if the database and the stress conditions are not the same and the order of features selected by mRMR is different, our accuracy values are in line and sometimes higher.

IV. Conclusion

This work presented a comparison of the performances of various ML algorithms for classifying physiological states using either HRV or PRV features. Our results evidence that HRV features allow for achieving higher accuracy than PRV and that it is easier to discriminate postural than mental stress from rest. Moreover, the NN classifier outperforms the other ones, even if LDA works better on PPI data. Finally, a feature selection phase through the mRMR algorithm allows to increase accuracy.

Future activities may consider using different feature selection algorithms, other classifiers (e.g. Random Forest [8]), data augmentation techniques and shorter HRV/PRV recordings (i.e. ultra-short term HRV [3]).

***Abstract*—Deep learning (DL) language models are increasingly used to map the neural correlates of language processing.**

A DL language model for Italian was used to estimate the Bayes surprise that indexes the mismatch between our predictions about future inputs and the input itself. These values were applied to functional MRI data recorded during a narrative listening experiment.

The Bayes surprise significantly mapped the neural signals in temporal and frontal regions bilaterally. The results are in line with previous studies, strongly support the use of DL models in encoding neural signals and motivate several applications in different scenarios.

***Keywords*—fMRI, Deep Learning, Natural Language Processing, Bayes surprise.**

I. Introduction

Deep learning (DL) models have shown remarkable results when performing human tasks, such as text [1] and image [2] generation. Due to their ability to learn complex tasks from raw data rather than a set of given rules they represent an interesting framework to study the neural mechanisms of complex high-order functions [3].

Among the high-order functions, the ability to generate and comprehend language is one of the most suited to be investigated using DL models. Recent studies showed that large DL language models, such as the Generative Pretrained Transformer version 2 (GPT-2) [4], can provide useful metrics to encode both behavioural and neural signals related to language processing [5]. Due to its architecture based on the so-called "attention mechanism" and the fact that it uses only the information received to generate/predict the next word [4], GPT-2 is considered one of the most biologically plausible DL models and it outperformed other attention-based DL model in encoding neural signal [5]. In particular, it has been successfully used to model the linguistic prediction mechanism that is behind language comprehension [6–8] and a recent study suggested that GPT-2 shares some computational principles with the human brain [6]. For instance, Russo et al. (2022) reported that, for periods of at least 60 s, the GPT-2 and the brain have a similar strategy to evaluate the received words and assign a probability score to the next incoming word [8]. However, the potential of large DL models, in addressing some aspects of the complex neural mechanisms behind language comprehension is far from being fully exploited.

A consistent body of research suggested that human beings grasp the meaning of a narrative by parsing it into discrete small events [9,10] and that at each instant they maintain a working event model representing the current event features [9,11]. This model is actively stored in the working memory as the events unfold over time, and it is used to make reliable guesses about the incoming inputs [12]. When there is a mismatch between the model's predictions and the external stimulus received the model is updated accordingly. However, this update is not free of charge, and the higher the mismatch between the prediction and the received input the higher the amount of neural resources are needed to integrate the new information. Previous studies showed that this mechanism is shared across individuals listening to the same story, however when analysing its temporal dynamic some idiosyncrasies could be observed [13]. Among the possible measures that can index this phenomenon, there is the Bayesian surprise (BS) [14] that is given by the comparison of two probability distributions indicating respectively the *a priori* event model (prior distribution, before the arrival of the external stimulus) and the *a posteriori* event model (posterior distribution, after the arrival of the external stimulus). In a recent preliminary study, the BS has been shown to successfully encode the behaviourally marked event boundaries (e.g., the change of a scene) of a narrative that coincide with the highest shifts in the internal event model and, as a consequence, with the highest integration costs [9]. It is worth noting that the BS does not simply measure errors in the sentence or semantic shift in the text, but it models the gap between our internal model of the story and the received word.

The aim of this work is to add insights into the neural correlates of this model updating mechanism that supports language comprehension and, possibly, provide a novel metric/tool to help in the assessment of linguistic impairments. For this purpose, a previously published naturalistic functional magnetic resonance imaging (fMRI) data set [15], from a group of Italian participants listening to a story in both forward (FW) and backward (BW) conditions, was re-analysed. First, a GPT-2 model was used to estimate the BS associated with each word of the story. Second, the estimated BS values were used to encode the fMRI signal elicited by the group of listeners. In light of previous studies, significant positive activations are expected in brain areas known to track both low-level speech information, such as the superior and the middle temporal regions, and high-level speech information such as the inferior and the middle frontal gyri.

II. Materials and Methods

A. Participants

The experimental data used in this work, have been acquired and processed in previous studies about the neural correlates of linguistic prediction during spoken narrative listening. Full details can be found in the original paper [15].

All the volunteers enrolled in the experiment (6 males, 21 females, mean age 24.5 ± 4.5 years old) were Italian native speakers, right-handed, without known psychiatric or neurological problems, with normal or corrected-to-normal vision, and without hearing, developmental and language-related problems. The study was performed in accordance with the Declaration of Helsinki.

B. Stimuli and experimental procedure

Participants listened to a short story (12 minutes) in both the original and reversed version, while in the MRI scanner. The reversed audio waveform was selected as control condition as, while keeping the auditory characteristics of the non-reversed version, it omits meaning and linguistic components and does not generate the necessity of storing a mental model of the discourse and inferring the next incoming word.

C. Image acquisition and pre-processing

MRI acquisition was performed with a 3T scanner (Magnetom Skyra, Siemens Healthcare, Germany) equipped with a 20-channel parallel head coil. Full details on the sequence parameters can be found in [15]. MRI data were pre-processed using FSL (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki) and the Data Processing Assistant for Resting-State fMRI toolkit (DPARSF 5.0 http://www.rfmri.org) that is implemented in MATLAB (The MathWorks, Inc., Natick, MA www.mathworks.com).

D. Definition of the Bayesian surprise

The notion of BS is defined as the Kullback-Leibler divergence between a prior and a posterior distribution [14] and can be estimated with the following formula:

$$Bayesian\ surprisal = -\sum_{v=1}^{V} p_v * \log(q_v) \quad (1)$$

where p_v and q_v are the probabilities belonging respectively to the prior and posterior distribution.

The BS can be interpreted as an index of how much our prior probability has been updated/changed according to the newly received information. Therefore, the larger its value the more our prior expectations have been violated and there is a need for an update. Compared to other measures tracking the violations of the expectations and successfully used in mapping both neural and behavioural signals, such as the surprisal [16,17], the BS has the advantage of considering the probability distribution in its entirety. For example, the BS can account for how much confident we are about our prior expectations as this is indexed by the width of the distribution, and it can track a complete change in our expectations [9].

E. Estimation of the Bayesian surprise

In this work, the BS was estimated using a version of the GPT-2 model for the Italian language, called GePpeTto [18]. GePpeTto includes 12 layers, 117M parameters, and a vocabulary of 30,000 tokens. It has been trained on a corpus of standard and less-standard Italian text for a total of 13 GB of data, and, for our purposes, was used without additional fine-tuning.

The narrative text, used as stimulus for the participants, was first tokenized (i.e., the narrative was split into smaller units) and then these tokens were used to estimate the BS. The narrative was sampled with a sliding window approach with a window size of 1024 tokens which is the maximum number of input tokens allowed. The tokens contained in the window were provided in input to the GPT-2 model and, for each step, the probabilities assigned to each word of the GPT-2's vocabulary was extracted. Therefore, the BS value was estimated as the difference between the distribution probability at word-point t-1 (i.e., prior distribution) and the distribution at word-point t (i.e., posterior distribution). A recent study showed that the BS estimated using this workflow is linked to prediction error, to the amount of information brought by the new word and to the shift from one part (e.g., a scene) to another of a narrative [9].

All these data were extracted using custom scripts written in python and mainly using PyTorch and NumPy package.

A graphical description of the experimental workflow and of the BS estimation is displayed in Fig.1.

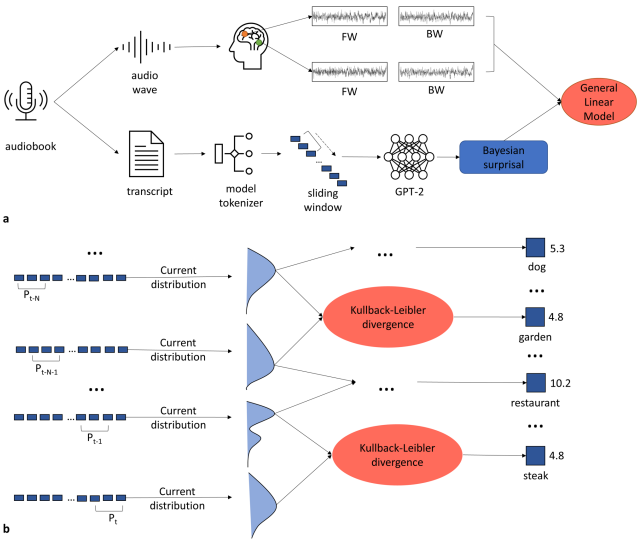

Fig. 1: Summary of the experimental framework (a) and of the workflow used to estimate the Bayesian surprise from the GPT-2 model (b).
Participants listened to a narrative twice, once in the forward (FW) and once in the backward (BW) condition while their brain signal was continuously measured using fMRI. Using a highly parcellated atlas, time series of fMRI signal were extracted for both narrative conditions for each region of the atlas itself. The transcript of the narrative was provided in input to the GPT-2 to extract the Bayesian surprise (a).
The transcript of the narrative was tokenized and sampled in a sliding window approach to be fed to the GPT-2 model. At each step of the sampling process, the distribution of probabilities over the vocabulary was first stored and then compared to the one extracted at the next step by using the Kullback-Leibler divergence. The resulting value was considered as the Bayesian surprise at that token-point and the process was repeated for each token in the narrative (b).

F. Functional MRI and statistical analysis

The estimated BS values were used as predictor of interest in a general linear model (GLM) where the dependent variable was the average neural signal of the 1000 region-of-interest (ROI) of the 7-networks Schaefer's parcellation [19] for both

speech conditions (i.e., FW and BW). For the GLM analyses only the time points characterized by the presence of the audio stimulus were retained, thus resulting in a set of functional data of 709 volumes, and the contrast between the FW and the BW conditions was evaluated. Besides the predictor of interest, other relevant linguistic features such as word duration (WD), lexical frequency (LF), and word sound (WS) were considered.

Before entering the mixed-effects GLM analysis, all the predictors were processed to account for the haemodynamic delay and the temporal resolution of the acquisition. In detail, the vector of surprisal values, LF, WD, and WS were convolved with a standard haemodynamic response function (HRF). The HRF represents the conventional approach for modelling the neural dynamics in the BOLD signals induced by a stimulus and it is derived from a Gamma distribution. As part of the convolution procedure, the resulting values are also downsampled to the fMRI temporal resolution (1 Hz), yielding a predictor matrix of size 709x4. A preliminary evaluation of the variance inflation factor (VIF) on the design matrix was performed to check possible collinearity and, due to their VIF being higher than 5, both WD and LF predictors were dropped from the final design matrix.

For each ROI the average fMRI signal was extracted for both speech conditions (i.e., FW and BW), concatenated along the time axis, and used as the dependent variable in a mixed-effects GLM analysis performed in MATLAB. As independent variables, the model included one categorical predictor encoding the speech direction (i.e., FW and BW), three fixed-effect predictors (i.e., BS, WS, and the interaction between surprisal and speech direction), and participants were considered as random-effect. To assess where the surprisal values significantly explained better the neural signal in the FW condition (i.e., comprehensible speech) compared to the BW condition (i.e., unintelligible speech), for each ROI the statistical value associated with the interaction between the speech direction and the BS was stored. The obtained statistical results were considered significant at $p < 0.05$ corrected with the Bonferroni criterion (considering $n = 1000$ comparisons), then were stored in a volumetric map (where they were assigned to the corresponding atlas' parcellation) that was eventually projected onto an inflated brain surface in the MNI space for visualization purposes using CAT12 (https://neuro-jena.github.io/cat/).

III. Results

The analysis of the head motion resulted in the exclusion of one participant due to excessive motion (translation/rotation higher than 3mm/3 degree) in one of the two fMRI runs. Therefore, the fMRI analysis was performed on a group of 26 participants (20 females).

The head motion was analysed also in terms of mean frame-wise displacement that resulted, for each participant, to be lower than the standard threshold of 0.5 mm.

The application of the BS predictor to encode the neural activity in the fMRI time series, observed in the contrast between the original and reversed version of the narrative (i.e., FW vs. BW) yielded a bilateral pattern encompassing temporal and frontal regions. In total, 102 out of 1000 ROIs were significantly activated ($p < 0.05$ Bonferroni corrected). The 102 significant ROIs were ranked in ascending order according to the elicited statistical value and the top 10 ROIs were reported in Table 1. The strongest effects for the BS were observed in ROIs located in the left superior and middle temporal gyrus (Table 1, Fig. 2). Activations were observed, in both hemispheres, also in frontal regions such as the middle and inferior frontal gyrus whose role in language processing is well established [20]. Finally, significantly positive activations were observed in the left, and to a lesser extent in the right, angular gyrus.

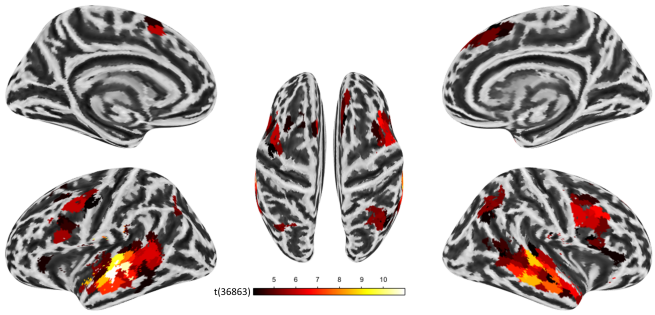

Fig. 2: Regional statistical map of the contrast FW versus BW projected on a surface in the standard MNI space (left and right hemisphere). Color-coded areas indicate the atlas' parcellations that yielded a significantly higher correlation with the BS predictor in the FW speech condition compared to the BW speech condition ($p < 0.05$, Bonferroni corrected). A bilateral regional pattern, encompassing regions mainly in the temporal and frontal areas was observed. The highest statistical values were observed in the areas located in the left superior/middle temporal gyrus.

Area	t(36863)	p-value	Coordnates (RAS space)		
7Networks_LH_Default_Temp_15	10.99	4.63E-28	-58	-14	-4

Table 1: The top 10 ROIs, ranked according to the statistical values elicited in the statistical analysis, are reported in the table. For each region, named

according to the naming convention of [19], the t-statistics, the p-value and the centroid in RAS space are displayed.

IV. Conclusion

Recent studies have demonstrated how DL language models represent powerful tools not only in performing or assisting human tasks but also in providing an independent model to investigate high-order cognitive functions. In this work, we provided further support to the latter idea and contributed novel findings about the neural correlates underpinning language comprehension.

The contribution of this study is two-fold: first our results show that, similarly to other metrics derived from the information theory (e.g., the surprisal [16,17]), the BS is able to capture the neural cost associated with the mismatch between the prediction about the next incoming input and the input received. Second, our findings illustrate that the BS is a reliable metric to encode the continuous update of the internal event model related to the unfolding of a series of events (e.g., events in a narrative) over time and the information carried with them. Therefore, the BS estimated from a DL language model for each word of a narrative can explain the impact of the newly received input and its information on our prior expectations, such as changes in the overall content of the narrative and the replacement of the current event model with a new one [9].

The observed bilateral activations are in line with previous studies supporting that language processing is not strictly confined to the left hemisphere [21]. The highest statistical values reported for the left middle/superior temporal gyrus are consistent with the putative role of these regions in tracking speech information and, in particular, in hosting a prediction mechanism [15,22]. In fact, activations in these areas have been reported in several previous studies that investigated language comprehension with both (simpler) stochastics [15,22] and DL-based language models [6–8,23]. The involvement of higher-order areas in frontal lobes is consistent with previous findings suggesting that these regions process speech information at paragraph level [20].

Our results highlight the versatility of the proposed experimental framework. In fact, the possibility of exposing to the same stimulus both a DL model and a group of human participants, with the purpose of generating predictors from the former and brain activations from the latter, can be applied to other scenarios that include different cognitive functions and biomedical signals [6,7]. Moreover, the possibility to generate informative predictors using parameters derived from DL models could have clinical applications. Indeed, this method could be highly suitable to investigate, and possibly assess, language dysfunctions in pathological coohorts such such as subjects affected by schizophrenia [24] or autism spectrum disorder [25].

***Abstract*—The mechanism of vascular stenosis development in haemodialysis arteriovenous fistula is still mostly unknown. Almost all computational fluid dynamics (CFD) studies are performed at given time after surgery, but evolution of fistula remodelling and failure has not been studied so far. We then performed a longitudinal study on morphological and hemodynamic changes in an arteriovenous fistula that showed progressive stenosis and failure 1.5 years after surgery. The comparison of CFD and morphological changes showed that vascular wall remodelling acted as a protecting response, with progressive expansion of the stenosis in the venous outflow tract that induced regularization of velocity waveforms and decreased the disturbed flow metrics.**

I. INTRODUCTION

NATIVE arteriovenous fistula (AVF) is the preferred vascular access (VA) for haemodialysis (HD) patients, but it is still associated with a high rate of failure due to stenosis development. The main cause of stenosis is the formation of neointimal hyperplasia (NH) in the juxta-anastomotic vein (JAV) [1]–[3].

Already in 1999, Sivanesan [4] observed that vascular stenosis consistently develops in three specific areas of the JAV, suggesting that excessive neointimal growth might be related to local hemodynamic conditions. In recent years, a growing body of evidence has suggested that the damage provoked to the endothelium by AVF surgery and the altered local hemodynamics, resulting from the artificially created vessel shunt [5], stimulate both the initiation and progression of AVF stenosis [6]–[8].

Despite their clinical relevance, the process and the mechanisms of stenosis development and evolution in AVFs are still poorly understood. Over the last few decades, high-fidelity computational fluid dynamics (CFD) simulations have been exploited trying to shed more light on the quantification of the hemodynamic forces acting on the AVF lumen [9], [10].

Despite numerous studies on AVF hemodynamics, CFD longitudinal studies on AVFs are rare in literature. Sigovan et al. [11] and He et al. [12] were the first to demonstrate in their pilot studies that vascular remodelling in AVFs could be investigated using repeated magnetic resonance imaging (MRI) acquisitions. However, they could not distinguish a defined relationship between disturbed hemodynamics and vessel lumen changes. Recently, Colley et al. [13] coupled ultrasounds (US) and CFD to analyse the hemodynamics in 1 patient with successful AVF maturation over 15 weeks, finding that wall shear stress (WSS) immediately after AVF creation may be a useful indicator for proper maturation. Northrup et al. [14] followed 6 patients (3 with assisted and 3 with non-assisted maturation) with MRI at 1 day, 6 weeks and 6 months after surgery. They reported that larger venous velocity, WSS, and vorticity immediately after AVF surgery may be crucial for later lumen enlargement and VA maturation. Also, a recent massive work of the Haemodialysis Fistula Maturation (HFM) Study Group followed 120 patients for 6 months after the intervention [15]. CFD results highlighted that high WSS and low Oscillatory Shear Index (OSI) were associated with greater vein lumen expansion after AVF creation surgery. Despite these investigations, the causes and mechanisms underlying the development and progression of vascular stenosis in AVF remain largely unknown.

Our group has recently developed a non-contrast-enhanced MRI protocol that provides high-resolution black-blood images within few minutes, allowing non-invasive and accurate imaging of patient's AVFs at different timepoints. This MRI protocol, coupled with high-fidelity CFD simulations in a complete MRI-to-CFD pipeline, has shown to be a promising approach to characterize AVF morphologic and hemodynamic evolution over time [16], [17].

Thus, the current study aims at: *i)* to analyse the lumen remodelling trajectory over 1.5 year of a newly created AVF failed due to stenosis formation and *ii)* to investigate the impact of the altered hemodynamics on pathological vessel remodelling and VA failure.

II. METHODS

A. MRI acquisitions

Non-contrast-enhanced MRI acquisitions were performed in a 72-year male referred for primary radio-cephalic AVFs at the Unit of Nephrology and Dialysis of Papa Giovanni XXIII hospital (Bergamo, Italy). The patient had to sign a written informed consent before undergoing the acquisitions. Image sequences were acquired using a 1.5T scanner (GE, Optima 450w GEM) with a flexible 16-channel phased array medium coil and were cardiac gated using peripheral pulse gating. After a first three-plane scout sequence acquisition to correctly localize the anastomosis, 3D fast spin echo T1-weighted imaging was executed with variable flip angles using CUBE sequence, covering an arm region of approximately 5 cm above and 3 cm below the anastomosis. Further details on the MRI protocol are reported in our previous publication [16]. MRI examination was performed at 3 days after AVF creation and then repeated at 40 days, 6

months, 1 year and 1.5 year after surgery. On the same days, a complete Doppler US examination of the patient AVF was performed and the vessel diameters and blood flow volumes in the proximal artery (PA), distal artery (DA) and in the vein were collected.

B. 3D model reconstruction and mesh generation

Starting from MRI acquisitions, the AVFs were digitally segmented using ImageJ. Thus, the 3D AVF surface models were generated exploiting the Vascular Modeling Toolkit (VMTK) [18]. The primitive 3D surface model was smoothed and straight cylindrical extensions of five diameters in length were added at the extremities to achieve full development of flow conditions inside the computational domain. FoamyHexMesh of OpenFOAM suite was used to discretize the internal volume, obtaining meshes of ~ 1,000 k cells for all AVF models, with dominant-hexahedral core cells, low orthogonality and predominant alignment to the vessel surface. Two thin boundary layers were generated in order to catch the sharp velocity gradients close to the vessel wall. The mesh resolution was chosen based on the refinement study recently performed in our previous publication [17].

C. Computational fluid dynamic simulations

CFD simulations were solved using pimpleFoam, a transient OpenFOAM solver for incompressible flows based on the finite volume method, set with second-order spatial and time integration schemes. The time step was adjusted automatically by the solver, setting a maximum Courant–Friedrichs–Lewy (CFL) number equal to 1 and resulting in a mean timestep of 0.1 ms. Patient-specific boundary conditions at the inlets of the PA and DA were imposed using volumetric flow waveforms derived from Doppler US examinations, while for the vein outflow a traction-free condition was set. Three complete cardiac cycles were solved and only the third one was used for post-processing to avoid start-up transients. Blood was modelled as patient-specific, non-Newtonian fluid using the Bird-Carreau rheological model, assuming a blood density of 1.05 g/cm^3, patient's measured haematocrit and a total serum protein value equal to 7 g/dL. The no-slip condition was prescribed at the vessel walls, assumed as rigid.

D. Morphological and hemodynamic analysis

A rigid co-registration of the models at the different timepoints was performed using the iterative closest point registration algorithm of VMTK. Vascular lumen cross-sectional areas (CSAs) along the models' centreline were obtained at 0.1 mm intervals in each model to characterize lumen remodelling. Moreover, the angle between the PA and the vein was quantified using Paraview software. The velocity changes over time were characterized using the blood velocity waveforms extracted along the models' centreline.

The near-wall hemodynamic was categorized using the Oscillatory Shear Index (OSI), that quantifies the degree of deviation of the WSS (τ_ω) from its average direction, as

$$OSI = \frac{1}{2}\left(1 - \frac{\left|\int_0^T \tau_\omega \, dt\right|}{\int_0^T |\tau_\omega| dt}\right) \quad (1)$$

Also, the Spectral Power Index (SPI) of WSS, another flow instability index, was computed as

$$SPI = \frac{\sum_{n=n_c}^{+\infty} |Y[n\omega_0]|^2}{\sum_{n=1}^{+\infty} |Y[n\omega_0]|^2} \quad (2)$$

where $|Y[n\omega_0]|$ is the magnitude of the Fourier-transformed signal, ω_0 the fundamental angular frequency of the periodic signal, and n_c the harmonic corresponding to the cut-off frequency set to 25 Hz [19].

III. RESULTS

Patient-specific AVF geometrical models reconstructed for each follow-up visit and the corresponding mean blood flow rates in the PA and DA are reported in **Figure 1.a**. Qualitative local variations in vessel lumen develop with time; in particular blood vessel's lumen dilated at the anastomosis and along the vein, and stenosis developed at the curvature of the JAV starting from 1 year after surgery. Moreover, the angle between PA and JAV remained unchanged between 3 days and 3 weeks, while it significantly decreased at 6 months and then remained stable until the end of the follow-up period. The vascular lumen changes were accompanied by changes in VA blood flow rate, which showed a constant increase in the first 6 months after surgery and was followed by a rapid decrease until last visit at 1.5 year, when the flow became too low to perform HD treatment.

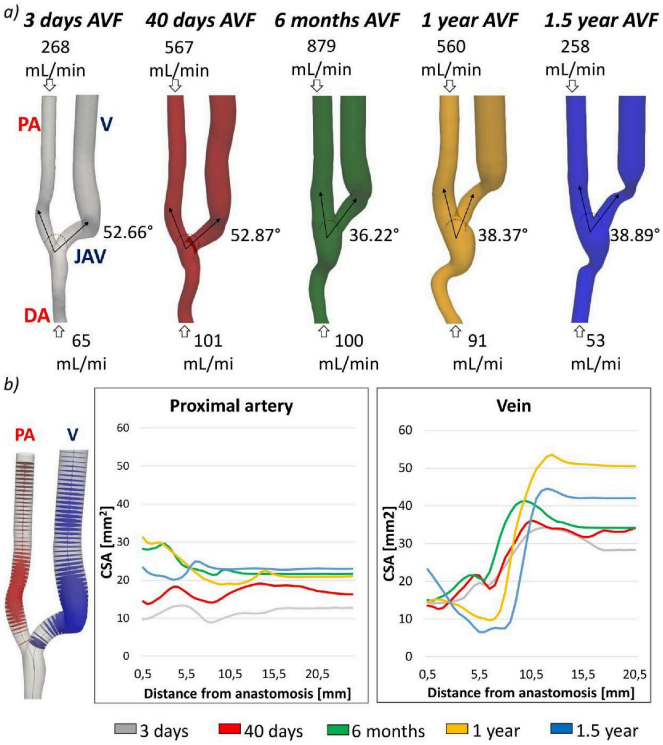

Fig. 1: a) 3D geometrical models and blood flow rates of the AVF at the five different timepoints. Notes: black arrows indicate the main direction of blood flow. b) Morphological changes occurring over time in the proximal artery (PA) and in the vein (V).

A quantitative analysis of the vascular lumen changes of PA and vein is shown in **Figure 1.b**. During VA maturation arterial dilatation was observed up to 6 months, with slight

regional-specific differences. The JAV segment also dilated after surgery and until 6 months, but at 1 year vessel stenosis developed, becoming very significant at 1.5 year.

Velocity–time traces at nine specific points sampled consistently along vessel centreline are shown in **Figure 2**. These points were similarly selected in all AVF models: points 1–3 are located in the PA, point 4 at the anastomosis, points 5–7 in the JAV, and 8 and 9 more distally in the vein.

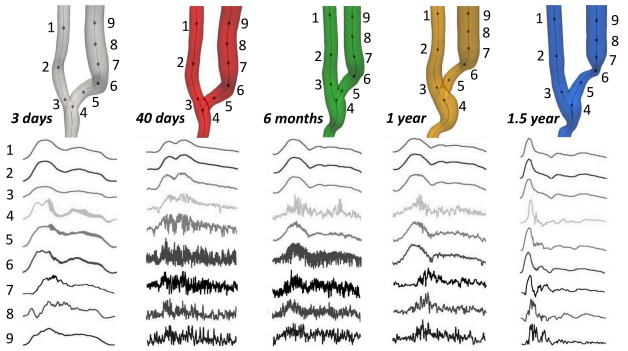

Fig. 2: Velocity-time traces, normalized by their respective cycle averages, at nine selected feature points along the centreline of the AVF model corresponding to the 5 different timepoints.

At all timepoints, velocity traces revealed stable laminar flow in the artery. Three days after surgery the velocity was stable also in the venous segment, while flow instabilities with high-frequency oscillations occurred starting from 40 days after surgery and at 6 months. After this time period, the vascular remodelling, mainly characterized by the enlargement at the anastomosis location and the stenosis formation at the curvature of the JAV, importantly reduced velocity fluctuations (1 year). The velocity traces then stabilized along the vein, specifically in the vessel segment where the stenosis developed, with an almost stable vein flow at 1.5 year.

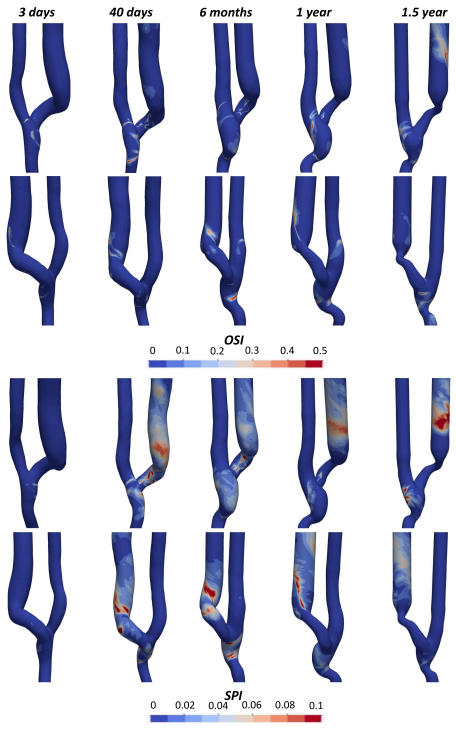

Fig. 3: Oscillatory Shear Index (OSI) and Spectral Power Index (SPI) maps at the five different timepoints.

Surface maps of OSI and SPI are reported in **Figure 3**. For all timepoints, OSI values are equal to zero in the PA, where the near-wall flow mostly maintains the main direction during the entire cardiac cycle. Areas of high OSI developed in the JAV starting from 40 days after surgery and were mostly located close to the inner curvature of the JAV. One year after surgery, lower OSI values were restored in the first segment of the JAV and in the stenotic area because of vessel remodelling, while areas of high OSI appeared in the distal segment of the vein. Same as OSI, SPI values are equal to zero in the PA. SPI values increase significantly during the first 40 days after surgery at the anastomosis and in the vein segment. Then, the vascular remodelling causes an important reduction of SPI values in the first segment of the JAV. Specifically, null SPI is progressively restored along the vein, following the stenosis progression. In the distal vein, on the other hand, flow instability still remains.

IV. DISCUSSION

In this study, morphological and hemodynamic AVF changes were investigated over a 1.5 year follow-up period after surgical creation. Interestingly, the patient under study developed a significant stenosis, allowing to investigate its progression until VA closure. Indeed, the patient's blood flow volume was sufficient to carry out HD until 1.5 years after surgery, when the AVF blood flow was not adequate to sustain the treatment. Patient-specific CFD simulations were performed at multiple timepoints to elucidate the possible impact of altered hemodynamics on pathological vessel remodelling and vessel stenosis.

The morphological analysis showed that the largest arterial dilatation occurred in the first postoperative 6 months and stabilized in the subsequent follow-up period. The vein also dilated until 6 months, but at 1 year a stenosis developed in the JAV, becoming very important at 1.5 year. These changes in the vessel lumen were accompanied by an increase in the blood flow rate during the first 6 months, followed by a progressive decrease starting from 1 year after surgery, resulting in the inadequacy to sustain HD treatment and the need of a new VA.

The hemodynamic analysis revealed the presence of laminar flow in the PA, but highly disturbed flow in the JAV after AVF maturation. These results are in line with previous findings by our [5] and other research groups [20]. Interestingly, the development of the venous stenosis was accompanied by the regularization of the blood flow pattern. The progressive expansion of the stenotic site along the distal vein occurred in parallel with velocity waveforms regularization along the centreline and a decrease of the disturbed flow indices, suggesting that vascular wall remodelling, and more specifically stenosis development, could be the result of a protective mechanism. Indeed, 1 year after surgery, flow parameters' disturbances in the stenotic site decreased, and the unsteady flow patterns shifted gradually along the distal vein. These results are in line with previous observations showing that the vessels remodel to restore the initial hemodynamic conditions [6], [21]. In this case vessel remodelling, like due to intimal hyperplasia, could be triggered by the presence of flow instabilities.

In literature there are just a few significant longitudinal studies on AVFs, and none of them have specifically

investigated the process of VA remodelling and closure and its relationship with local hemodynamic conditions. Despite He et al. [12] being the first ones to use a contrast-free MRI to CFD pipeline in the context of a longitudinal study, they only assessed vascular hemodynamics and remodelling in 1 patient with images taken at 4, 5, and 7 months after AVF creation. Probably due to the choice of those timepoints they just discussed the feasibility of the MRI-to-CFD pipeline. Sigovan et al. [11] studied 3 patients preoperatively and at 1 and 3 months after surgery, focusing again on the feasibility of the technique and not on the correlation between local hemodynamic conditions and vascular remodelling. More recently, Colley et al. [13] followed 1 patient with successful AVF maturation for 15 weeks, suggesting that baseline WSS at time of creation may be a useful indicator for successful maturation. Northrup et al. [14] studied 6 patients and reported that venous velocity, WSS, and vorticity may be used as indicators to diagnose poor AVF maturation earlier. The HFM Study Group followed 120 patients for 6 months, finding that high WSS and low OSI are associated with a positive AVF maturation [15]. All these studies show the potential of hemodynamic parameters as possible predictors for successful maturation, but do not investigate the dynamics of stenosis formation and evolution. Our work is the first longitudinal study that has followed an AVF over time until almost complete closure, allowing to investigate remodelling over time as well as the relation between local hemodynamics and vessel lumen stenosis formation and progression.

From a clinical perspective, this study raises the question of whether a close monitoring of hemodynamics may allow to identify AVFs which are developing stenosis.

The results suggest the presence of a biomechanical stimulus, that might act on the endothelium as well as on other vascular cells. This might explain the lack of a clear and specific correlation between AVF remodelling and conventional disturbed flow parameters and opens up to speculations on the role of the vascular wall itself. Fluid structure interaction might be used to better understand the biomechanical stimuli that might act in the AVF walls.

A limit of the present study is that it was performed on a single patient. Therefore, future clinical investigations with higher number of participants are required to extend current preliminary findings.

V. Conclusion

In this longitudinal study, performed on a AVF that developed stenosis after 1.5 year from surgery, we showed the presence of a focal remodelling process in the vein that was followed by progressive disturbed flow regularization. Our data suggest that local flow instabilities, mostly located in the JAV, may have induced progressive intimal hyperplasia during time with consequent narrowing of vessel lumen that was instrumental for blood flow stabilization.

***Abstract*—Among the different treatments for ventricular tachycardia (VT), catheter ablation guided by the electroanatomic mapping is increasingly adopted. Ablation targets are currently identified by visual inspection from the cardiologist during the mapping procedures. To improve the outcome and consequently reduce the VT recurrences, in this study, an automatic approach exploiting the deep learning on intracardiac bipolar electrograms (EGMs) is proposed. A balanced dataset composed of 752 physiological and 752 abnormal ventricular potentials (AVPs) was collected from nine post-ischemic VT patients. By adopting the synchrosqueezed wavelet transform, for each EGM a time-frequency representation was obtained to be used for feeding a siamese neural network, known to be usable on small dataset. Our findings revealed accurate classification capabilities, thus encouraging the introduction of deep learning tools in the recognition of AVPs and paving the way for their use in supporting clinicians for targeting arrhythmogenic sites.**

***Keywords*—Cardiac electrophysiology, ventricular tachycardia, arrhythmogenic sites identification, abnormal ventricular potentials, deep learning.**

I. Introduction

VENTRICULAR tachycardia (VT) is one of the main causes of sudden cardiac death and unfortunately this is still one of the main cause of death in Europe [1], [2]. Different options for the treatment of this condition have been proposed, including drugs, implantable cardioverter defibrillators, and catheter ablation. The latter is increasingly adopted, because of the advantages with respect to the other two, such as the cost-efficacy ratio, the avoidance of following a long-term therapy and/or no need to implant any external device in the patient body. Although the advantages are interesting, it also presents some drawbacks; indeed, the electroanatomic mapping (EAM) procedure, which the catheter ablation relies on, is very time-consuming; furthermore, the interpretation of the intracardiac electrograms (EGMs) recorded locally on the ventricular endocardium depends obviously on the experience and on the attention of the cardiologist, as the identification of the arrhythmogenic sites to be ablated, to terminate the VT. Remarkably, a computer-aided analysis of the intracardiac recordings could increase the success ratio of the ablation procedure by fast and operator-independent interpretation of the EGMs, or at least support the electrophysiologist during the EAM. In this perspective, different solutions based on artificial intelligence have been introduced, both using machine learning [3], [4] and deep learning [5], trying to discriminate between physiological EGMs and abnormal ventricular potentials (AVPs). Recently, in [5], we adopted a deep learning approach by transfer learning, to overcome the limitation of our dataset size. The AlexNet convolutional neural network (CNN) [6], previously trained on the ImageNet dataset [7], was used along with the EGMs time-frequency representation computed via synchrosqueezed wavelet transform (SSWT) [8]. This choice was driven by previous findings [4] highlighting statistical differences in the spectral components among physiological EGMs and AVPs. Leveraging the spectrograms, AlexNet carried out the binary classification with an accuracy above 90%, underlining the efficacy of the SSWT in extracting the distinguishing features in time and frequency domains for both classes.

On the other hand, siamese neural networks (SNNs) [9] resulted effective in several applications exhibiting limited dataset size, also in cardiac electrophysiology applications. Specifically, in [10] a SNN has been used to recognize EGMs featuring highly distinguishable activations among a large set of signals in atrial fibrillation procedures, obtaining accuracy above 90% on a small dataset (N = 1006) and even outperforming of about 20% a traditional CNN with an equivalent number of parameters. As such, in order to deal with a limited dataset to train a CNN designed from scratch, in this work we investigated the adoption of a SNN for the identification of AVPs in real bipolar EGMs, with the final aim of improving the current CNN classification results and allowing for an effective computer-aided system to target arrhythmogenic sites in post-ischemic VT substrate mapping procedures.

II. Materials and Methods

The SNN architecture has been designed leveraging on a simple subnetwork to reduce the number of weights to be updated. Subnetworks are composed of an input layer, followed by a set of four stacks of 3 layers, i.e., a convolutional layer followed by a ReLu layer and then by a Max Pool layer, except for the fourth element of the stack where the last layer is replaced by a fully connected one. A detailed description of the subnetworks is reported in Figure 1 and in Table 1.

TABLE I: SUBNETWORKS ARCHITECTURE

Type	*Size (number)*	*Activation*

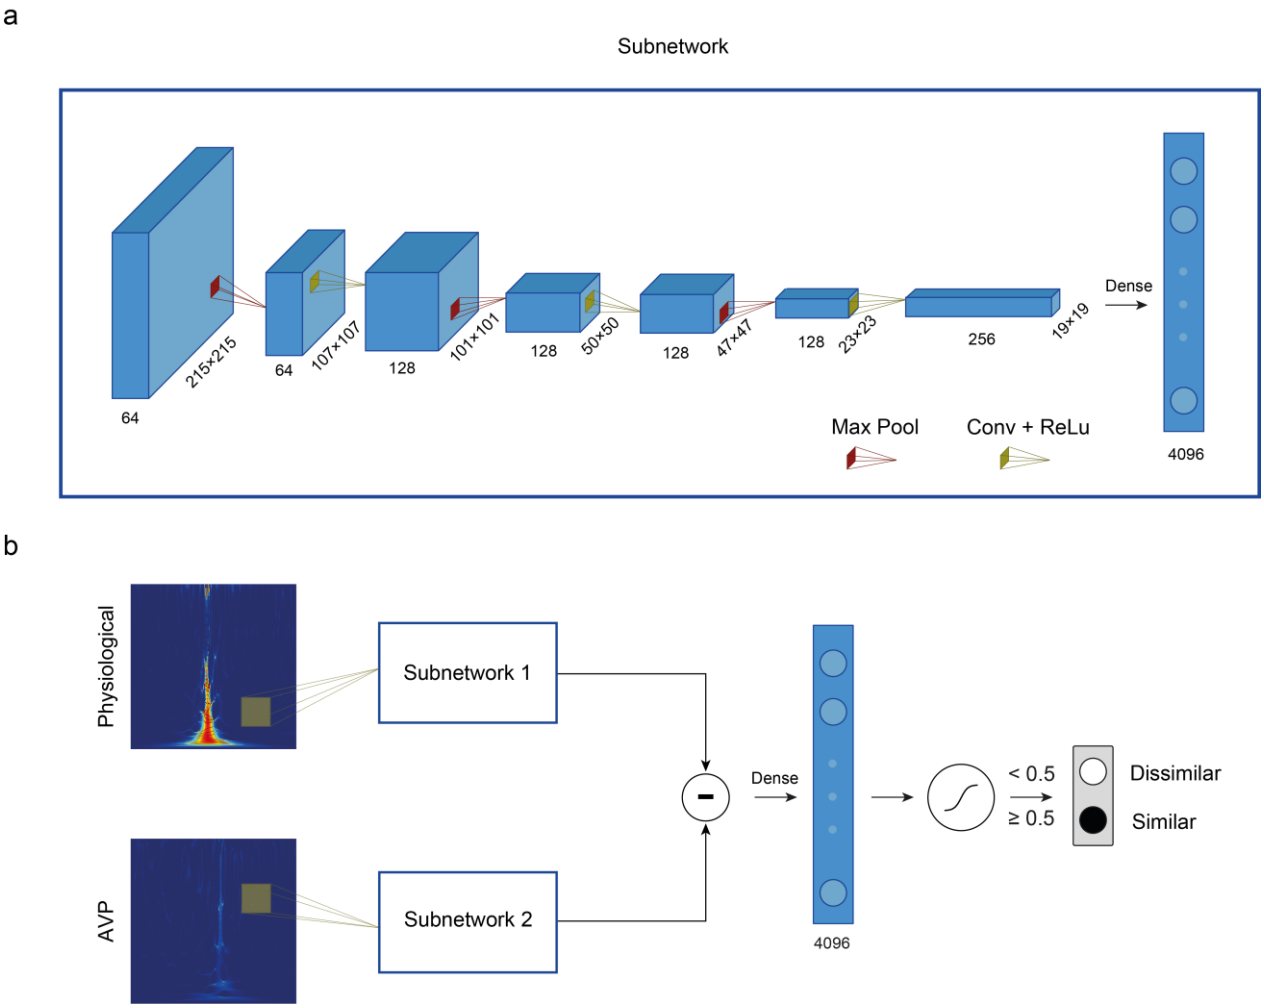

Fig. 1: In the top panel (a) the proposed subnetwork architecture of the siamese neural network; in the bottom panel (b) the overall classification algorithm architecture

The weights of the convolutional layers were initialized by random sampling from a normal distribution with zero mean and standard deviation of 0.01. Then, the difference between the subnetworks outcomes was used as input for the final fully connected layer.

As regards the training parameterizations and settings, different choices were made. Specifically, we performed a 10-fold cross validation by dividing the dataset in ten balanced and stratified folds: as such, eight folds were used for the training, while the remaining two were used for validation and testing, respectively. In this way, in each partitioning, 1204 samples (80%) were exploited for train, 150 samples (10%) for test, and 150 samples (10%) for validation. To update network weights, we used the stochastic gradient descent with momentum as training algorithm, and the binary cross-entropy as loss function to compute the gradient. We imposed a learning rate equal to 0.001, while the momentum was set to 0.9. Furthermore, a batch size of 30 instances per iteration was selected, to provide a stable and reliable training, which can improve generalization of the network predictions [11]. During the training phase, an early-stop condition was imposed to avoid overfitting, by evaluating the validation set every 50 training iterations, and halting the training after nine times in which the loss stopped decreasing. In this condition, the model with the minimum value of validation loss was kept for subsequent analyses. Once trained, the SNNs were tested by measuring the similarity between the test sample and a set of reference images for both classes, selecting as final class the one with the highest number of matches. The provided reference set corresponded to the validation one.

A. Dataset creation

The bipolar EGMs adopted in this study were recorded from nine patients with post-ischemic VT during left ventricle electroanatomic mapping procedures performed at San Francesco Hospital in Nuoro, Italy, by using the CARTO®3 mapping system (Biosense Webster, Inc., Diamond Bar, California). The intracardiac signals were acquired at a rate of 1000 Hz and band-pass filtered between 16 and 500 Hz. The EGMs were annotated by a cardiologist using a custom MATLAB graphical user interface. After this labelling procedure, a balanced dataset of 1504 signals, consisting of 752 physiological potentials and 752 AVPs, was extracted and adopted in this study.

The input images for the SNN were generated by computing the modulus of the SSWT of each 500-ms EGM, which provides information about AVPs and physiological EGM instantaneous spectral contents. Each image was stored as a .jpg file with a resolution of 224x224x3 pixels, which corresponds to the input layer size of the adopted architecture.

B. Performance evaluation

We computed various metrics to assess SNN performance:

$$Acc = (TP + TN)/(P + N) \quad (1)$$
$$TPR = TP/P \quad (2)$$
$$TNR = TN/N \quad (3)$$
$$PPV = TP/(TP + FP) \quad (4)$$
$$F1 = 2\,(TPR \times PPV)/(TPR + PPV) \quad (5)$$

where P represents the total number of samples of AVPs, N represents the total number of physiological EGMs, TP represents the number of EGMs that were correctly classified as AVPs, FP represents the number of EGMs that were incorrectly classified as AVPs, and TN represents the number of EGMs that were properly recognized as physiological signals. The exploited metrics are commonly indicated as accuracy (Acc), sensitivity (TPR), specificity (TNR), precision (PPV), and F1-score.

All computations have been carried out in MATLAB R2022a.

III. Results

Table 2 presents the mean and standard deviation of performance results from 10-fold cross-validation, along with the metrics obtained by AlexNet [5] for comparative purposes. The results show high discrimination performance, above 89% for Acc, TPR and F1 score, with a mean TNR and PPV above 86%. Though the performances of the SNN are generally worse than those obtained by transfer learning with AlexNet in previous studies, by looking at the TPR metrics, a slightly higher number of AVPs were correctly targeted by the SNN, which is a positive aspect in this application scenario. Despite the computation required for the SNN, the training time was fast, taking an average of 2143.6 ± 641.1 seconds on a 64-GB NVIDIA Tesla P100 GPU cluster, with a 1605 ± 480 number of training iterations. The best model was achieved after 1155 iterations on average.

TABLE II: Accuracy of the classification

Index	*CinC22*	*This work*
Acc (%)	*93 ± 3*	*90 ± 4*
TPR (%)	*92 ± 4*	*93 ± 3*
TNR (%)	*93 ± 3*	*86 ± 8*
PPV (%)	*93 ± 3*	*88 ± 6*
F1-score	*0.92 ± 0.03*	*0.90 ± 0.03*

IV. Conclusion

This study investigated on the use of SNN for the automatic identification of AVPs in VT electrophysiological procedures, representing potential arrhythmogenic sites to terminate VTs by catheter ablation.

The results reveal overall a good efficacy in the classification performance of the proposed method, slightly worse than previous studies adopting a CNN with the same dataset. However, the AVPs detection performance was better, which is in practice the most important metrics to avoid missing any ablation target. However, a fine-tuning of the SNN parameters can be performed to improve the performance, as commonly accepted values for the hyperparameters were used in this work.

Moreover, a deeper investigation involving a more complex SNN architecture and an hyperparameter optimization is being pursued.

Acknowledgement

The authors wish to thank Mr. Alberto Valdes Rey for his valuable contribution in the preliminary development of this study. The authors wish to thank the Division of Cardiology of San Francesco Hospital (Nuoro, Italy) for providing access to the clinical data used in this study. This work was carried out under the ARGO (Ablation Reinforcement by computer-aided Guidance and Optimization) project, approved by Azienda Tutela Salute Sardegna (ATS Sardegna).

***Abstract*—Breast density is an established risk factor for developing breast cancer. In clinical routine it is qualitatively assessed by visual inspection of mammographies by radiologists on the basis of the American College of Radiology (ACR) Breast Imaging Reporting and Data System (BI-RADS) guidelines. This might lead to intra- and inter-observer variability.**

As a consequence, many Computer-Aided Diagnosis (CAD) systems, based on machine learning and artificial intelligence, have been developed in recent years to support radiologists in breast density evaluation. One difficulty arises when considering the evaluation of the performance of a CAD. It is well known that very large data sets must be used to obtain a reliable assessment of generalization ability. However, according to ACR guidelines, if the breasts appear not to be of equal density only the denser category should be reported; therefore it is not possible to access to densities of both breasts when analyzing retrospective data. This leads to difficulties in gathering large data sets of clinical mammographic images.

As a large number of clinical breast images data sets have been acquired using BI-RADS one can pose the question if it is possible to train an automatic system using one single label for both breasts potentially different.

In this study, we evaluated the what extent differences in density between breasts of the same patients occur in a real population. In particular we extracted multiple radiomics features from breast parenchyma using the Pyradiomics library and a preliminary clustering analysis has been conducted. Preliminary results showed different densities between right and left breast occur in 25-30% of cases.

***Keywords*—Breast density, Clustering, Digital mammography, Radiomic**

I. INTRODUCTION

Automatic assessment of risk factors is a major challenge for the early identification of breast lesions and increasing the survival rate. In fact, identifying risk factors in patients allows implementing personalized screening strategies by defining adequate exam scheduling, using appropriate radiological methods and prioritizing image analysis [1]. Full-Field Digital Mammography (FFDM) is considered the cornerstone in breast cancer (BC) diagnosis and also assumes a very important role in the identification of risk factors, specifically breast density (BD) [2]. In many previous studies, it has been established that women with dense breasts have an increased risk of developing BC [3], [4]. Moreover, breast density also affects the possibility to detect breast cancer, as mammography suffers from a loss of sensitivity [5], [6], despite the widespread effort to develop ever more effective methods for improving the quality of mammographic images [7], [8]. In clinical practice, BD is assessed only on a *qualitative* basis, through a visual evaluation, by the radiologists, based on the international guidelines BI-RADS (Breast Imaging - Reporting and Data System) by the American College of Radiology (ACR). According to these guidelines, four classes of breast density are defined on a qualitative basis [9]:

- Class A: Predominantly fibro-adipose;
- Class B: Scattered areas of fibroglandular tissue;
- Class C: Heterogeneously dense;
- Class D: Extremely dense.

This might lead to intra- and inter- observer variability, as well as the difficulties in creating automatic algorithms for supporting radiologists in critical decision for borderline breasts. Many Computer-Aided Diagnosis (CAD) systems which have been developed in recent years for breast density assessment have been typically based on quantitative approaches such as radiomics computation combined with Artificial Intelligence (AI) algorithms [10], [2], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24]. The extraction of radiomic features from the breast parenchyma can offer quantitative parameters to evaluate the composition of fibroglandular tissue compared to adipose tissue, providing objective assessments of breast density. The analysis of this huge amount of data can be done only through the aid of AI algorithms, giving rise to automatic classification systems of breast density.

One of the most relevant and problematic aspects of automatic classification algorithms, especially in the medical field, is their performance evaluation. In fact, a correct classification is essential for the algorithm to be of support to the clinicians. While many AI algorithms are being developed in medical research, those actually being applied in clinical practice are not much numerous. To date, an emerging discipline is the Explainable AI (XAI) which seeks to understand what is happening inside the black box of the algorithm to give a more reliable explanation to the results [25], [26].

In this case, the evaluation of the performance of the classification algorithms is based on the agreement with the diagnosis made by the radiologists. According to the BI-RADS

[†]These authors (F.A. and A.M.P.) contributed equally

guidelines used by radiologists, however, when the two breasts of a patient are of different density only the denser must be given in the clinical report. This leads to difficulties in gathering data-sets of clinical breast images with a reliable labelling for both breasts. It is apparent that when a single label is available for both breasts, disagreements between the results of the classifiers may appear because they analyze each image individually, capturing the differences in the features extracted between the two images of the right and left breast. This obviously affects the performance of the model.

As a large number of clinical breast images dataset have been acquired using BI-RADS one can pose the question if it is possible to train an automatic system using one single label for both breasts potentially different.

In this study, we evaluated the what extent differences in density between breasts of the same patients occur in a real population. In particular we extracted multiple radiomics features from breast parenchyma using the Pyradiomics library and a preliminary clustering analysis has been conducted.

II. Methods

A. Image acquisition and dataset

The reference dataset was acquired over a period of 5 months, from June 2020 to October 2020, for a total of 177 patients, all women, aged between 38 and 84 years. All women underwent bilateral, medio-lateral-oblique (MLO) full-field digital mammography (FFDM) under standard clinical protocol, using Giotto Class (IMS GIOTTO S.p.A., Sasso Marconi, Bologna, Italy). The mammography unit has been used with the aid of the Raffaello software in its version 4.11 which allows the visualization of the acquired images.

The subsequent processing has been carried out on the "FOR PROCESSING" images, i.e. original 16-bit DICOM images (of which 13-bit stored) without the processing step generally applied by proprietary mammography software to visually enhance the difference between tissues, because, being proportional to the attenuation of the X-rays on the breast tissue, they preserve the original information on the attenuation of the X-rays and therefore are more suitable for quantitative analysis [21]. In summary, two MLO images (right and left) for each patient were acquired, for a total of 354 images.

An expert radiologist reviewed each patient providing the breast density evaluation in the BI-RADS report. Moreover, he performed manual segmentation for removing background and pectoral muscle in order to subsequently compute radiomics features only on breast tissue. Fig. 1 shows a comparison among the visualization of the breast image before and after the manufacturer software processing with the relative manual segmentation from radiologists.

B. Features extraction

Radiomic features were extracted using PyRadiomics library (version 3.0.1) [27] in Python, following the guidelines of the Image Biomarker Standardisation Initiative (IBSI) [9].

The features extracted can be summarized:

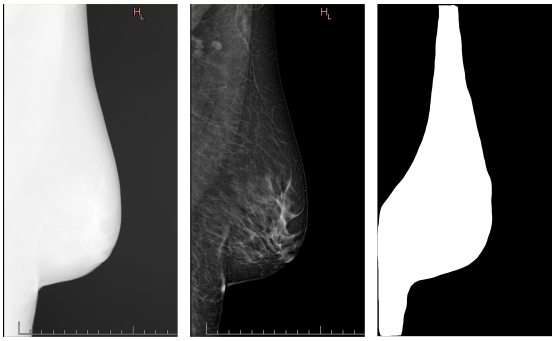

Fig. 1: Comparison among (a) "FOR PROCESSING" image (b) "FOR PRESENTATION" image (after manufacturer software processing) and (c) manual segmentation from radiologists.

- 18 first-order features (energy, total energy, entropy, kurtosis, maximum, minimum, mean, median, interquartile range (IQR), skewness, range, mean absolute deviation (MAD), robust mean absolute deviation (RMAD), root mean squared (RMS), variance, uniformity, 10th percentile and 90th percentile);
- 75 higher-order texture features (24 Gray level co-occurrence matrix (GLCM) features, 14 Gray level dependence matrix (GLDM) features, 16 Gray level run-length matrix (GLRLM) features, 16 Gray level size zone matrix (GLSZM) features, 5 neighboring gray tone difference matrix (NGTDM) features). For texture feature calculation, 128 levels of gray were considered in this study.

In particular, first-order statistics help describe how voxel intensities are distributed within the mask-defined region of the image (ROI) through common statistical metrics and commonly used metrics such as the maximum and minimum intensity within the ROI, entropy and energy. Higher-order texture features allow even more to evaluate the relationship between intensities of pixels within the ROI, through the calculation of some matrices, such as GLCM, a matrix that defines the distribution of grayscale values of pixels on an image by defining how often pairs of pixels with a specific value and position operator occur in the image, or GLSZM that quantifies the gray level zones in an image by calculating the number of connected voxels that share the same gray level intensity. All the listed features were used to perform the clustering analysis.

C. Cluster analysis

Breast tissues composition might be associated to textural features on mammographic images [28]. With this assumption in mind we performed a cluster analysis of our data-set: breasts of similar composition should have been assigned to the same cluster.

We used two distance-based clustering methods where a similarity quantification between objects is based on the distance. In particular, we used both a k-means algorithm [29] and a partitioning around medoids (PAM) algorithm [30]

which can overcome the problems of centroids initialization sensitivity and interpretability.

III. Results and Discussion

Preliminary results relating to the application of clustering algorithms to the dataset are shown in Fig. 2 and 3: for representation purposes data have been projected onto principal components. Breast images have been clustered in four groups corresponding to the four breast density BI-RADS categories. Each point in the figures corresponds to a single breast: the label indicates breast category, subject ID and laterality.

Looking at the results of the k-means algorithm, in Fig. 4 is shown the clustering vector and it is possible to note that for the same patient, the right and left breasts, which are two consecutive values in the clustering vector, are not always clustered in the same class. In particular, as shown in the Table I, out of a total of 177 patients, for 46 patients have right and left breasts not belonging to the same cluster, which corresponds to the 26.0%.

The clustering vector of the PAM algorithm, which overcomes the above mentioned limitations of the k-means algorithm, is shown in Fig. 4. In this case, as shown in the Table I, out of a total of 177 patients, 54 patients have right and left breasts not belonging to the same cluster, which corresponds to the 30.5%.

With both clustering algorithms we obtained a comparable number of patients presenting different BI-RADS densities between right and left breast. Nevertheless, since PAM algorithm is based on medoids, offers the most robust results to noise and outliers. The number of dissimilarities between right and left breasts is quite large compared to the total number of patients examined. From the results of this exploratory study, it is possible to note that the percentages of disagreement between the right and left breasts densities are not negligible confirming that this is an aspect to be taken into consideration when evaluating the agreement between the radiologist's diagnosis and the results of the classification algorithms, significantly affecting the performance of the classification models.

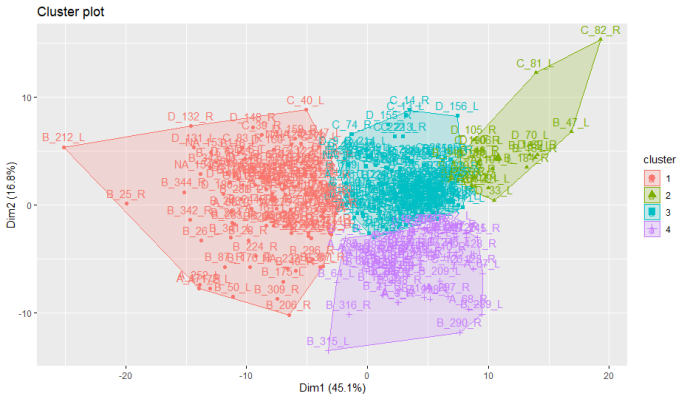

Fig. 2: Distribution of 354 breast images, corresponding to right and left breasts of each patient, grouped in four clusters using the k-means algorithm. Each image is labelled with the BI-RADS class, a patient identifier and right/left indication.

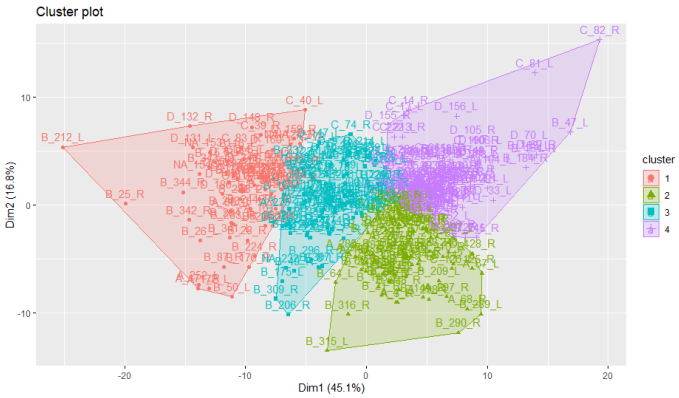

Fig. 3: Distribution of 354 breast images, corresponding to right and left breasts of each patient, grouped in four classes using the PAM algorithm. Each image is labelled with the BI-RADS class, a patient identifier and right/left indication.

IV. Conclusion

Breast density is an important risk factor, whose evaluation can help to early identify patients with a higher risk of developing breast cancer; these patients should be subjected to *ad hoc* screening programs to increase survival rate. Currently, breast density is qualitatively evaluated in the clinical environment, with inter- and intra-observer variability. Many efforts are being put into developing expert systems and artificial intelligence for objective assessment of BD.

One of the difficulties often encountered in developing such systems is the performance evaluation which should be done on the basis of adequately gathered large data set with proper labeling of both breasts. However, BI-RADS guidelines

indicate reporting only the denser breast in the case the patient has different breast densities. As a large number of clinical breast images dataset have been acquired using BI-RADS one can pose the question if it is possibile to train an automatic system using one single label for both breasts potentially different.

This study aimed to preliminary investigate to what extent this problem might affect automatic systems evaluation. Results from the present study, by applying a cluster analysis, suggest that in about 30% of cases the breasts of a single patient have different densities. As the percentage is not negligible further investigations might be required to address this problem.

***Abstract*—The early diagnosis of Non-Alcoholic Fatty Liver Disease (NAFLD) is crucial to prevent fibrosis progression or onset of advanced chronic liver disease. Among the non-invasive methods, ultrasound (US) B-mode imaging is recommended for population screening and follow-up. Hamaguchi's score was proposed to improve the objectivity in the evaluation of the fatty liver US imaging evaluation. In this study, we aimed to preliminary assess the possibility to estimate Hamaguchi's score by means of an advanced ultrasound image semi-automatic analysis.**

The study encompassed a dataset of 220 bariatric patients with NAFLD diagnosed by liver biopsy who underwent ultrasound assessment at the Liver Clinic at Trieste University Hospital. The classification models for the estimation of the three Hamaguchi's sub-scores were produced by semiautomatic US image analysis based on clustering and CNN with transfer learning techniques.

The results showed that the produced models were able to estimate the three sub-scores with high classification accuracy. The predictive models produced for the estimation of liver brightness hepatorenal echo contrast, the diaphragm deep attenuation, and the vessel blurring sub-scores presented a classification accuracy on the validation set of 90.5%, 83.3%, and 84.0%, respectively.

In conclusion, in this preliminary study, the results assessed the possibility to produce the NAFLD computer-aided diagnostic models based on analysis of US images.

***Keywords*—NAFLD, Hamaguchi's score, ultrasound images, Artificial Intelligence.**

I. Introduction

NAFLD represents a spectrum of diseases related to excessive fat deposition in the liver, ranging from simple steatosis (i.e., non-alcoholic fatty liver, NAFL) to non-alcoholic steatohepatitis (NASH), characterized by lobular inflammation and hepatocyte ballooning, which over time can increase liver fibrosis, thus promoting liver cirrhosis or hepatocellular carcinoma [1]. NAFLD is the most common chronic liver disease in the world (approximately 25% of the global population has been affected by NAFLD [2] and is projected to be 33.5 % by 2030 [3]). Current clinical guidelines recommend dietary treatment as the most efficient preventive intervention in addition to early evaluation and monitoring of liver functions to prevent advanced fibrosis or hepatocellular carcinoma [4], [5]. The gold standard for staging is liver biopsy, which is expensive and invasive, making it unsuitable for broad screening at the population level [6].

Among the noninvasive methods, ultrasound B-mode imaging has been recommended as the preferred first-line diagnostic procedure for imaging of NAFLD in adults by the clinical practice guidelines of the European Association for the Study of the Liver released together with the European Association for the Study of Diabetes and the European Association for the Study of Obesity [7].

But this method has the limitation that the evaluation of a US image is operator dependent: several studies conducted have reported significant intra- and inter-observer variability in the assessment of ultrasonographic findings of hepatic steatosis [8]-[10]. In particular, an agreement between pairs of experienced observers of only 47-59% on the first reading and 59-64% on the second reading was reported [9].

In daily practice, physicians evaluate hepatic steatosis on the US image by analyzing some of its features: the echogenicity of the liver parenchyma compared with the echogenicity of the kidney, the visibility of intrahepatic vessels and the diaphragm blurring [11]. These features allow physicians to assess the presence of hepatic steatosis because an excess fat component in the liver would make it shine brighter to a greater extent than in the kidney (normally isoecogenic) and would attenuate the ultrasound probe's beam making visualization of intrahepatic vascular structures and the diaphragm poor.

To improve objectivity, Hamaguchi et al. proposed a semi-quantitative US-based scoring method [12]. In particular, the proposed scoring system is based on the comparison of liver and kidney echogenicity, assessment of liver brightness (scored liver brightness from 0 to 3), of deep attenuation of diaphragmatic contours by the liver (scored from 0 to 2), and of liver vessel blurring (scored from 0 to 1). The sum of the aforementioned sub-scores yields Hamaguchi's score ranging from 0 (corresponding to a healthy liver) to 6 (corresponding to a fatty liver). Although Hamaguchi's score improved the standardization of the degree of hepatic lipid accumulation in the liver, it still suffers from the fact that the assessment is a subjective measure strongly influenced by the expertise of the physician evaluating the US image.

Over the past decade methods based on Artificial Intelligence (AI) are used for identifying and predicting patterns or connections within large datasets in various fields of medicine, demonstrating utility in the diagnostic process. A recent meta-analysis on the AI-based methods for liver diagnosis reported high-accuracy results of the application of these methods on diagnostic imaging for the diagnosis and staging of NAFLD [13]. However, despite the numerous

applications of AI in the diagnostic field of NAFLD, methods based on AI have never been applied to the analysis for Hamaguchi's score estimation. The aim of this study is to develop Machine Learning (ML) and Deep Learning (DL) algorithms for the advanced analysis of US images that can estimate the sub-scores of the various categories of Hamaguchi's score and thus propose a new approach for automatic analysis of the same.

II. Materials and Methods

A. Data acquisition and dataset definition

The study includes 220 bariatric patients with NAFLD diagnosed by liver biopsy who underwent US assessment at the Liver Clinic at Trieste University Hospital. The clinical and radiological data of included patients were analyzed to create the study dataset. The inclusion criteria were liver biopsy-based NAFLD diagnosis, and US assessment characterized by the visibility of liver and renal parenchyma, visibility of intrahepatic vessels, and visibility of the diaphragm.

To assign the sub-scores constituting the Hamaguchi score, three parameters must be evaluated on the US image, but not in all cases all three parameters are assessable on a single US scan as it depends on the bariatric patient's physical conformations: there are patients who have all three parameters of interest in one US image, patients who have liver and kidney in a single US image while diaphragm and intrahepatic vessels in another, as well as patients who have all three parameters in three different US images. So, with the support of physicians in the selection, three datasets were created: the Hepatorenal dataset, the Diaphragm dataset, and the Vessel dataset.

All three datasets contain 220 US images (one for each patient). For each of the three datasets, the images were appropriately evaluated by four physicians who independently assigned the respective sub-scores constituting the Hamaguchi score, and where ratings were not equal, the scores were reviewed and decided by consensus.

B. The proposed framework to evaluate automatically Hamaguchi's score

The proposed approach for automatic estimation of Hamaguchi's score is based on separate estimation of sub-scores by semiautomatic analysis of US images. Considering that the sub-score assessments are based on the identification of different features, three sub-score related algorithms were developed. For the evaluation of the liver brightness hepatorenal echo contrast score, a semi-automatic evaluation based on clustering was adopted, while for the evaluation of the diaphragm deep attenuation score and of the vessel blurring score a semi-automatic methodology based on the development of two CNNs with transfer learning techniques was implemented.

Considering the variability of the US images and moderate sample size, to produce performant classification algorithms, additional pre-processing was performed by manually delineating the ROIs to define Diaphragm dataset and Vessel dataset.

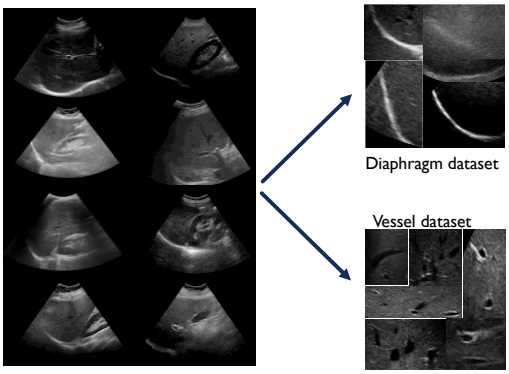

Fig. 1: The ROIs definition from raw US images for the Diaphragm and Vessel datasets.

C. Estimate of liver brightness hepatorenal echo contrast score

For the calculation of liver brightness hepatorenal echo contrast, two ROIs were manually identified by the medical team: one in the lighter region of the liver parenchyma, and the other in the darker area of the cortical area of the kidney. A script written in Python allows to select two ROIs (of size 5x5 pixel to ensure that the cortical region of the kidney is selected without including its interface with the liver) and process them to extract the feature of interest. In this way, features related to the echogenicity of the liver were obtained for each US image sample. All previously saved features are later analyzed with K-means by setting the number of four classes (liver brightness hepatorenal echo contrast score could be 0, 1, 2, and 3). In this way, four classes were distinguished.

Based on this clustering, a classification model was built to evaluate the feature extracted from an ultrasound image of the liver by assigning it a score ranging from 0 to 3.

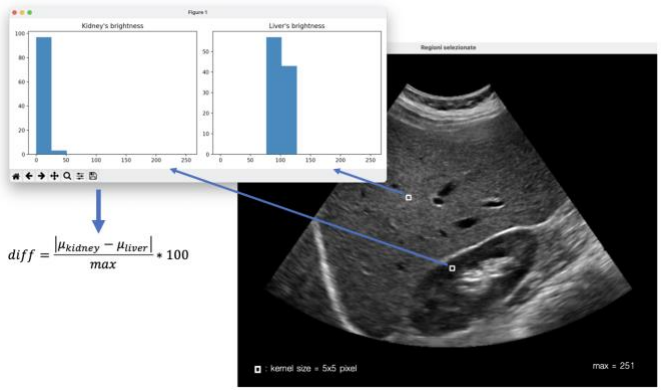

Fig. 2: The feature extraction for the liver brightness hepatorenal echo contrast sub-score. The two ROIs are manually selected by the physician from the raw image. One is in the lighter region of the liver parenchyma, and the other is in the darker region of the cortical zone of the kidney. When these two ROIs are selected, a feature is extracted by calculating the distance between the average intensity level of the area corresponding to the liver (μ_{liver}) and the average intensity level of the area corresponding to the kidney (μ_{kidney}). The difference is divided by the maximum intensity present in the US image.

D. Estimate of diaphragm deep attenuation score and liver vessel blurring score

The diaphragm deep attenuation score is evaluated according to how well the diaphragm is visible: the greater the presence of fat in the liver, the greater the absorption of ultrasound signal and thus the lower the visibility of the diaphragm. Similarly for liver vessel blurring score. So, we chose to evaluate these scores using CNNs and transfer learning for each kind of score.

Before implementing and training the CNNs, the image datasets of both the diaphragm's dataset and the vessel's dataset are divided into three sub-sets of images each: training set, validation set, and test set with a ratio of 75%, 15%, and 10% respectively. So, the sub-set consists of 165, 33, and 22 US images on the training set, validation set, and test set respectively. The test set is used only once the model has been fully trained. To give correct assessments, the test set must be well maintained and contain a variety of images covering the various classes of each sub-score.

Although the transfer learning technique is used to produce CNNs with high classification accuracy, many images are still required in the training set, and the sample case histories need to be balanced. So, the training set has been also augmented and balanced via data augmentation and the techniques which consisted of 10° right/left rotation, random in/out zooming ranging from 0.8 to 1.2, and horizontal flip operations in a random manner.

Ten CNNs were implemented with transfer learning techniques (TABLE I) to choose the most suitable and performing network for the diaphragm deep attenuation score and the vessel blurring score. The networks' development was implemented with Python scripts by importing the Tensorflow and Keras libraries. In particular, the pre-trained networks VGG-16 and VGG-19 from Keras are imported as the base model.

TABLE I: ARCHITECTURES OF THE TEN IMPLEMENTED CNNs

#	Base model	Additional convolutional block	Classification block
1	VGG-16	-	Flatten layer Dense layer (512 nodes) Dense layer (256 nodes) Output layer
2	VGG-16	Conv2D layer (512 nodes) Conv2D layer (512 nodes) MaxPooling2D layer	Flatten layer Dense layer (512 nodes) Dense layer (256 nodes) Output layer
3	VGG-16	Conv2D layer (512 nodes) Conv2D layer (256 nodes) MaxPooling2D layer	Flatten layer Dense layer (4096 nodes) Dense layer (512 nodes) Output layer
4	VGG-16	Conv2D layer (512 nodes) Conv2D layer (256 nodes) MaxPooling2D layer	Flatten layer Dense layer (4096 nodes) Dense layer (4096 nodes) Output layer
5	VGG-16	Conv2D layer (512 nodes) Conv2D layer (256 nodes) MaxPooling2D layer	Flatten layer Dense layer (512 nodes) Dense layer (256 nodes) Dense layer (128 nodes) Output layer
6	VGG-16	Conv2D layer (512 nodes) Conv2D layer (256 nodes) Conv2D layer (128 nodes) MaxPooling2D layer	Flatten layer Dense layer (1024 nodes) Dense layer (512 nodes) Dense layer (256 nodes) Output layer
7	VGG-16	Conv2D layer (512 nodes) Conv2D layer (256 nodes) Conv2D layer (128 nodes) MaxPooling2D layer	Flatten layer Dense layer (1024 nodes) Dense layer (512 nodes) Output layer
8	VGG-19	-	Flatten layer Dense layer (512 nodes) Dense layer (256 nodes) Output layer
9	VGG-19	Conv2D layer (512 nodes) Conv2D layer (256 nodes) MaxPooling2D layer	Flatten layer Dense layer (512 nodes) Dense layer (256 nodes) Output layer
10	VGG-19	Conv2D layer (512 nodes) Conv2D layer (256 nodes) Conv2D layer (128 nodes) MaxPooling2D layer	Flatten layer Dense layer (1024 nodes) Dense layer (512 nodes) Dense layer (256 nodes) Output layer

In output to VGG-Nets, a convolutional layers' block is added with trainable parameters to extrapolate additional features. After this block, there is a flatten layer that brings all the outputs of the previous layer onto a one-dimensional array to be given as input to the top layer. The top layer of the different implemented architectures shown in TABLE I change depending on the number of convolutional layers and the number of nodes per layer. All top layers share the fact that they have the same activation function (the Rectified Linear Unit - ReLU). Between the various dense layers of all models, there are dropout layers: these layers keep the overfitting of the model under control.

The output layer of the models differs between the two scores: the diaphragm deep attenuation score could be 0, 1, or 2, so should be able to predict three classes. Instead, the vessel blurring score should only involve two classes (0 or 1).

For the diaphragm deep attenuation score, which is a multi-class problem, then the network outputs an array containing the probability associated with each score value. The array index that will have obtained the highest probability will constitute the final output. The activation function is a softmax and the loss function is the categorical cross entropy. Instead the vessel blurring score is a binary problem and then the output layer has only one neuron. This neuron will report the value of the predicted parameter and the probability of the realized prediction. This is a binary classification problem, so the activation function is a sigmoid, and the loss function calculation is the binary cross entropy. The performances of models were evaluated by classification accuracy, loss, Area under the ROC curve (AUC), and precision.

III. RESULTS

The predictive model produced for the classification of liver brightness hepatorenal echo contrast score presented a classification accuracy of 90.5% considering the sub-scores labeled by physicians. In the misclassified cases the maximum error for this sub-score was one point. Regarding the model for estimation of the diaphragm deep attenuation and the vessel

blurring sub-scores, architecture #10 and architecture #2 (TABLE I) showed the best classification performance on the validation dataset, respectively. The classification accuracy, loss, AUC, and precision obtained for these models are reported in TABLE II.

TABLE II: THE PERFORMANCE PARAMETERS OF THE TWO SELECTED MODELS OF EACH SUBSCORES

	Accuracy	Loss	AUC	Precision
Diaphragm deep attenuation	83.25 %	0.48	0.93	83.0 %
Vessel blurring	84.05 %	0.44	0.89	89.0 %

The identified models were subsequently tested on the test dataset. The confusion matrixes for diaphragm deep attenuation and vessel blurring sub-score models are reported in TABLE III-A and III-B, respectively. The algorithm for the estimation of diaphragm deep attenuation showed an accuracy of 81.8%. The misclassified scores were under or over-estimated by one point. Reading the vessel blurring sub-score model the identified model presented a classification accuracy of 86.4% on the test dataset. In both cases, the models maintained the performance obtained during the training and validation process.

TABLE III: COMPARISON OF THE PREDICTED SUBSCORE AND THE SUBSCORE ASSIGNED BY THE PHYSICIANS ON THE TEST SET REPRESENTED BY A NORMALIZED CONFUSION MATRIX

A) DIAPHRAGM DEEP ATTENUATION SUBSCORE

True label	Score 0	0.875	0.125	0
	Score 1	0.125	0.75	0.125
	Score 2	0	0.125	0.875
		Score 0	Score 1	Score 2
		Predicted label		

B) VESSEL BLURRING SUBSCORE

True label	Score 0	0.73	0.27
	Score 1	0	1.00
		Score 0	Score 1
		Predicted label	

IV. DISCUSSION

The early diagnosis of NAFLD is important to prevent fibrosis progression, liver cirrhosis, or hepatocellular carcinoma [4], [5]. Among the noninvasive methods, US B-mode imaging is recommended for population screening and follow-up [7]. But this method has the limitation that the evaluation of a US image is operator dependent [8]-[10]. Hamaguchi's score improved the standardization of the degree of hepatic lipid accumulation in the liver [12], but this score suffers from the fact that the assessment is a subjective measure strongly influenced by the expertise of the physician evaluating the US image. In this study, we aimed to preliminary assess the possibility to estimate Hamaguchi's score by means of advanced image analysis.

The results of this study showed that methods based on AI can estimate the three sub-scores which determine Hamaguchi's score. Indeed, the produced models presented a high classification accuracy for all three sub-scores. The results obtained for all three sub-scores are clinically relevant and suggest that such decision support systems in the future may support the diagnosis of liver disease in a way that will reduce intra- and inter-operator assessment error.

The study presents the following limits: the possible reliance on manual segmentations, the use of images acquired from only one type of US scanner, the moderate sample size, and the retrospective nature of the study. The latter limited the possibility to build a dataset with balanced case histories.

These preliminary results should be confirmed and potentially improved on a larger sample size and more clinically balanced dataset. In addition, the presented approach could be additionally improved by developing an automatic tool for ROI selection.

In conclusion, in this preliminary study, the results assessed the possibility to produce the NAFLD computer-aided diagnostic models based on analysis of US images.

***Abstract*—We present a novel approach for objectively measuring pathological changes in soft tissue, specifically those resulting from genetic disorders such as Osteogenesis Imperfecta (OI) and Pulmonary Arterial Hypertension (PAH), using Ultrasonography. The method employs high-frequency sound waves to generate images of internal soft tissue structures within the human body. Convolutional Neural Networks (CNNs) have been shown to be powerful techniques for evaluating the pathological status of soft tissue. However, the availability of high-quality echographic images for training machine learning models is often limited. We propose a technique that leverages expert knowledge to simulate pathological soft-tissue alterations of the desired degree in echographic images. Our results demonstrate that when a CNN is trained with such images, it is able to accurately separate images of healthy subjects from those with OI and PAH pathology, respectively with sensitivity of 0.93 and 0.97 and specificity of 0.91 and 0.81.**

***Keywords*—US Imaging, CNN, Disease Prediciton, Expert Knowledge.**

Ultrasonography is a widely used diagnostic technique that employs high-frequency sound waves to generate images of internal soft tissue structures within the human body. This modality can be used to detect pathological alterations in soft tissue, such as those resulting from disorders like Osteogenesis Imperfecta (OI) [3] and Pulmonary Arterial Hypertension (PAH) [13].

OI is a heterogeneous group of genetic disorders that affect the production of collagen type I in connective tissues and bones [19], [23]. For this reason it can affect various body parts, such as the skeletal system, the skin, and the teeth.

PAH is a lung disease that causes the narrowing of blood vessels in the lungs, leading to an increase in resistance to blood flow and strain on the right heart ventricle [8], [16]. People with PAH often experience fatigue and tiredness, which results in reduced movement and muscle performance [15].

Both OI and PAH have hence a significant impact on soft tissue, particularly noticeable in areas that humans normally use on a daily basis, such as the forearms for hand movement and the thighs for walking [5].

Convolutional Neural Networks (CNNs) have been shown to be powerful techniques for evaluating the pathology degree of biomedical imaging data [1], [17], [10], including echographic images of hard [14] and soft tissues [22], [20]. However, the availability of data for training machine learning models is often limited, which can negatively impact the performance of models trained on these images. To address this limitation, image generation methods such as deep generative models and generative adversarial networks have been proposed [6], [4].

Unfortunately, when data is scarce, these methods often fall short in accurately simulating pathological conditions [2]. In such cases, expert human knowledge is crucial in guiding the generation of high-quality [9] synthetic images that closely mimic real-world pathological scenarios [21]. The incorporation of expert knowledge in image generation is a promising strategy for improving the performance of machine/deep learning models in medical imaging.

This is where our approach comes in: we introduce a simple yet powerful technique that leverages expert knowledge to simulate pathological soft-tissue alterations of the desired degree in echographic images.

To do so, we take soft-tissue images of healthy subjects and we sample the Pathology Index (PI) from a uniform distribution. The healthy image is then corrupted with an adulteration level proportional to the random PI.

We demonstrate that when a CNN is trained with such images, it is able to accurately separate healthy subjects from those with pathology. This approach is particularly useful in situations where data is scarce and expert knowledge is required to generate pathological images. Our results suggest that the use of expert knowledge in image generation can be a valuable tool in improving the performance of machine learning models in the medical field.

By training the CNN model on a large dataset of synthetic images generated using expert knowledge, we aim to create a model that can accurately predict the degree of pathological changes in soft tissue. This will make the CNN model a valuable evaluation tool for the assessment of OI and PAH.

I. Methods

In this section, we will firstly describe the process of synthetic image generation for mimicking the effects of soft-tissue pathology in echographic images. We developed an algorithm utilizing a trial-and-error approach to capture and incorporate the expert knowledge of a specialist in the field.

By randomly sampling a Pathology Index from a uniform distribution, we are able to appropriately modify the original images and transform them into pathological ones. Secondly, we will describe the CNN architecture used in our work.

A. Synthetic Image Generation

In order to generate synthetic echographic images that accurately mimic the effects of soft-tissue pathology, we developed an algorithm utilizing a trial-and-error approach. Through this method, we were able to capture and incorporate the expert knowledge of a specialist in the field regarding the appearance of soft tissue disease on echographic images.

The training set consists of echographic images of the forearm and the thigh of subjects without known disease. For each image, the Pathology Index $\mathrm{PI} \sim \mathcal{U}(0, 100)$ is randomly sampled from a uniform distribution between 0 and 100. The PI value is then used to appropriately modify the original image and transform it into a pathological one.

The procedure is detailed in pseudo code in Algorithm 1. The core computation consists in the application of a *Shift* operator that horizontally translate the image by the desired number of pixels, followed by a pixel-wise *Max* operation between the original image and the shifted one. This computation is repeated as many times as the PI value to simulate the desired pathology level on the image. The *Shift* operator has a cyclic boundary symmetry such that column elements that are shifted beyond the last position are re-introduced at the first position. The final image serves as input for the CNN network, as well as the PI value serves as the target value for the network's regression model.

Algorithm 1 Creation of a random pathological image given an healthy one.

Require:
Dataset of US BMode 2D images of healthy subjects.
Max Pathology Index ($\mathrm{PI}_{\mathrm{max}}$) value.
Operator $\mathrm{Shift}(I, s)$, that given an image I and a shift value s return the original image shifted horizontally by s pixels.

(a) $\mathrm{PI} = 0$ **(b)** $\mathrm{PI} = 50$ **(c)** $\mathrm{PI} = 100$

Fig. 2: Simulated images with increasing Pathology Index (PI)

In Fig. 1 we show the real appearance of the OI and PAH disease on echographic images. In Fig. 2 we show the result of the application of Algorithm 1 to the BMode image of an healthy subject.

Along with the *Shift+Max* operators, we came up with other heuristics to simulate pathological images, such as addition of Gaussian blur and addition of white horizontal patches. These heuristics were poorly judged by the expert specialist, and hence discarded.

B. CNN architecture

AlexNet [12] is a classic convolutional neural network architecture. It consists of convolutions, max pooling and dense layers as the basic building blocks. Our network is a modified version of the AlexNet and consists of 6 Convolutional layers and 3 Linear layers. The activation used is the Rectified Linear Unit (ReLU). The structural details of each layer in the network can be found in the table I.

TABLE I: Network details, variation of the AlexNet [12].

Layer	in	out	post computation
Convolution	1	6	ReLu + MaxPool
Convolution	6	16	ReLu + MaxPool
Convolution	16	32	ReLu + MaxPool
Convolution	32	64	ReLu + MaxPool + Flatten
Linear	flattened	25	ReLu
Linear	25	1	-

II. Experiment

In this section, we will discuss the dataset used in our study and the process of fitting and evaluating the CNN regression model performance.

A. Dataset description

We recorded echographic Bmode images from 24 subjects: 22 healthy, 1 with Osteogenesis Imperfecta, and 1 with Pulmonary Arterial Hypertension. From each subject we acquired bilaterally images from: proximal third of the forearm and distal third of the thigh. Patient laying in supine position, palms down, and probe perpendicular to the table. Five axial sections were taken from the forearms, while for the thighs we took also five longitudinal sections. The acquisitions were performed with an *EchoStation* device (Echolight S.p.a., Italy) equipped with a linear probe of 40 mm and a graphical user interface specifically designed for this task. For more details please refer to [7], [18]. The total number of images available were 720 (24 subjects $\times$ 30 images per subject), from which we generated the training and testing set accordingly to the following procedure.

The train set is composed by all and only the 660 images (22 healthy subjects $\times$ 30 images per subject) coming from healthy subjects, preprocessed as follows. After a resize to 256×256 grayscale image space, we transformed the healthy images to pseudo-pathological ones according to the procedure described in §I-A, and lastly normalized them pixel-wise to have zero mean and unitary standard deviation.

The test set is composed by all the 60 images of non healthy sucjects, namely the ones with Osteogenesis Imperfecta and Pulmonary Arterial Hypertension, plus all the 660 images coming from healthy subjects, preprocessed as above, but this time not altered by the pathology mimicking preprocessing algorithm, leading, for this last reason, to a never-seen-before testing set. The numerosity of the total data used for the testing set amount hence to 720 images.

B. Model fitting and evaluation

We fitted the CNN model described in § I-B, with the training pseudo-pathological images as input of the network, and the associated Pathological Indexes as output. We trained the network for 30 epochs and batch-size 8 with the *Adam* optimization algorithm [11] and the *Mean Squared Error* cost function, until convergence of the latter was reached.

Performance on the test set was computed by fitting the predicted PI for the three classes Healthy, OI, and PAH with three Gaussian distributions $\mathcal{N}(\mu_c, \sigma_c^2)$, where c is the class label. Then we computed the sensitivity and specificity, along with the area under the Receiver Operating Characteristic curve, by using as threshold value the intersection point between the probability density functions.

III. Results

In Fig. 3 we show the histogram of PI predicted by the CNN regression model for the three classes Healthy, OI, and PAH images.

In Fig. 4 and Tab. II we present the results in terms of AUC, sensitivity and specificity when the class separation threshold is the one identified by intersection of the Gaussian probability density functions used to fit the PI values predicted by the CNN regression model. The latter is able to accurately separate images of healthy subjects from those with OI and PAH pathology, respectively with AUC of 0.98 and 0.96, sensitivity of 0.93 and 0.97, and specificity of 0.91 and 0.81.

IV. Discussion

The study presents a valuable approach for objectively measuring pathological changes in echographic images of soft

tissue by using expert knowledge to simulate pathological changes in healthy images. It is intended as a promising preliminary investigation, which carries some initial limitations.

One limitation is that the sample size of pathological subjects may be too small to generalize the results to the entire population. However, we attempted to address this by collecting more images from different body regions and acquisition planes. It is nevertheless important to conduct more extensive studies with more variety in the pathological origin of the images to obtain more reliable and robust findings.

The simulated images are inherently different from real-world images, as they lack the noise, defects, and variability that are present in actual data. Nevertheless, by increasing the Pathology Index many more hyperechoic straight structures appear in the images as compared to the original healthy one. Such images seems then to provide enough variation in terms of size, location, of the artificial structures, to enable the algorithm to generalize to true pathological cases. Another strategy adopted to increase variation was to use in the learning phase images acquired on different anatomic sites and with different acquisition planes. With this strategy, the model is forced not to focus on specific anatomic details and not to take into account the unique characteristics of each body site or acquisition plane other than the ones needed for predicting the Pathology Index.

V. Conclusion

The results of this preliminary study show that a CNN trained on these pseudo-pathological images can effectively distinguish between healthy subjects and those with genetic disorders such as Osteogenesis Imperfecta and Pulmonary Arterial Hypertension, and that the simulation approach may be particularly useful in situations where data availability is limited.

***Abstract*—Imaging Genetics (IG) focuses on integrative studies to assess the influence of genetic architecture on brain structure and function, which is particularly relevant to decrypt the underlying mechanisms of complex pathologies such as Alzheimer's Disease (AD). To this aim, in this work, we exploited a Multi-Channel Variational Autoencoder (MCVAE) for investigating the genetic underpinnings of Grey Matter (GM) and White Matter (WM) modulations in the AD continuum with the twofold goal of (i) capturing the associations among multimodal features in the latent space; (ii) assessing the generative potential of the model to be eventually exploited for data augmentation and mitigation of the data skewed problem. Three channels were considered, respectively representing morphometric, microstructural and genetic features. The resulting common latent space was well aligned across the different channels, highlighting a clustering of the latent components concordant with different stages of AD. Regarding the generative performance, reconstruction accuracy revealed that diffusion MRI led to the best performance, especially when decoded from structural MRI, while neither the microstructural nor the genetic channel allowed effective decoding of the others. This might most probably be due to the limited data numerosity and the inherent limitations of the MCVAE architecture. Our preliminary results provide evidence of the potential of multi-modal feature integration with MCAVE models for decoding subtle disease signatures and highlight some limitations of the model providing hints for further improvement.**

***Keywords*—MCVAE, Imaging Genetics, diffusion MRI, structural MRI, SKAT**

I. INTRODUCTION

Alzheimer's Disease (AD) is the most common cause of dementia, affecting 46.8 million people worldwide [1]. There is still much debate about the pathophysiology underpinning brain modulations in Alzheimer's Disease (AD). For example, while structural Magnetic Resonance Imaging (sMRI) derived phenotypes (IDPs) are well-established biomarkers for AD detection [2], it is not clear whether white matter (WM) alterations are related to, or independent from, gray matter (GM) degeneration in AD. For this reason, the role of microstructure is increasingly being considered in AD studies [3]. Moreover, there is consistent evidence of a strong genetic contribution to AD. Recent strategies to extract genotype traits linked with AD overran the classical Single Nucleotide Polymorphism (SNPs) approach and moved towards grouping multiple SNPs into the so-called SNP sets. A natural grouping technique consists in taking all SNPs that are found within a gene. Among such approaches, Wu and colleagues proposed the Sequence Kernel Association Test (SKAT) [4], a logistic kernel-machine regression model for testing the association between SNP sets and a given disease which has demonstrated promising results in different conditions, though its exploitation in AD is still limited. There is hence growing evidence that multimodality can aid in providing a more thorough understanding of mechanisms underlying complex and multifaceted diseases such as AD. The specific association between genetic measures and IDPs is, in particular, the target of Imaging Genetics (IG), which focuses on integrative studies to assess the influence of the genetic architecture on brain structure and function [5]. To this aim, mass-univariate methods or more advanced latent space based methods have been typically proposed [6]. However, because they are not generative, these approaches provide limited information regarding how this latent representation is reflected in the data as they do not provide a mean to sample observations when the distribution of latent variables (LVs) is known. To overcome this limitation, Kingma *et al.* [7], proposed a generative model for high-dimensional single-modality data, the Variational AutoEncoder (VAE). VAEs are models that couple a recognition function (encoder) to infer a lower dimensional representation of the data, with a generative function (decoder) which transforms the latent representation back to the original observation space. This approach was further expanded by Antelmi et al. [8] to ensure multimodal data could be enclosed in this framework without the need to concatenate multiple channels in a single input. In particular, a multichannel VAE (MCVAE) was proposed with each channel representing a different modality, requiring that their associated latent representation match a shared target distribution. This technique was successfully adopted in multiple scenarios, among which the very recent work of Diaz Pinto *et al.* where the authors predicted myocardial infarction through retinal scans and minimal personal information [9]. In relation to AD, an extension of MCVAE was recently exploited in [10] aiming at the modeling of the spatio-temporal dynamics of longitudinal imaging and clinical biomarkers along the history of the disease.

Along this line, the aim of this work is to assess the capabilities of multi-channel biomarkers for decrypting the underlying mechanism across AD continuum. We exploited

the MCVAE relying on two different imaging techniques describing both WM and GM IDPs, as well as gene-based variant scores as genetic determinants (GDs) aiming at assessing both the unsupervised latent space clustering and the decoding performance of one channel from another addressing skewed data compensation.

II. Materials and Methods

A. Study cohort and feature processing

IDPs and GDs were obtained from the ongoing Alzheimer's Disease Neuroimaging Initiative (ADNI) Phase 3 dataset. The cohort comprehended 297 subjects divided into 220 controls (CN) and 79 patients (PAT), 19 of which were AD while the remaining were mild cognitive impairment (MCI) subjects.

3D T1-weighted (T1-w) MRI and diffusion MRI (dMRI) volumes were used for IDPs extraction (3D T1-w: sagittal accelerated MPRAGE, $1mm$ isotropic voxel; single shell dMRI: $2mm$ isotropic voxel, b=$1000s/mm^2$). The T1-w volumes were preprocessed for bias-field correction with FSL (version 6.0). Subsequently, 84 anatomical Regions of Interest (ROIs) were extracted using FreeSurfer (version 7.0) including thicknesses and volumes for cortical and subcortical ROIs, respectively. The subcortical volumes were normalized by the estimated total intracranial volume of each subject. The ROIs were averaged over hemispheres resulting in 42 features. The dMRI volumes were preprocessed by applying brain extraction followed by Eddy currents correction (FSL, version 6.0). The data was then denoised using local principal component analysis (PCA) via empirical thresholds relying on Python *dipy* library. Subsequently, nonlinear registration to the MNI space was applied to correct for EPI-induced currents. The Diffusion Tensor Imaging (DTI) [11] model was fitted, and Fractional Anisotropy (FA) and Mean Diffusivity (MD) indices were extracted. The tract-based spatial statistics (TBSS) pipeline from FSL was then applied (FA threshold of 0.2). For all subjects, the average value of FA and MD was retained from 48 ROIs derived from the JHU-DTI atlas available in FSL and averaged over hemispheres, resulting in 27 features for each index. For the GDs, quality control (QC) procedures were conducted on genotype data (PLINK, Version 1.9). SNPs and subjects were filtered out based on missingness ($geno > 0.2$, $mind > 0.1$), minor allele frequency ($MAF > 0.05$) and deviations from Hardy–Weinberg equilibrium ($hwe > 1e{-}06$). QC kept 303.150 SNPs out of the 759.993 SNPs collected in ADNI3. No subjects were filtered out. SNP set analysis was applied using SKAT including the top ten principal components from PCA, age and gender as covariates. SNP sets were defined at the gene level, each one including only SNPs located in exon regions. Then, for each subject and for each significant gene resulting from SKAT, a gene-based variant score was extracted as a measure of the mutation rate of the SNP set located in each gene, resulting in 408 features for each subject. All the input features for each channel were standardized to reach zero mean and unitary variance. The influence of age was regressed out from imaging channels.

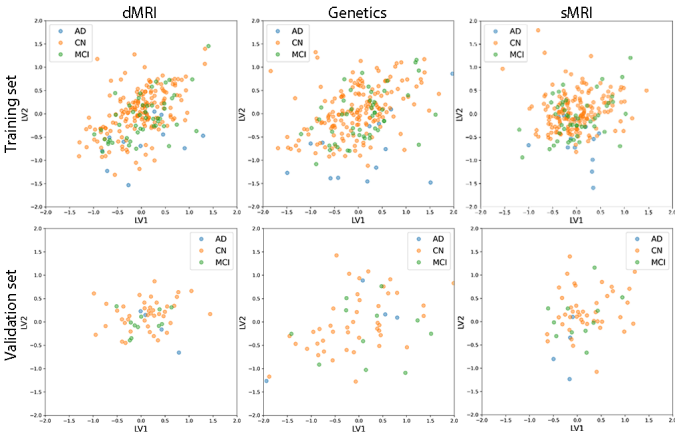

Fig. 1: Latent representation of the training and validation sets (rows) considering the two most significant LVs, separately for each input channel, namely dMRI, sMRI and genetics (columns, AD: blue, CN: orange, MCI: green)

B. Experimental Settings

A three channels MCVAE was employed. The 42 T1-w derived IDPs (cortical thickness/subcortical volumes) represented the sMRI channel, while the 54 tract-based average values for FA and MD were used for the dMRI channel. Finally, the 408 gene mutation scores were included in the genetic channel. A multivariate Gaussian distribution was assumed for the posterior, hence the encoder aimed at finding the parameters, representing the mean and variance for each channel. A single layer (linear) architecture for the encoder and the decoder was employed. This architecture resulted as the best performing in the experimental tests presented in [8]. Moreover, we performed several empirical tests by varying the number of layers and introducing nonlinearities, as well as dropout layers, without achieving a significant increase in performance. Three LVs were chosen for the latent space. Validation was performed following a 5-fold Cross Validation (CV) strategy. Decoding performance was assessed through the computation of Mean Squared Error (MSE) of each decoded feature for each channel, considering the best model derived from the 5-fold CV.

III. Results

A. Latent space

Fig. 1 shows the latent space generated by the first and the second LVs, separately for each input channel (columns) for both the training and the validation set (rows). The LVs were chosen based on the associated dropout probability, which reflects the related importance. In general, the latent spaces for each channel were well aligned, with the dMRI and the genetic components showing a more similar distribution compared with the sMRI one. Moreover, for the training set, a class clustering was present and was coherent among the input channels, with the AD subjects being located in the bottom-right part of the plot, and the MCI being located in the center

TABLE I: MSE reconstruction values for dMRI channel

dMRI feature reconstruction from Genetics		dMRI feature reconstruction from sMRI	
	MSE		MSE
PCT_MD	0.594	RLIC_MD	0.260
PLIC_MD	0.617	SCR_MD	0.296
CST_MD	0.643	SLF_MD	0.313
ALIC_MD	0.686	PLIC_MD	0.322
SCR_MD	0.741	SS_MD	0.344
EC_MD	0.752	FXST_MD	0.365
CST_FA	0.758	ALIC_MD	0.389
SLF_MD	0.784	PCT_MD	0.393
PCR_MD	0.817	EC_MD	0.395
CP_MD	0.841	SFO_MD	0.398

dMRI acronyms: Pontine crossing tract (PCT), Posterior limb of internal capsule (PLIC), Corticospinal tract (CST), Anterior limb of IC (ALIC), Superior corona radiata (SCR), External capsule (EC), Superior longitudinal fasciculus (SLF), Posterior CR (PCR), Cerebral peduncle (CP), Retrolenticular part of IC (RLIC), Sagittal stratum (SS), Fornix/Stria terminalis (FXST), Superior fronto-occipital fasciculus (SFO)

and overlapped with CN mostly located in the upper-left area. This clustering was not clearly present for the validation set.

B. Best-reconstructed features

Tab. I provides the reconstruction performance of the top ten best-reconstructed dMRI features for the validation set, decoding from genetics and sMRI. The ranges of the feature values for the standardized input feature were $[-5.355, 4.847]$ for sMRI, $[-5.611, 4.237]$ for dMRI, and $[-2.989, 4.658]$ for genetics, respectively, having zero mean and unitary variance after standardization. Fig. 2 shows the scatter plots of the top ten best-reconstructed features for the dMRI channel.

In general, a better reconstruction of dMRI features, compared with sMRI ones (not reported in table) was recorded. In particular, the best dMRI reconstructed features were the MD-derived either decoding from genetics or sMRI. SMRI led to the best reconstructions. The tracts part of the external and internal capsule were among the best-decoded ones with low MSE values (RLIC: 0.260; PLIC: 0.322; ALIC: 0.389; EC: 0.395). The SCR reached an MSE of 0.296, much lower compared to the 0.741 reached by decoding from genetics. The other well dMRI decoded features starting from sMRI were the SLF, SS and FXST with an MSE of 0.313, 0.344, 0.365 respectively. Considering the decoding performance of genetic features, they generally showed higher MSE, with the best-decoded dMRI metric being the PCT (MSE = 0.594). Moving to the reconstruction of sMRI features, better reconstruction was achieved decoding from dMRI compared to genetics. The decoding from dMRI saw the accumbens having the lowest MSE of 0.790 followed by the bankssts and the posterior cingulate gyrus (MSE = 0.826, 0.844). All the other top ten best-decoded features had an associated MSE higher than 0.9. Considering the genetic as decoding input, all the sMRI reconstructed features had an MSE greater than 0.9, with the AC being the best-decoded feature (MSE = 0.926). The other features were mainly part of the cingulus and the cuneus, each having an MSE value higher than 1.

IV. Discussion

In this work, we presented preliminary results for unraveling the underlying association between brain structural and microstructural modulations with gene-based variant scores in AD relying on an unsupervised MCVAE. A latent space consisting of 3 LVs was used along with three input channels, corresponding to the multi-modal features. In particular, ROI-based volumes and thicknesses represented the sMRI channel, tract-based FA and MD values the dMRI one, and gene-based variant scores the genetics. We analyzed both the resulting latent space, defined by the LVs having the lowest dropout probability, and the decoding performance of one channel from another. Our results showed that there is a good alignment between the latent spaces derived from each channel, as well as sufficient clustering between AD stages. Instead, the decoding performance was not competitive.

Our work is inspired to [9] where the MCVAE model proposed by [8] was applied for predicting myocardial infarction from retinal scans. The MCVAE and a deep regressor model were trained to estimate left ventricular mass and left ventricular end-diastolic volume and predicted the risk of myocardial infarction using only the retinal images and demographic data. Their results indicated that it is possible to identify patients at high risk of future myocardial infarction from retinal images that are available in every optician and eye clinic. Moreover, an extension of the MCVAE recently proposed by [8] was applied in relation to AD[10] to model the dynamics governing the joint evolution of longitudinal imaging and clinical biomarkers along disease progression. More in detail, the authors accomplished to simulate the effect of the intervention time and drug dosage on the biomarkers' progression in an ADNI study cohort, further verified on a separate independent AD cohort.

To the best of our knowledge, our work is the first attempt to jointly investigate genetics, sMRI and dMRI as inputs to a MCVAE model to highlight their association in the AD continuum, as well as their capability in differentiating AD stages in an unsupervised manner, and the pair-wise decoding capabilities of the considered modalities. With this work we firstly demonstrated that the obtained latent space for each channel resulted well aligned to the others, particularly for the training set and between dMRI and genetics channels. This confirms that a common representation between channels was effectively found by the MCVAE. Moreover, a gradient of the different classes considered, starting from CN and arriving at AD, passing through MCI, was also present, highlighting that despite the MCVAE being unsupervised, a latent space representative of the disease continuum could be captured. Moving to the reconstruction performance, the lower MSE was obtained when decoding dMRI from sMRI data. The genetic channel did not achieve sufficient reconstruction performance in either decoding from sMRI or dMRI IDPs. However, this possibly seeds in the MCVAE architecture. In fact, VAEs are trained to optimize a lower bound on the likelihood of the data which is a trade-off between the reconstruction error

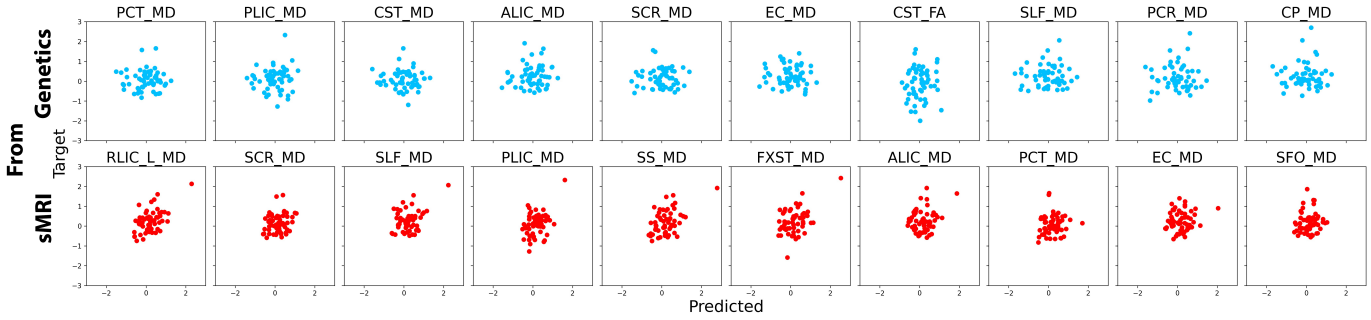

Fig. 2: Scatter plots of the best-reconstructed dMRI features decoded from the other two channels. The reconstructed features are plotted against the respective ground truth

and the divergence between the approximate posterior and the true posterior. This trade-off can result in the model prioritizing a low divergence over a high reconstruction accuracy, which leads to less precise reconstructions, while obtaining informative latent representations. Additionally, the posterior distribution estimated for the latent space of each channel is a multivariate Gaussian, which well fits the distribution of imaging data but not the genetic one which instead follows a categorical distribution. This represents the major limitation of this approach with the chosen input data. However, it is still interesting to analyze the best-decoded IDPs for clinical interpretation and validation. For dMRI, which achieved the best performance, the MD-derived IDPs were the best decoded, compared with FA. In particular, the best-decoded tracts were part of the internal capsule and the corona radiata which were also found with increased diffusivity in MCI compared to healthy controls in [12], demonstrating a relevant role in AD continuum. Decoding dMRI from sMRI can potentially impact clinical applications where important constraints related to image acquisition timing hold, particularly when dealing with AD patients. MRI image translation, is being hence studied since it would allow to exploit standard clinical acquisitions to derive advanced metrics such as microstructure IDPs [13]. In this respect, our results show the possibility to decode tract measures from sMRI images through MCVAE deserving further investigation. Future works will rely on a different prior latent space distribution from the Gaussian used in this study in order to better reflect the input feature distributions and thus potentially allowing to reach also better reconstruction performance. Finally, extending the study cohort would allow having an independent test set besides the validation sets of the 5-fold CV considered in this study in order to further evaluate the performance of the proposed MCVAE model.

V. Conclusions

This work is the first step towards the application of MCVAE with the twofold goal of finding a common latent space between input channels and decoding one channel from the other, demonstrating its potentialities to uncover the association between imaging (sMRI and dMRI) and genetics (gene-based variant scores) in the AD continuum.

***Abstract*— Advanced Magnetic Resonance Imaging (MRI) techniques, such as Diffusion Weighed Imaging, usually require long acquisition times and an open challenge is to reduce the acquisition time more and more in order to allow their use in the clinical routine. Downsampling k-space is a way to speed up MRI, but this can generate artefacts in the resulting images when reconstructing them with standard Fourier transform methods.**

Here, we used deep learning to perform the inverse Fourier transform from k-space to the Diffusion Weighted (DW) images. and used it to assess the quality of images obtained from significantly reduced k-space acquisition strategies. The hypothesis is that a deep learning algorithm would preserve data quality, learned from the fully sampled k-space association. We tested our deep learning algorithm by reducing the number of acquired k-space rows by 30%, which would correspond to a total acquisition time reduction. We considered different types of k-space downsampling. All the trained networks were able to map the relationship between k-space and DW images, reducing artefacts.

In conclusion, this work paves the way to designing acquisition strategies for fast diffusion imaging.

***Keywords*— k-space, deep learning, reduce time acquisition, diffusion magnetic resonance.**

I. INTRODUCTION

MAGNETIC resonance imagining (MRI) is a very powerful tool used in the clinical field to diagnose, to monitor and to study mechanisms behind human behaviour, function and dysfunction. The great power of MRI depends on the fact that this tool can be exploited to investigate several organ systems and that it can be made sensitive to specific properties of the tissues, such as the diffusion of water molecules to probe tissue microstructure. Diffusion Weighted Imaging (DWI) is sensitive to Brownian motion of water molecules in tissue and, hence, to the microstructure and its alterations in pathological conditions [1][2].

The use of MRI in the clinic is limited to qualitative assessments of brain lesions and morphology due to both high costs and long acquisition times for quantitative MRI.

Furthermore, it is to note that when an MRI acquisition is performed, the signal received with the coil is stored as an image containing the spatial frequency information of the object, called k-space. Importantly, each point of the k-space contains phase and frequency information about the signal coming from the entire sample. For this reason, applying the inverse Fourier transform (FT) to the k-space provides the image in physical space [3] [4].

Moreover, it is known that k-space is highly redundant [5]. It is indeed endowed with Hermitian symmetry [4]. Traditionally, the relationship between k-space data and image data is the Fourier transform (FT) [3].

Here we aimed to shorten the acquisition times of DWI of the brain reducing k-space coverage (i.e. the signal) and substituting the FT operation with a deep learning network, while maintaining image quality. In this way, one of the novelty of our method is that it was possible to downsample the k-space, in order to reduce the acquisition time, obtaining an image that is very similar to the one reconstructed from the entire k-space.

Previous work used a deep learning network to pass from the k-space to the DW physical image of the breast with the main goal of reducing DW-related artifacts [6]. However, in this work the network used as its input the entire acquired k-space, instead of a downsampled version like we did here.

We therefore optimised a network previously proposed [7] for reconstructing T1 and T2 weighted images from their k-space and adapted it to the specific case of DWI data [1]. One of the challenges is that DWI can produce very different contrasts depending on the applied diffusion weighting; mathematical or signal models can then be fitted to DWI data to obtain microstructure parameters maps. The automated transform by manifold approximation (AUTOMAP) [7] network was therefore adapted and optimised here to work with DWI k-space data, independently on the diffusion weighted applied. We gave it as input the k-spaces of the diffusion acquisitions and as output the corresponding magnitude images.

II. METHODS

A. Subjects

The database included images of 18 healthy controls (HC, 13 Females, 55.2±9.4 years), 8 primary progressive multiple sclerosis (PPMS, 3 Female, 56.3±9.9 years), 2 relapsing-remitting multiple sclerosis (RRMS; 1 Females, 64±3.6 years), and 31 secondary progressive multiple sclerosis (SPMS; 21 Females, 55.3±7.3 years). 18 subjects were acquired a second time, 18 months after baseline. The total number of datasets was 77.

B. MRI acquisition

A 3T Philips Ingenia CX scanner was used. The Diffusion Weighted (DW) imagining protocol included a spin-echo EPI with TR = 6287 ms, TE = 96 ms, 76 volumes with b = 1000/2000/2800 s/mm2 (20/20/36 DW per b-value) and 3 b0 volumes. The spatial resolution was 2x2x2 mm^3 and the matrix size was 112x112x72.

C. Network design

Each DW dataset was used as an independent sample, regardless of whether it belonged to a subject previously acquired. This choice depended by the fact that the problem to be solved was to associate each k-space with its magnitude image. Since the problem could be reduced to assess a regression between datasets, i.e. finding a relationship between input and output, instead of classifying them in different groups, we therefore used the entire dataset regardless the group (i.e., healthy subject or patient), gender (female or male), or any other demographic feature. The 77 acquisition samples were divided as follows: 53 acquisition samples were used for training, 12 for validation and 12 for test. In each set (training, validation and test) there were both healthy and MS subjects.

The magnitude image was calculated for each slide from real (Re(DW)) and imaginary images (Im(DW)):

$$magnitude\ image = \sqrt{Re(DW)^2 + Im(DW)^2} \quad (1)$$

Using the Fourier transform (FT), the k-space of the magnitude images was calculated:

$$k - space = FT(magnitude\ image) \quad (2)$$

Only DW volumes with a b-value of 0 or 1000 s/mm^2 were considered, so 23 volumes were used for each acquisition dataset. We limited the number of volumes by using the most commonly acquired b-value [8] in order to reduce the amount of data and thus the training time to cope with long calculation times and memory problems. Consequently, for training, the number of input data was 76337 (53 subjects, for each subject 23 volumes, and for each volume about 63 slices), for validation 18699, and for test 18446.

The k-space data had to be normalised before being passed as input: for each batch size, the real and imaginary part was divided by magnitude of the maximum of all values in the entire database.

The 2D k-space matrices in axial planes were then given as input to the network. The real and imaginary parts of the k-space were provided as 2 input channels.

The output target for the network was the magnitude image corresponding to the DW k-space data.

We adapted the AUTOMAP architecture [7]. The network was developed using TensorFlow (Keras) [9] and each network training was run using an NVIDIA Tesla T4 GPU.

We had a k-space of size m x n: the complex data of the k-space were separated into real and imaginary parts and were given to the network as input to two different channels (m x n x 2). The network architecture is pictured in Fig.1.

This architecture was made of two fully connect layers (FC) at the beginning, followed by three convolutional layers (Conv). Because of the fully connected layers, the number of network parameters increases noticeably and makes training very slow. For this reason, it was necessary to resize the k-space from a 112x112 matrix to a 64x64 one. The k-space and DW images were resampled using spline interpolation.

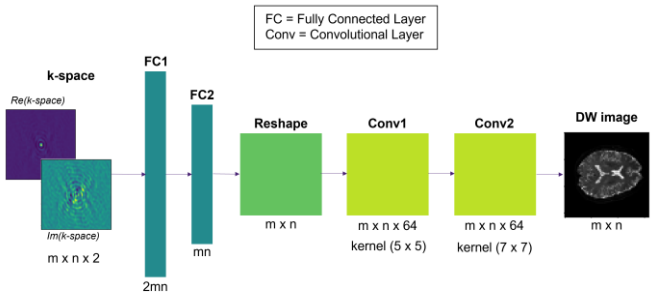

Fig. 1: Architecture of AUTOMAP.

D. Network training

The tuning of the hyperparameters was conducted by giving as input the k-space and as output the corresponding DW magnitude images, both of reduced size i.e. 64x64; we called this experiment *from 64 to 64*.

We searched manually for the best hyperparameter configuration by training the network several times and changing the loss function, activation functions and optimizer. The best hyperparameters were selected minimizing the Root Mean Square Error (RMSE) on the validation set.

In order to prevent the overfitting we applied data augmentation on the fly [10] using two different ways: images were randomly rotated anti-clockwise by 0, 90, 180 or 270° and images were scaled in intensity by a random value so that they became darker or brighter.

E. Network applications

Once the hyperparameters of the network were fixed, four experiments were considered to train the network accordingly:

- *from 64 to 112:* from a k-space of size 64x64 to a magnitude image of 112x112, increasing the resolution along each of the 2D dimensions of the image from 64 to 112. The DW magnitude image was therefore in the original space.
- *Zero fill*: from a k-space of size 64x64, with the last 19 rows filled with zeros, to a corresponding magnitude image of size 64x64.
- *Delete rows:* from a k-space of size 45x64, where the last 19 rows were deleted, to a corresponding magnitude image of size 64x64.
- *Mixed downsampling*: from a k-space of size 45x64, where the last 19 rows (top) or the first 19 rows (bottom) were deleted, to a corresponding magnitude image of size 64x64. This last network aims to test whether AUTOMAP can cope with different downsampling or needs retraining every time k-space

is sampled differently.

In the last three experiments we reduced the k-space acquisition of 30%, applying some downsampling by deleting k-space rows from different positions. Importantly, k-space was downsampled in ways that could be easily implemented from a pulse sequence design point of view, i.e., directly modifying sequences on an MRI scanner.

F. Quantitative evaluation

To compare the DW magnitude images obtained with the traditional FT of k-space and those obtained with the network, it was necessary to normalise the intensity of both images to eliminate simple scale factors. For each acquisition sample, both DW images (GT and network) were divided by the value of the maximum of the respective 4D volume (i.e. including all 23 DW volumes), limiting the calculation to voxels in the brain.

To quantitatively assess how much the two images (DWI GT and DWI network) differed, we calculated the difference image considering the case *from 64 to 64*.

For the experiment with mixed downsampling, we tested the network by giving as input once the first 45 rows (top) and once the last 45 rows (bottom) of k-space.

The Root Mean Square Error (RMSE), Mean Absolute Error (MAE) and Structural Similarity Index (SSIM) [11] calculated between the magnitude DW image and the network output within the brain were chosen as performance metrics.

III. RESULTS

The best hyperparameters were found to be: the sum of RMSE and SSIM as loss function, the hyperbolic tangent for the fully connected layers and the REctified Linear Unit (ReLU) for the convolutional layers using as activation function and the Root Mean Square Propagation (RMS Prop) as optimizer.

Fig. 2 shows the input, the k-space with real and imaginary part, the desired output (GT) and the output of the network of the performed experiments: from 64 to 64 (A), from 64 to 112 (B), zeros fill (C), delete rows (D), mixed downsampling (top) (E) and mixed downsampling (bottom) (F).

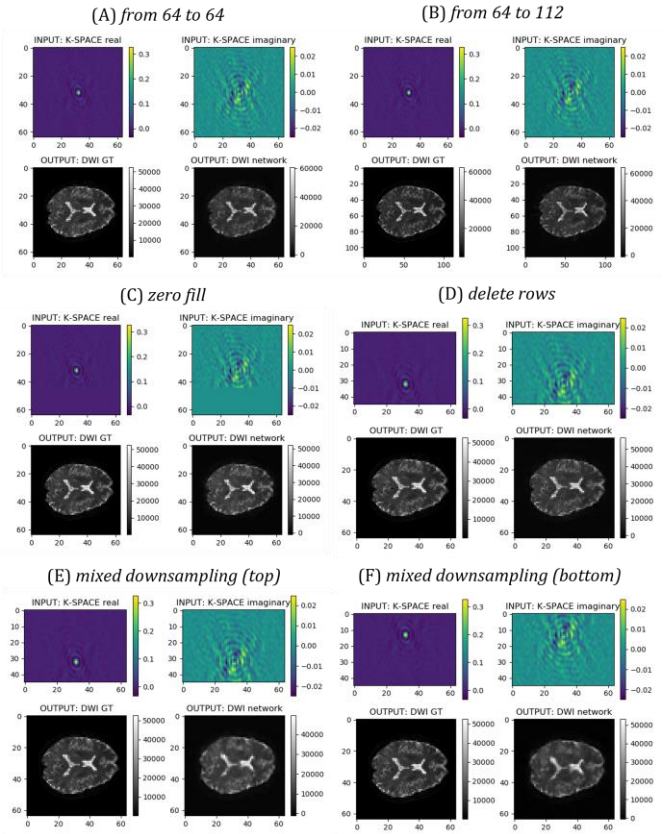

Fig. 2: Each different experiment is shown in each image from (A) to (F). The first row shows the input to the network: on the left the real part and on the right the imaginary part of the k-space. The second row shows the magnitude Diffusion Weighted (DW) image: on the left the ground truth (GT) (desired output) and on the right the output of the network.

Fig. 3 shows for a random test subject the DW images, i.e., DWI GT and DWI network, after the intensity normalization and their difference image in the case *from 64 to 64*.

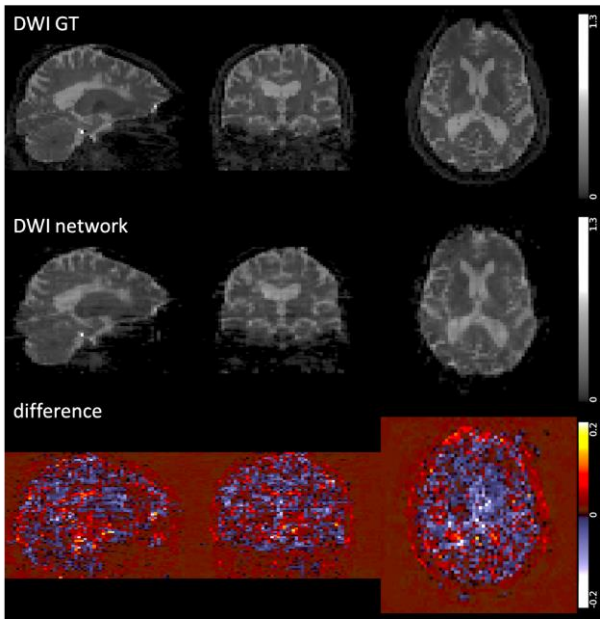

Fig. 3: The first row shows the DWI GT, the second row the DWI network and the third row the image of the difference between the first two rows for a random test subject.

Table I shows the performance metrics (mean and standard deviation) between the GT DW images and the network DW images, calculated on the 12 test subjects over voxels that belong to the brain mask.

TABLE I: PERFORMANCE METRICS ON THE TEST SUBJECTS FOR EACH NETWORK EXAMPLE.

	RMSE	**MAE**	**SSIM**
from 64 to 64	0.035 ±.0.004	0.022 ±.0.004	0.757 ±.0.057
from 64 to 112	0.020 ±.0.007	0.015 ±.0.006	0.734 ±.0.228
zeros fill	0.030 ± 0.012	0.020 ± 0.007	0.660 ± 0.208
delete rows	0.032 ± 0.01	0.021 ± 0.007	0.655 ± 0.206
mixed downsampling (top)	0.034 ± 0.011	0.021 ± 0.007	0.658 ± 0.207
mixed downsampling (bottom)	0.034 ± 0.011	0.022 ± 0.008	0.657 ± 0.207

IV. DISCUSSION AND CONCLUSION

We adapted the AUTOMAP network to obtain DW images starting from the relative k-space data.

The network was trained in five different types of experiment. In the simplest case, we started with a k-space of size 64x64 and obtained an image of 64x64. In this case, the best values of the performance metrics were obtained (RMSE = 0.035±0.004; MAE = 0.022±0.004; SSIM = 0.757±0.057).

Notably, the DW images reconstructed with the network showed no region-specific bias with respect to the original ones, as demonstrated with the difference image (Fig. 3).The next four experiments were performed to reconstruct the original DW images from a reduced k-space.

The network is able to capture the relationship between k-space and DW images, even in experiments performed to reconstruct the original DW images from a reduced k-space (Fig. 2; Table I).

In the mixed downsampling case, the network was trained by considering different downsampling of the k-space, i.e. removing rows from above or below the centre of the k-space. In this case, the output obtained on the 12 test subjects achieved similar performance by applying one of the two downsampling strategies.

Furthermore, it is to note that DW images obtained with the network appear to be less noisy. The intrinsic denoising function of the network may be due to the fact that the network learns the relationship between input and output only by structured associations and since noise is random, it is not learned.

To strengthen this work, further analysis will be performed: in the future, we will apply k-cross validation to better estimate the intrinsic power of the model and to assess it for potential overfitting. Furthermore, to evaluate the sensitivity of our DL reconstructions to the presence of pathology, we will calculate quantitative maps from DW images in both cases (i.e., GT and network) and perform group comparisons between healthy and neurological cohorts. We will therefore determine whether the images reconstructed with the network are able to maintain the details of the original images and are sensitive to pathology (e.g. in lesions of subjects with multiple sclerosis).

Furthermore, it would be useful to check whether it would be possible to further reduce the number of k-space rows without losing the quality of the DW image.

***Abstract*—The identification of the primary tumor location in patients with head and neck carcinoma of unknown primary involves an invasive and complex diagnostic protocol, thus fostering the development of non-invasive methods. Herein, a radiomic-based approach was proposed to distinguish between oropharynx and nasopharynx primary tumor location from the lymph nodes segmented in magnetic resonance images of head and neck cancer (HNC) patients. A total of 200 HNC patients (100 oropharynx and 100 nasopharynx) were considered. 10-fold cross-validation with class proportion was applied. Five different feature selection methods and five machine learning classification algorithms were tested. Overall, a high classification performance was achieved by all the combined feature selections/machine learning algorithms, with the best results obtained from the support vector machine and the neural networks algorithms with neighborhood component analysis (acc 100%).**

***Keywords*—Radiomics, machine learning, head and neck cancer.**

I. Introduction

Head and neck cancer (HNC) is the seventh most common type of cancer worldwide and affects around 660,000 people each year[1]. It is an aggressive and clinically and biologically heterogeneous disease, which makes patient stratification and treatment decisions challenging. Several different malignant tumors that grow in or around the throat, larynx, nose, sinuses, and mouth are referred to as HNC [2].

Up to 5% of all HNC are carcinomas of unknown primary, i.e., cancer that has spread to lymph nodes in the upper neck, but it is not known where it was first formed in the body[3]. The diagnostic protocol to identify the primary occult tumor is complex and extensive, but it is essential to guide the treatment. The protocol consists of initial clinical assessment (including fiberoptic laryngoscopy) followed by computed tomography and/or magnetic resonance imaging (MRI). When these examinations fail to identify the primary tumor, patients are requested to undergo a whole-body positron emission tomography imaging. Nevertheless, if the primary tumor is still occult, a panendoscopy with biopsy is performed at risk hidden tumor sites. As a result, developing methods to better and non-invasively identify the origin of the unknown primary tumor is a necessity [3], [4].

In recent years, radiomics has emerged to be a valuable tool in precision medicine. It is a novel type of omics that involves extracting high-throughput quantitative features from medical images and developing machine learning prediction models based on the extracted images features. It is capable of characterizing the overall tumor non-invasively while accounting for heterogeneity [5], [6]. Radiomics can also help to better diagnose and classify pathologies, guide treatment selection by forecasting illness evolution and even guide comprehensive postoperative care [7]–[9]. Moreover, radiomics provides a quick, low-cost, and repeatable method for longitudinal monitoring. Thus, it is a valuable tool to be used as clinical decision support [10], [11].

In previous studies, researchers have used radiomic and machine learning techniques in MRI images to build prognostic models in oral and oropharyngeal cancer [12], to predict the treatment response of metastatic cervical lymph nodes in nasopharyngeal carcinoma [13] and to grade and stratify risk in nasopharyngeal carcinoma [14], [15]. Ho et al.[16] aimed to distinguish malignant from benign and extranodal extension (ENE) from non-ENE lymph nodes in HNC patients. However, to the best of our knowledge, the differentiation of lymph nodes with respect to two primary tumor locations (oropharynx or nasopharynx) has never been addressed using radiomics and machine learning techniques. This study aims to fill this gap by developing and validating a novel MRI-based radiomic prognostic model for patients with HNC of unknown primary. The goal is to design the best machine learning model capable of assisting clinicians in predicting the primary tumor site of patients diagnosed with head and neck carcinoma of unknown primary.

II. Patients and Methods

A. Patient description

The dataset is composed by HNC patients collected within the European project BD2Decide (https://www.bd2decide.eu/), which consists in developing personalized prognostic tools for HNC patients with the goal to maximize the outcomes of the treatment while minimizing the effects. Details on the dataset can be found in [17]. In particular, a subgroup of the patients was considered: 100 having the primary tumor location found in oropharynx (OPh) and 100 in the nasopharynx (NPh) area. Table I summarizes the clinical characteristics of these patients. The region of interest (ROI) was defined as cervical lymph nodes manually segmented from T1-weighted (T1w) and T2-weighted (T2w) images acquired using turbo spin-echo pulse sequences. The protocols were approved by the Ethical Committee of the National Cancer Institute of Milan (Italy), and all patients signed an informed consent.

B. Methods

The proposed radiomic workflow was based on a supervised learning approach and consisted in five steps: 1) feature extraction, 2) feature preprocessing, 3) dataset partition, 4) feature selection, 5) model development and validation. The software Matlab R2022b (MathWorks, USA) was adopted to accomplish these steps.

1) Feature extraction

Radiomic features were extracted using Pyradiomics software [18], including shape and size features, first order features, second order features as well as wavelet features [6]. A total of 1072 features were computed. Features stability was assessed using geometrical transformations (translations) of the ROIs as in [19] by applying different translation of the ROI in the positive and negative direction of the x and y, respectively. The entity of the translation was 10% of the length of the bounding box of the tumor in the corresponding direction (x or y). For each patient, the radiomic features were extracted from 5 different ROIs (the original cervical lymph node and the 4 translated versions). Intraclass correlation coefficient (ICC) was used to quantify the stability of each radiomic feature [20]. A feature was considered stable if ICC was higher than 0.75 [21]. The stability analysis was performed to first order, textural and wavelet features. A total of 265 stable radiomic features per patient was thus considered.

2) Feature preprocessing

In the feature preprocessing step, the redundant radiomic features were removed using pairwise correlation. In particular, when a pair of features had an absolute Spearman correlation coefficient above 0.85, the one with lower mean correlation with all the other *n-2* features was selected. After removing the highly correlated features, z-score standardization was performed to the remaining features.

3) Dataset partition

Dataset was partitioned by applying 10-fold cross validation method and considering the class proportion. As a result, a training set and test set composed of 180 and 20 patients were obtained, respectively.

4) Feature selection

To reduce the dimension of the feature set, feature selection was performed on the training set previously obtained. In particular, five feature selection methods were assessed, namely, sequential forward selection (SFS), sequential backward selection (SBS), sequential forward floating selection (SFFS), neighborhood component analysis (NCA) and minimum redundancy maximum relevance (MRMR). Both SFS and SBS feature selection techniques were applied in the study using Matlab function *sequentialfs*. The NCA and MRMR algorithm were assessed using Matlab function *fscnca* and *fscmrmr*, respectively. Concerning the SFFS method, the implemented algorithm consisted mainly in two parts: one that included features and the second that excluded. Every time a feature was included or excluded, an accuracy was obtained and compared with the previous maximum accuracy. When the current accuracy increased by adding (excluding) a feature, that feature was kept in (removed from) the feature set. In this way, the algorithm assessed the existent feature combinations extensively.

5) Model development and validation

After selecting the most relevant features according to each feature selection algorithm, various machine learning models were developed and validated with the test set. The five machine learning models assessed were neural network (NN), naïve Bayes (NB), support vector machine (SVM), decision tree (DT) and bagged trees (BT). Thus, for each feature set obtained from a feature selection method, the five models were trained and tested, resulting in a total of 25 radiomic-based models. To compare the performance of the models, accuracy and area under the ROC curve (AUC) were computed.

III. RESULTS

A systematic analysis was performed to study the influence of the feature selection methods (SFS, SBS, SFFS, NCA and MRMR) and machine learning algorithms (NN, NB, DT, BT and SVM).

Concerning feature selection methods, the summary of feature categories selected by each method is listed in Table II. The total number of features selected by each method was distinct, ranging from 3 features selected by MRMR algorithm and 26 selected by SBS. Overall, wavelet features were more often preferred by the feature selection methods compared to the original features. This might be attributed to the intrinsic characteristics of wavelet radiomic features compared to the original ones, such as: (i) the ability to highlight intricate details and allow for a more nuanced analysis of image texture and morphology at various scales, making them suitable for complex morphologies, and (ii) the increased robustness to noise [22].

TABLE II: LIST OF RADIOMIC FEATURE CATEGORIES SELECTED BY DIFFERENT METHODS

Feature selection	*Original*			*Wavelet*		*Total*
	SS	*FOF*	*SOF*	*FOF*	*S0F*	
SFS	1	1	1	3		6
SBS	2	3	2	6	13	26
SFFS	1		1	2		4
NCA	1	1	2	6	3	13
MRMR			1	2		3

SS: shape and size; FOF: first order feature; SOF: second order feature.

The influence of the feature selection methods and machine learning models were simultaneously compared plotting colormaps as represented in Figure 1, where each colormap refers to a performance metric (accuracy and AUC) obtained by the training set or the test set. The rows represent the feature selection methods (SFS, SBS, SFFS, NCA and MRMR), whereas the columns represent a machine learning model (NN, NB, SVM, DT, BT).

Comparing the colormaps obtained for each machine learning model, it is evident that NN and SVM (first and third columns in the figure) outperformed the other models. In particular, the accuracy ranged between 95% to 100% and the AUC was over 99% in the test set for NN. Similarly, SVM obtained an accuracy between 90% and 100% and an AUC over 92% in the test set. The performance of these models was not largely affected by the feature selection methods. However, there were differences in parsimonies of feature selection methods: MRMR, SFFS and SFS selected less than 10 features (3, 4 and 6, respectively), whereas the SBS and NCA methods selected a larger feature set (26 and 13, respectively).

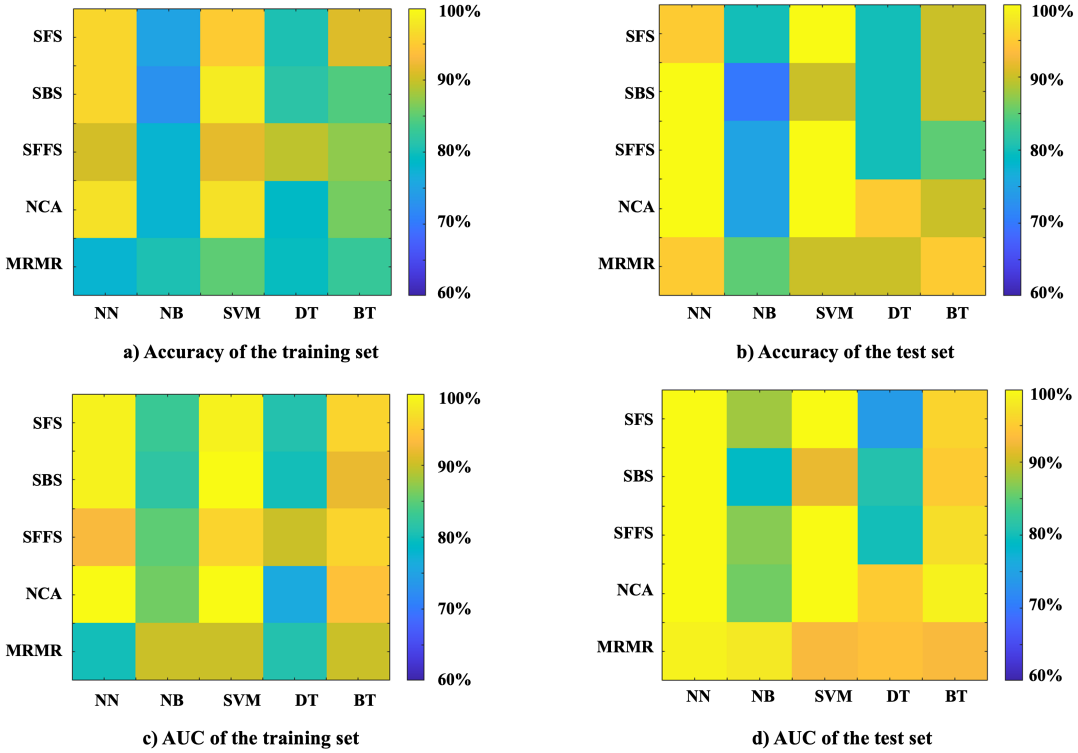

Figure 1: Influence of the feature selection methods in machine learning models

IV. DISCUSSION AND CONCLUSION

In the present study an MRI-based radiomic approach was proposed to develop machine learning models for the identification of the tumor primary location (OPh or NPh) from the lymph nodes segmented in MRI images of HNC patients. Different features selection methods as well as machine learning classification algorithms were tested.

As regards the machine learning models, NN and SVM outperformed NB, DT and BT, with the highest performance reached through the NCA feature selection methods obtaining an accuracy of 100% and an AUC of 100% in the test set. However, overall, the feature selection method did not marginally affect the performance of the models. Thus, the feature selection method resulting in fewer selected features should be preferred, favoring a more parsimonious model. In this case, the ideal trade-off between the number of features and the performance is reached by the six radiomic features selected by SFS together with SVM models. These features are:

- T1w_waveletLHL_firstorder_90Percentile,
- T1w_waveletLHL_firstorder_Median,
- T2w_waveletLLL_firstorder_InterquartileRange,
- T2w_original_shape_LeastAxisLength,
- T2w_original_firstorder_Entropy,
- T2w_original_glcm_Idm.

The first three features are wavelet-based first-order statistics that measure the distribution of pixel values in the wavelet sub-bands of T1w and T2w images. The fourth feature, “LeastAxisLength”, is a shape-based feature that measures the length of the shortest axis of the tumor in a T2w image. The fifth feature, “Entropy”, measures the randomness and complexity of the texture in a T2w image. The final feature,

"Idm", is a grey-level co-occurrence matrix feature that measures the local homogeneity of the texture in a T2w image.

In this study a simple binary classification problem was addressed, by considering only the two most prevalent primary tumor locations of HNC of the BD2Decide database patients (i.e., NPh and OPh). Thus, the excellent results that were achieved in this study, should be confirmed in future works by considering the more realistic and complex scenario characterized by the presence of other primary tumor locations such as larynx, oral cavity and hypopharynx.

In conclusion, the approach proposed herein demonstrated the potentiality of radiomics in the discrimination between OPh and NPh primary tumor locations from the lymph nodes in HNC patients. These findings suggest that radiomics can provide a remarkable contribution as preliminary assessment of the primary tumor location in head and neck carcinomas of unknown primary.

***Abstract*—This work proposes a machine learning algorithm for analyzing the composition of each voxel in Magnetic Resonance Imaging framework. Since the voxel defines the spatial resolution limit of the system, conventional imaging approaches are not able to distinguish an homogeneous voxel (composed by a single tissue) from an heterogeneous one (composed by several tissues). It causes loss of useful diagnostic information not allowing to detect tissues smaller than the voxel dimension. This paper proposes a neural network detection algorithm that, exploiting several acquisitions of the same voxel, is able to distinguish heterogeneous voxels from the homogeneous cases. A synthetic dataset was designed for the neural network training: homogeneous and heterogeneous voxels were simulated and several imaging sequences have been considered to acquire voxel signals. Results seem to be promising, in particular regarding on its application in a real clinical context: in order to analyse the voxel, the algorithm requires a reduced number of acquisitions (that means reduced time for the clinical examination) and its low computational complexity allows a quick analysis of all voxels of the examined body slice, as proved by the algorithm validation through a test on a real magnetic resonance data.**

***Keywords*—Magnetic resonance imaging, intra voxel analysis, machine learning, deep learning**

I. INTRODUCTION

Magnetic Resonance Imaging (MRI) is one of the most used method in diagnosis, staging and follow-up of disease for a variety of conditions. It is based on the non-invasive and non-ionising interaction between hydrogen protons and magnetic fields and the image acquisition occurs thanks to radio-frequency (RF) pulses applied to the interested area. In particular, RF pulses create a non-equilibrium state and after they have been switched off a relaxation phenomenon arises, characterised by two constants: *spin-lattice* relaxation time T_1 and *spin-spin* relaxation time T_2 [1]. Different tissues present different values of relaxation times and diseased tissues often have substantially altered relaxation time compared to healthy ones [2] - [4]. These differences form the basis for introducing contrast into the MR image. Depending on the application, the involved tissues and the acquisition sequence, images based on T_1 differences (named T_1-*weighted* images) or images based on T_2 differences (named T_2-*weighted* images) could be acquired and exploited for the diagnosis.

During an MRI acquisition, the investigated body area to scan results divided in voxels, whose number and size depend on to the system resolution. Per each voxel, the information about its tissues composition is brought with the respective pixel value in the MR image in term of T_1 or T_2. In case of homogeneous voxel (composed of a single tissue), pixel value describes exactly that single contribute. In case of an heterogeneous voxel (composed of two or more tissues), the respective pixel value describes it as the mean value of all the contributes, making it difficult to discriminate the quantity of the involved tissues and their nature. It involves that tissues smaller than the voxel dimension cannot be discriminated and detected in the MR image.

From a diagnostic point of view this represents an obstacle since in many pathologies the possibility of detecting the smaller diseased tissue could be very helpful in term of prevention and early diagnosis. In cancer lesions, for instance, it is well known that the sooner a diseased tissue is detected, the better is the prognosis [5]-[7].

In this framework, in order to avoid a further improvement of the spatial resolution of the system, a novel methodology was proposed in scientific literature, known as *Intra Voxel Analysis* (IVA) [8]. It works on T_2-*weighted* images and is able to analyse an heterogeneous voxel performing the detection of the number of contributions within it and the estimation of which tissues are involved, generating a T_2 distribution instead of a single value. This method was validated on a real brain MR image, providing to be promising and overcoming the standard non-negative least square fitting method [9] in term of noise-robustness and number of necessary acquisitions. Nevertheless the approach is not very suitable in clinical near real-time context, because of its computational complexity and time cost.

Also Yu Thomas at al. [10] proposed a methodology to recover the T_2 voxel distribution, in particular for the application on myelin water fraction mapping in brain tissues. Differently form [8], they exploit a machine learning algorithm that demonstrates to recover more accurate, robust and plausible T_2 distribution than standard methods. Although it overcomes the limit of the IVA approach in term of less computational complexity and time cost, it requires a huge number of acquisitions compromising the suitability of this approach in the real clinical context. High number of acquisitions means a strong increase in time for the medical examination.

This work aims to propose the a similar machine learning approach used in [10] exploiting its computational speed and reduced complexity, but in a simplified scenario: the proposed algorithm is able to detect pixels corresponding to heterogeneous voxels (distinguish them from the homogeneous case) but, differently form [8] and [10], it does not reconstruct

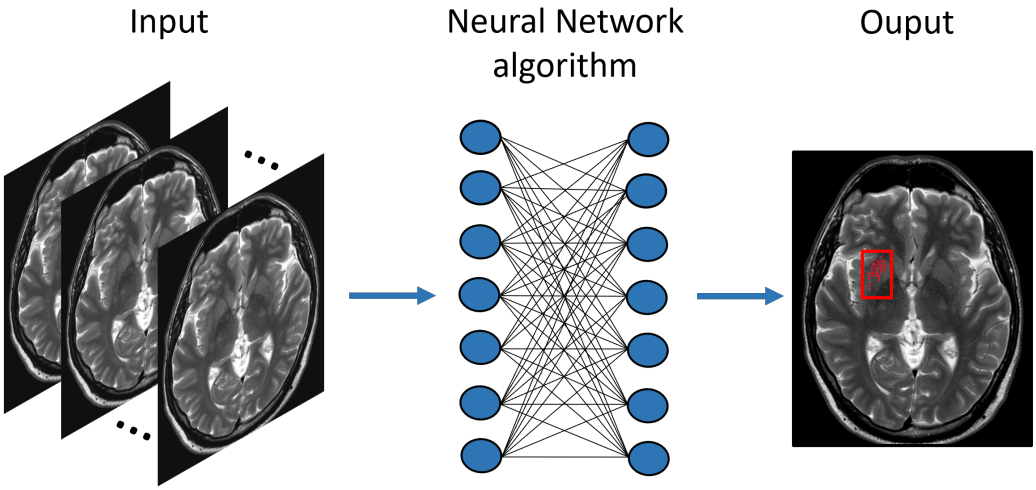

Fig. 1: Simplified sketch of the proposed machine learning algorithm. In order to detect pixels corresponding to heterogeneous voxels (highlighted in red in the output image), the neural network algorithm exploits L acquisitions of all the voxels of the body slice (the input images stack)

the respective T_2 distribution.

This simplification allows a quick analysis of the whole MR image and requires, at the same time, an acceptable number of acquisitions, making the method suitable in a clinical near real-time context and in the framework of prevention and staging of pathological patients, which need fast and frequent follow-up [11].

II. Mathematical model

Through several available sequences in the framework of MR image acquisition, the spin echo (SE) [1] is the one exploited in this paper.

According to SE and focusing on the particular case of T_2-*weighted* image acquisition [8], the signal amplitude of each voxel can be modeled as:

$$g(l) = ke^{-T_E(l)/T_2}, l = 1, ..., L \tag{1}$$

where k and T_2 depend on the tissues composing the voxel and T_E is an imaging parameter.

More in detail, k is a coefficient that takes in account proton density and *spin-lattice* relaxation time and T_2 is the *spin-spin* relaxation time.

The imaging parameter T_E is the vector of the *echo* times and allows to obtain several acquisitions of the same voxel, as many as its length L [12].

The hypothesis under the Eq. (1) is that the signal g comes form an homogeneous voxel since a single tissue relax back with its decay constant T_2. Actually, an heterogeneous scenario is possible [1], where more than one tissues compose the voxel. In this framework, considering the simplified case of a maximum of two tissues, the signal can be modeled as:

$$g(l) = k(1)e^{-T_E(l)/T_2(1)} + k(2)e^{-T_E(l)/T_2(2)}, l = 1, ..., L \tag{2}$$

where $\{k(1),\ T_2(1)\}$ and $\{k(2),\ T_2(2)\}$ describe, respectively, the two tissues merged in the voxel.

III. The proposed method

In this paper, a supervised machine learning [13] approach is exploited to analyse each voxel composition in the framework of magnetic resonance imaging. More in detail, a neural network (NN) algorithm is trained in order to detect heterogeneous voxels which present two tissues composing their volume.

As shown in Fig. 1, the algorithm takes as input several acquisitions of the examined body slice. Through the voxel-wise analysis done by NN inner layers, it returns the detection response per each voxel classifying it as homogeneous or heterogeneous. The output is a map in which pixels corresponding to the detected heterogeneous voxels are highlighted.

A. Neural Network Architecture

In the framework of neural network algorithms, a fully connected architecture was exploited: two fully connected layers and forty-five nodes per each layer. The activation function used was the ReLU one [14]. Batch normalization [15] was added to the first layer showing better learning and faster processing. Log SoftMax function after the last layer is the one expected by the negative log likelihood loss function used. Since the analysis is made voxel-wise, input layer of the neural network presents a number of nodes equal to L, as the number of acquisitions of the examined voxel, while the output layer presents two nodes assuming the voxel probability of belonging to homogeneous and heterogeneous case.

About the training, the optimization algorithm used was Adam [16] and the training parameters were: learning rate equal to 10^{-4}, batch size 64 and number of epoch equal to 30. The analysis have been made on a 24 GB NVIDA Quadro RTX 6000 gpu, through PyTorch framework, in Python.

B. Dataset

In order to train the proposed neural network architecture, a synthetic dataset has been generated for a total of one million {*input*, *target*} samples. Since the *input* part is the vector of the L acquisitions, first step was the design of synthetic voxels, second step their acquisition through the imaging sequence. One million voxels differing from their nature and composition was designed changing the two tissue characteristic parameters T_2 and k. Regarding T_2, two possible scenarios have been considered: homogeneous voxel composed by a single tissue and heterogeneous voxel composed by two tissues. Both cases present a contribute of an healthy tissue. In addition, the heterogeneous case presents a second contribute simulating a diseased tissue. Since this work is focused on brain imaging, their value must be coherently chosen. According to [17], T_2 values of healthy tissue are chosen randomly from uniformly distributed range [40, 150]ms, while values for tissue out of the healthy range are chosen randomly from uniformly distributed range [110, 250]ms. Moreover, in the heterogeneous case the volume percentage occupied by the two tissues varies per each sample. First contribute occupies a random value form 20% to 80% of the entire voxel volume, while the second contribute occupies the remaining part. About k, per each voxel it is chosen randomly from the uniformly distributed range [10^3, 10^5], according to [8] dataset and proportional to its image amplitude.

Once all synthetic voxels were generated, second step was their acquisition through the spin ehco sequence. According to it, the imaging parameter T_E was set in range [10, 350]ms, but several simulations have been done changing its length and spacing. Therefore, per each fixed T_E configuration, a new dataset made by one million samples was generated.

For a more realistic scenario, the whole datasets was corrupted by additive white Gaussian noise with mean SNR = 20dB.

Moreover, in order to obtain a good training of the designed neural network algorithm, balanced datasets were simulated splitting in half homogeneous and heterogeneous cases.

Since the proposed approach solve a detection problem, *target* values are labels representing the voxel class: homogeneous or heterogeneous.

IV. Analysis and Results

In this framework, an analysis was made to find the best spin echo acquisition scheme that lets the designed neural network better performs in the purpose. Once T_E range was selected ([10, 350]ms), seven cases were considered, in which T_E is linearly spaced in its range but differs in its length. The first case presents $L = 4$, the last $L = 10$.

In order to test the neural network algorithm considering all these configurations, seven datasets were generated, each one made of one million samples. Per each dataset, the 90% was used for the training and the last 10% for the validation.

Once the neural netoworks were trained, for the purpose of evaluating their performance, one testset per each dataset was simulated, each made by twenty-five thousand samples, splitted equally between homogeneous and heterogeneous cases.

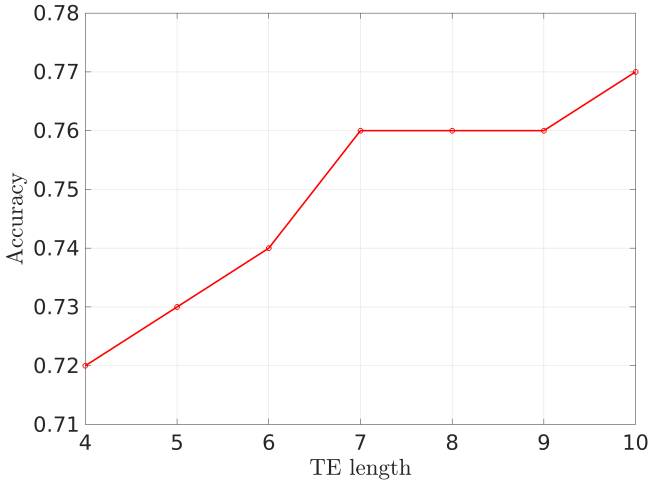

Fig. 2: Accuracy values achieved per each different acquisition scheme. Per each case T_E vector is linearly spaced in range [10, 350]ms, but several length were tested, from 4 to 10

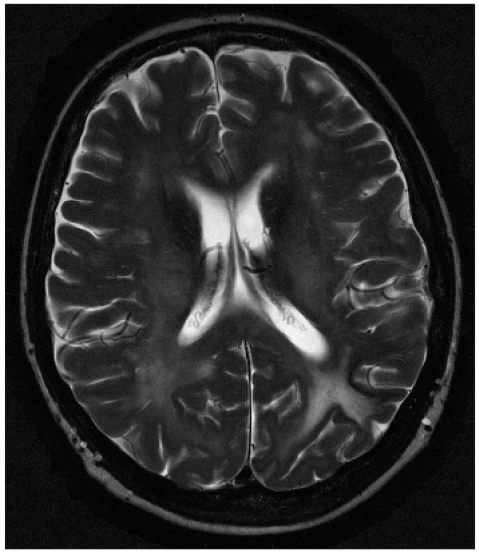
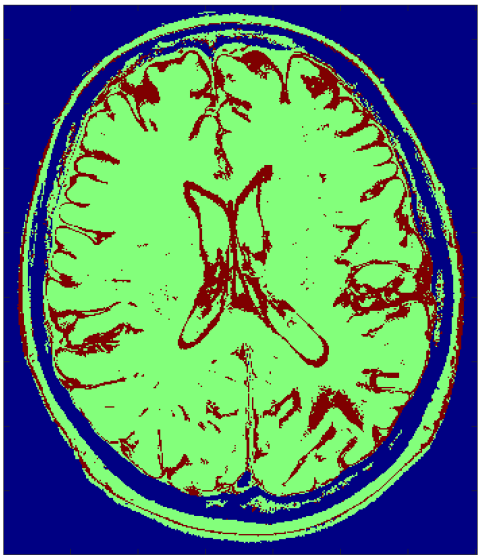


The analysis in Fig. 2 shows the comparison among the achieved results. It is possible to notice performance increasing with the increasing of the number of acquisitions L. Nevertheless, after $L = 7$ the improvement is not so sensitive. According to this scenario, T_E values are [10, 66.7 123.3 180 236.7 293.3, 350]ms and it represents a good compromise between the reached accuracy (76%) and length L, since the fewer are the acquisition the less is the time request by the clinical examination.

A real brain MR data was also available for the validation of the proposed method. It is an axial slice of the head, made of 351x426 pixels. It is composed by five spin echo images acquired with T_E = [82.45, 130, 180, 250, 350]ms. Despite it follows the same acquisition sequence considered in the simulation (i.e. spin echo sequence), this data does not fix exactly the best configuration found in the simulated scenario: T_E belongs to the range [10, 350]ms range, but differs for spacing (it is not linearly spaced) and length (five instead of seven). Consequently, in order to train the neural network in according to the real data acquisition parameters, a new synthetic dataset was generated assuming the right echo times.



The testing result on the real data is the one shown in Fig. 3(b). According to [8], heterogeneous voxels are detected in the lesion region. The same results is obtained in boundary areas. Since they represent non-homogeneous transition areas between tissues, multiple contributes in a single voxel are expected.

V. Conclusions

This manuscript proposes a neural network algorithm to analyse voxels in MRI framework. In particular, it demonstrate to detect heterogeneous voxels distinguish them from the homogeneous cases achieving a good level of accuracy (more

(a)

(b)

Fig. 3: Validation of the proposed method in a real case study. In (a) a single slice of the available real MR brain data is shown, where an edema lesion is present in the occipital region (bottom right of the image). In (b) the result of the proposed detection algorithm. Blu is the background, green represents homogeneous voxels, red the heterogeneous ones.

than 70% considering a noisy scenario with mean SNR = 20 dB).

As proved by the validation of the method through the available real MR data, despite the approach works voxel-wise, it analyses all the brain image voxels in less than 2s. In addition, both in simulated and real data, a standard imaging sequence was used (i.e. the spin echo one), allowing the proposed detector to be used with any already existing MRI systems. Finally, the algorithm needs an acceptable number of acquisitions without involving an increase in time for the medical examination. All these features make the method exploitable in the clinical context and in near real-time applications.

Future work will focus on the extension of the approach to any other available imaging sequences as well as to other anatomical body areas.

A multi-step approach is also possible, combining the proposed neural network algorithm with an other technique able to add quantitative information on tissues composing the heterogeneous voxels, like [8],[9]. Since these algorithms are typically characterized by high computational time and complexity, the combination with the proposed detector, considered as pre-screening procedure, can be, potentially, a good candidate for almost real time analyses.

***Abstract*—Diffusion tensor imaging (DTI) allows the non-invasive characterization of white matter integrity, thanks to a model fitting the diffusion profile of water inside the brain. It has been demonstrated that patients affected by psychosis show alterations in the white matter (WM), when investigated with DTI. At the same time, an involvement of immune system in psychosis has been shown, with pro-inflammatory changes. In this study, we combined the analysis of immunomarkers and white matter integrity, in a DTI-general linear model (GLM) framework, to identify possible interactions. We consider a sample of 100 subjects (DTI and peripheral blood immunomarkers, 29 first episode psychosis (FEP) patients, 26 chronic patients and 45 healthy controls), and applied a TBSS analysis with multiple aims: identifying differences in WM integrity between groups; identifying relationships between WM and immune system markers; identifying interactions between FA, immune system and group. We found, in aligmnent with the existing literature, that chronic patients show altered WM in respect both to controls and to FEP patients. Additionally, in FEP and chronic patients we found correlations between a pro-inflammatory status and WM alterations. Finally, we also demonstrated an interaction between group, WM integrity and immune system in the comparison between HC, FEP and chronic patients.**

I. Introduction

Psychosis is a symptom common to several pathological conditions that involves alteration in the relationship with reality. The first episode of psychosis (FEP) is defined as the first occasion on which the subject manifests psychotic symptoms. It has been demonstrated that FEP patients show altered brain microstructure [1], measured with diffusion tensor imaging (DTI). DTI allows the quantification of diffusion indexes such as fractional anisotropy (FA), which measures how much one diffusion direction is prevailing on the others inside a particular voxel, or mean diffusivity (MD), related to the magnitude of the diffusion. In a 2013 meta-analysis [1] several white matter areas where significant FA changes can be observed in FEP were defined. In particular, a decrease in FA was identified in various regions, and the most significant changes were located in the corpus callosum, the uncinate fasciculus and the longitudinal fasciculus. With regard to the immune system, in FEP, a significant increase in blood levels of interleukin-1β (IL-1β), interleukin 12 (IL-12), interferon-γ (IFNγ), transforming growth factor α (TGFα) and especially tumor necrosis factor α (TNFα) has been ascertained [2], [3]. Since these are acute phase cytokines, they would probably indicate the presence of a proinflammatory state at a peripheral level. This state could have repercussions on the brain since these molecules are capable of altering the permeability of the blood-brain barrier. Regarding brain-derived neurotrophic factor (BDNF), a decrease in FEP was observed compared to healthy controls. This alteration tends to be accentuated when the psychosis becomes chronic [4]. In this work, we aim to investigate the complex interrelations between immune system and white matter in psychosis, at the early stages and in chronicity.

II. Materials and Methods

A. Subjects recruitment and data acquisition

100 subjects were involved in this study. Specifically, we included patients following a first psychotic episode (FEP; n = 29, 28.0 $\pm$ 10.1 years old (y.o.), 16 males), patients with chronic psychotic disorders (e.g., schizophrenia, bipolar disorder, and major depressive disorder) (CHR; n = 26, 35.0 $\pm$ 12.4 y.o., 18 males), and a group of healthy controls with no history of psychiatric disorders (HC; n = 45, 35.3 $\pm$ 12.4 y.o., 16 males). All the procedures were approved by the Biomedical Ethics Committee of the Azienda Ospedaliera di Verona and are in accordance with the Helsinki Declaration of 1975. All subjects signed a written informed consent to the protocol. MRI data were acquired on a 3T machine (Philips Achieva) with the following parameters: 35 diffusion directions, 1 non-diffusion weighted volume, b-value 1000 mm/s^2, TR = 5 s, TE = 0.12 s, flip angle = 90°, voxel size 1x1

mm^2, slice thickness 3 mm, matrix 256x256x50. Whole blood samples were collected in 2.5 ml PaxGene vials (Qiagen) and stored at -80 °C within 2–6 h of collection. RNA was extracted using the QIAsymphony PAXgene Blood RNA Kit. Real-Time qPCR for the analysis of Interleukin-10 (IL-10), Interleukin-12 alpha (IL-12α), Interleukin-6 (IL-6), Interleukin-1 beta (IL-1β), interferon gamma (IFNγ), Tumor necrosis factor alpha (TNFα) and Brain Derived Neurotrophic Factor (BDNF) was performed.

B. MRI data pre-processing

The acquired images were analysed using FSL (FMRIB Software Library) [5]. The images were skull-stripped using the brain extraction tool of FSL, and distortions due to eddy currents and small head motion were corrected aligning the diffusion-weighted images to the baseline using affine transformations (eddy currents correction tool from FSL). Subsequently, the data were fitted to the tensor model, as implemented in the function FDT in FSL, and FA values were obtained. TBSS [6] is a multiple steps procedure. Briefly, all FA images are non-linearly registered to a standard space and a mean FA image is created. Then, a skeleton consisting of the center of white matter tracts is obtained, which represents the center of the WM tracts common to all subjects.

C. Statistical Analysis

Data were then processed with voxel-wise cross-subject statistics, using FSL randomise function [7] ($p<0.05$). We corrected the results for multiple comparisons using threshold-free cluster enhancement (TFCE [8]), an approach similar to cluster-based thresholding. Age, gender and education were treated as nuisance variables. We used three distinct general linear model (GLM) approaches to investigate:

a) The differences in FA between groups
b) The influence of the immunological markers on FA in patients (FEP or CHR)
c) The interaction of immunological markers, FA and group (HC, FEP, CHR)

III. Results

A. Differences in microstructural integrity between groups

CHR and FEP showed statistically significant differences, after correcting for multiple comparisons, in corpus callosum, internal and external capsula, left longitudinal inferior fasciculus, and frontal and inferior gyri (Figure 1). The comparison between HC and CHR showed diffuse differences similar to those observed between CHR and FEP, located in the major white matter tracts (Figure 1). No significant differences were found between HC and FEP.

B. Regression between FA and immunomarkers

In the case of FEP patients, the only cytokine in which a statistically significant trend was observed was BDNF, which has an influence on FA of the left superior longitudinal fasciculus, as depicted in Figure 2. The linear regression between expression of BDNF and FA is depicted, as in all subsequent figures, for a representative voxel (the voxel with the lowest p-value was chosen among all the voxels with significant results). It is to be noted that the regression depicted in the figures has only representation purpose.

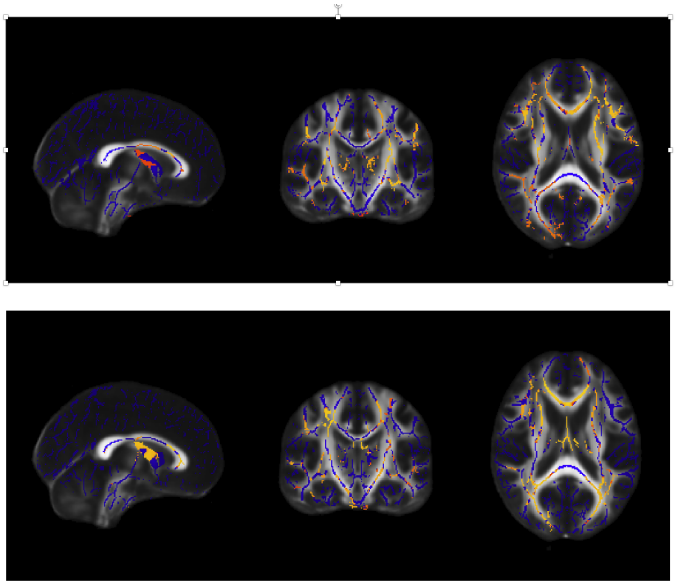

Fig. 1: (A) Results of TBSS comparison between FEP and CHR (B) Results of TBSS comparison between CHR and HC. Blue voxels: White matter skeleton; red-yellow voxels: significant voxels after multiple comparison correction.

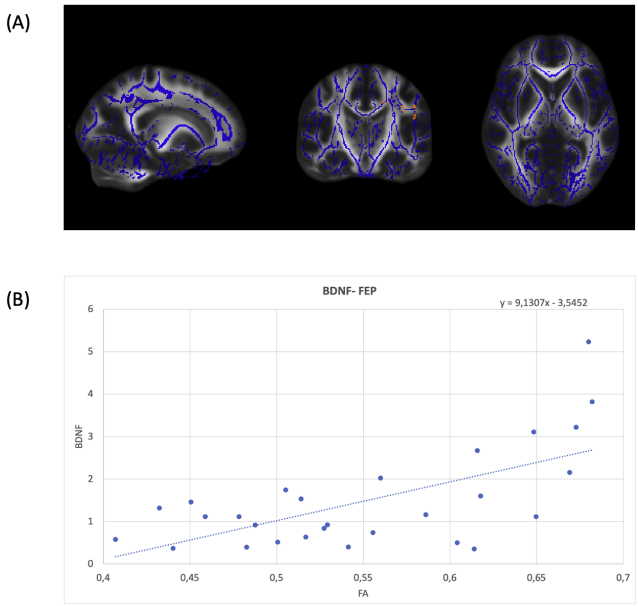

Fig. 2: (A) White matter tracts with significant correlation between FA and BDNF in FEP. The highlighted area is located in the left longitudinal superior fasciculus. Blue voxels: White matter skeleton; red-yellow voxels: significant voxels after multiple comparison correction. (B) Linear relationship between FA and BDNF for a representative voxel (p=0.02)

In CHR patients, a statistically significant trend was found

in the case of IFNγ. The white matter tracts in which the correlation is highlighted in these subjects can be viewed in Figure 3, and are located in particular in the splenium of corpus callosum and in the right internal capsule.

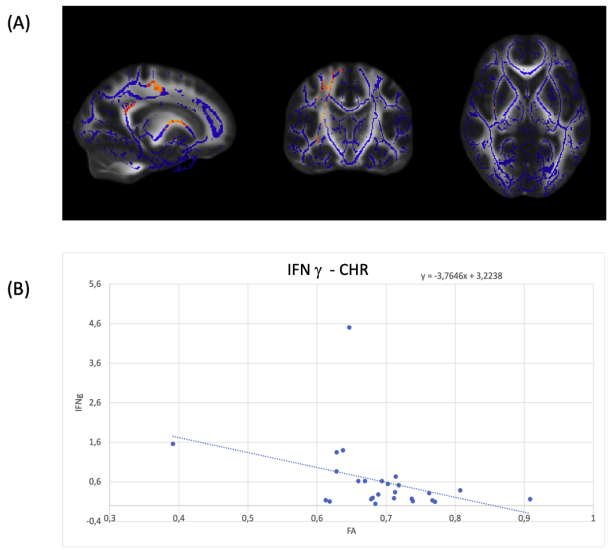

Fig. 3: (A) White matter tracts with significant correlation between FA and IFNγ in CHR. The highlighted area is located in the splenium of corpus callosum. Blue voxels: White matter skeleton; red-yellow voxels: significant voxels after multiple comparison correction. (B) Linear relationship between FA and INFγ for a representative voxel (p=0.03)

C. Interaction of FA, group and immunomarkers

This analysis showed the presence of differences regarding FEP compared to HC when assessing TNFα expression. In Figure 4 it is possible to observe that these differences occur at the level of the corpus callosum, in particular at the level of the genu. While in the controls a negative correlation was observed, in FEP subjects the correlation is positive. A significant interaction was found for TNFα also comparing FEP and CHR. In this case it mainly involves the left superior longitudinal fasciculus and the white matter of the left medial frontal gyrus (Figure 5). In this case, both in CHR and in FEP there is a negative correlation between expression of the pro-inflammatory cytokine and FA. However, this relationship is more evident in chronic patients. In fact, while in FEP patients the concentration of TNFα does not vary significantly depending on the FA values, in CHR patients the relationship is marked.

Finally, in the comparison between FEP and CHR a different relationship emerged also between FA and IFNγ expression. It appears to be more extensive than TNFα and is expressed in the occipital area, the frontal corpus callosum, the anterior cingulate and the white matter of the superior occipital gyrus (Figure 6).

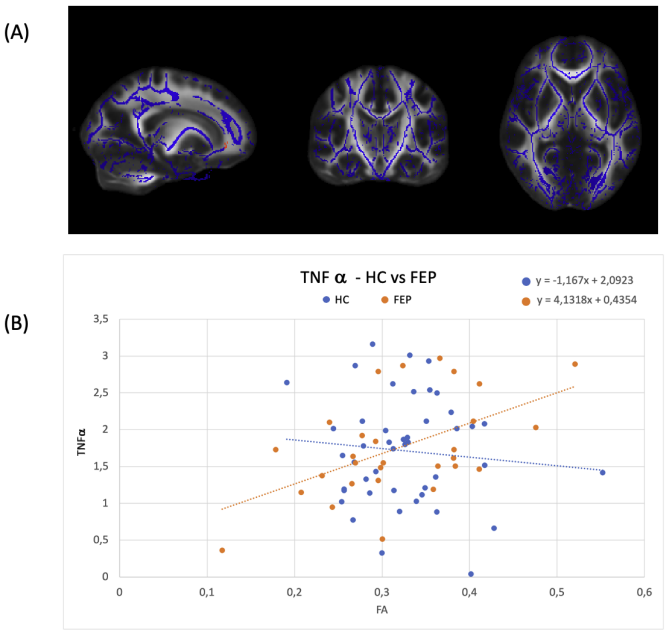

Fig. 4: (A) White matter tracts with different relationships between FA and TNFα in HC vs FEP. The highlighted area is located in the genu of corpus callosum. Blue voxels: White matter skeleton; red-yellow voxels: significant voxels after multiple comparison correction. (B) Relationships between FA and TNFα in a representative voxel (p=0.02)

IV. Discussion

Our TBSS results from the comparison of FA values between groups are in line with the literature, with decreased FA in CHR in respect to HC and FEP. A decrease in FA is due to the presence of alterations in the cerebral white matter, alterations which can be due to various causes such as anomalies concerning the integrity of the axons, their membrane, their orientation or their degree of myelination. In general, the presence of alterations in WM supports the "disconnection theory" underlying psychotic disorders such as schizophrenia. Our study highlighted the presence of alterations in the frontal white matter, especially involving the frontal gyrus. These structure is involved in attention, working memory, and the evaluation of linguistic and emotional information. The presence of these alterations seems to be related mainly to the presence of anomalies in executive functions, therefore in the planning, organization and regulation of behaviors [9]. Also the involvement of cingulate and corpus callosum in psychosis are confirmed by the literature [10], [11]. Regarding our results concerning the immune system, BDNF has a protective role in nervous system development and brain plasticity. Several studies have found a decrease in BDNF in various pathological conditions affecting the CNS, including schizophrenia [12], [13]. Several studies and meta-analyses [14] have found the presence of high levels of IFNγ in subjects with chronic psychosis. In addition, it was observed that these patients experienced a decrease in the concentration of this marker following drug therapy. It is likely that in subjects

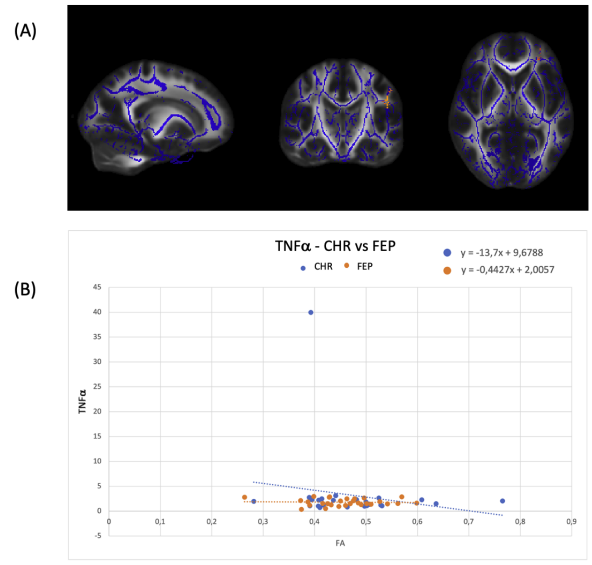

Fig. 5: (A) White matter tracts with different relationships between FA and TNFα in HC vs FEP. The highlighted area is located in the genu of corpus callosum. Blue voxels: White matter skeleton; red-yellow voxels: significant voxels after multiple comparison correction. (B) Relationships between FA and TNFαin a representative voxel (p=0.02)

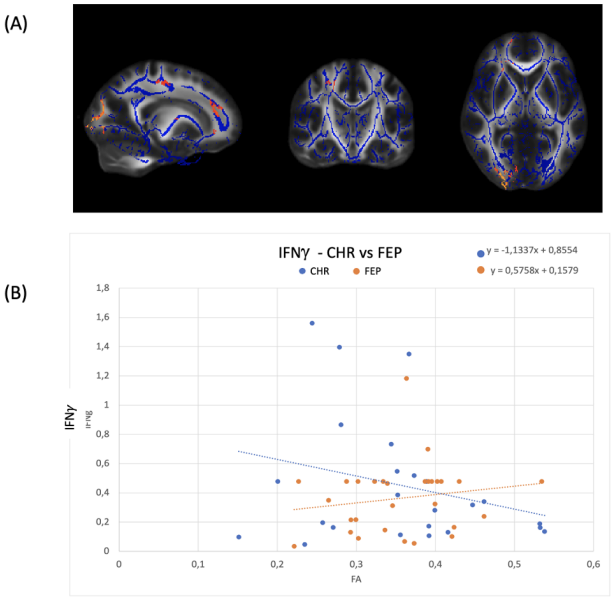

Fig. 6: (A) White matter tracts with different relationships between FA and IFNγ in CHR vs FEP. The highlighted areas are located in the corpus callosum, in the anterior cingulate and in the occipital area. (B) Relationships between FA and IFNγ in a representative voxel (p=0.01)

with chronic psychosis who have a higher concentration of IFNγ there is a greater degree of cerebral disconnection and therefore lower FA. Finally, the different interaction between immunological markers and FA in the different groups may explain a greater complexity in the interaction between the immune system and white matter integrity. In fact, although in FEP and in CHR there is an activation of the immune system in a pro-inflammatory sense which over time leads to progressive structural damage in the WM, it is possible that in the initial stages of the disorder there is a dys-regulation of the immune system which in limited brain areas it would determine a protective effect on WM. The association of DTI, TBSS, GLM and immune markers measurement allowed us to infer complex relationships between immune system and WM integrity.

V. Conclusion

Our study suggests the existence of a complex interaction between cerebral white matter and the immune system in psychotic patients and the need to further study these interactions. In this way, not only the additional elements involved in the pathogenesis of psychosis could be highlighted, but also which factors could slow down the onset and evolution of the structural alterations that characterize the disorder. This could have important repercussions from a prognostic and therapeutic point of view in psychotic subjects.

***Abstract*—Virtual Reality (VR) can support traditional physiological treatments to help oncological patients who require positive stimuli and to be distracted from unpleasant thoughts, providing tools for relaxation and pain reduction. To date, VR is not implemented in clinical routine practice to support the mental states of oncological patients. Further research studies are needed to prove the correlations between VR and autonomic physiological signals. As such, we conducted a study to show the effects of VR on the autonomic signals of oncological patients. Photoplethysmography (PPG) and electrodermal activity (EDA) were recorded via a wearable device during VR sessions of 27 individuals. Linear Mixed-Effects Models (LMMs) were obtained using twenty-one parameters extracted from PPG and EDA. Our findings showed significant changes in some PPG variables comparing pre- and post- VR treatments due to the relaxation effects and in some EDA features due to the positive arousal and level of engagement experienced with the VR. Further studies are needed to better solidify the positive effects of VR as a complementary psychological intervention.**

I. Introduction

Virtual Reality (VR) represents one of the most disruptive technologies developed in recent years, capable of creating a virtual environment and making feel the user completely immersed in it. VR technology is primarily enjoyed through portable head-mounted displays (HMDs), projecting the computer-generated virtual environment and occluding the view to the outside world [1].

Beyond the entertainment field, VR has proven to be a useful tool for many applications, not least in the health domain. Albeit limited to the research context, VR has been used as a complementary psychological therapy to treat various mental health conditions. Although it cannot substitute traditional psychological interventions, VR has been offering a new way of conveying positive stimuli, capturing the users' attention and distracting them from the current unpleasant situation, while simultaneously offering a feeling of relaxation [2].

The efficacy of VR interventions can be evaluated through either explicit or implicit methods. The former are based on an explicit evaluation by the user through interviews or questionnaires; the latter do not require an active involvement of the user, rather they are based on assessing the user's behaviour, for example by analysing the physiological reaction to VR stimuli [3].

Physiological reaction to VR can be assessed by properly processing the so-called autonomic signals, namely those physiological signals strongly influenced by the autonomic nervous system (ANS), which represents the neural system involuntarily reacting to external stimuli [4].

Examples of autonomic signals are photoplethysmography (PPG) and electrodermal activity (EDA). PPG represents the variations occurring in the blood flow at each heartbeat. The cardiovascular system is strongly influenced by both sympathetic and parasympathetic branches of the ANS, in particular by regulating the heart rate. These effects can be appreciated by conducting a Heart Rate Variability (HRV) analysis [5]. EDA provides information about the electrical conductance level of the skin, changed by the sweat secretion of eccrine sweat glands, in turn innervated by the ANS' sympathetic branch [6].

The aim of this study is to assess the physiological reaction to VR in oncological patients involved in a palliative care home program. Patients are provided with a VR-HMD and a wearable device to record autonomic signals.

II. Materials and Methods

A. Study design

The study is an interventional exploratory randomized controlled trial. Fifty-three patients have been recruited at Fondazione ANT and were then randomly divided into a VR group (27 patients) and a CTR one (26 patients). Tablets were provided to CTR participants and VR-HMD and wearable devices to monitor physiological signals to the VR ones. Only data from the VR group were analysed for the aims of this work. This study was approved by the Ethical Committee of Area Vasta Emilia Centro (Bologna, Italy; approval n° 542-2019-OSS-AUSLBO). All patients gave written informed consent.

B. VR headset and wearable device

Each VR participant was provided with a VR-HMD, a Lenovo Mirage Solo, to be freely used at home for four days. Patients were suggested to use the VR-HMD when experiencing moments of psychophysical discomfort, as growing anxiety and pain, but no minimum or maximum number of uses has been established. At the end of the four days, the log file of the VR sessions was downloaded by the investigator and later used to synchronize it with the physiological signals' recordings. VR-HMD was provided with both non-interactive and interactive contents: the former consisted in immersive 360° videos with different natural and relaxing scenarios, while the latter consisted in a basic skill game set in an underwater world specifically developed for ANT patients [7].

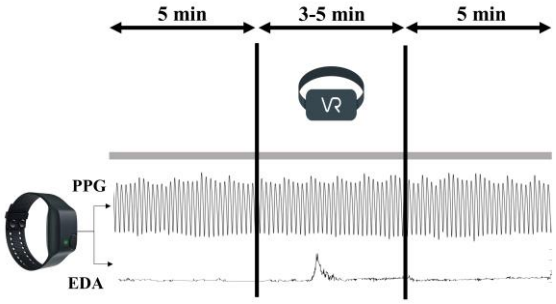

Figure 1 - Signal segmentation

The Empatica E4 wristband, a class IIa CE medical-grade wearable device, was used to monitor physiological signals. The following signals were recorded:

- Photoplethysmography (PPG), whose sensor is equipped with four light sources (two green, two red) and two photodetectors, and with a sampling frequency of 64 Hz.
- Electrodermal activity (EDA) is recorded by two dry electrodes placed on the ventral part of the wrist, with a sampling frequency of 4 Hz.
- Skin temperature (TEMP) is recorded through a thermopile with a sampling frequency of 4 Hz.
- Accelerometer (ACC) data is recorded through a tri-axial accelerometer with a sampling frequency of 32 Hz.

Before and after each use of the VR-HMD, the patient filled the digital version of the Edmonton Symptoms Assessment Scale (ESAS) [8], a simple and reliable multi-item instrument developed to rate the intensity of nine common symptoms experienced by cancer patients (pain, tiredness, nausea, depression, anxiety, drowsiness, appetite, well-being, and shortness of breath).

C. Synchronization

To assess the effect of VR through the analysis of physiological signals, we segmented the physiological signals' recordings into three phases:

- pre-VR phase: 5-minute window before the VR session
- VR phase: up to 5-minute window during the VR session
- post-VR phase: 5-minute window after the VR session

VR sessions were cut into 5-minute slots to extract features on a comparable time window compared to pre-VR and post-VR phases. For each VR session, the following rules were applied:

- If the VR session has been performed when the Empatica E4 wristband was not recording, that VR session was discarded
- If two VR sessions were closer than 5 minutes, the VR sessions have been merged and the pre-VR and post-VR phase have been selected as the pre-VR of the first merged session and the post-VR of the last merged session.

D. Signal processing

Only PPG and EDA were analysed for the aim of this work.

A 5th-order Butterworth band-pass filter [0.5 – 12] Hz was applied for each PPG recording. The algorithm by Elgendi et al. [9] was adapted to detect the systolic peak and systolic feet of each pulse. Each pulse was then z-scored and subjected to a signal quality check procedure [10], using information both from PPG and ACC data. It is worth noting that not all the available VR sessions will then be exploited for physiological parameters extraction because it can happen that a phase does not contain any reliable PPG pulse.

Once the interbeat intervals (IBIs) were estimated as time differences between two consecutive PPG pulses' systolic feet, we extracted 10 HRV parameters:

- 4 from time domain: mean heart rate (meanHR), standard deviation of normal heartbeats (SDNN), root mean square of successive differences between normal heartbeats (RMMSD), standard deviation of successive IBI differences (SDSD)
- 3 from the non-linear domain: Poincaré plot standard deviation perpendicular (SD1) and along (SD2) the line of identity, and Approximate Entropy (ApEn)
- 3 from the frequency domain: absolute power of the low frequency band (0.04 – 0.15 Hz) (LF), absolute power of the high frequency band (0.15 – 0.4 Hz) (HF), ratio between LF and HF (LF/HF).

EDA was filtered with a 4th-order Butterworth low-pass filter, with a cut-off frequency of 1 Hz and an automatic algorithm that uses EDA, TEMP, and ACC data was applied for quality check analysis [11]. Bad quality segments were replaced by a linear interpolation between the last and the following good quality segment. The normalized EDA signal, with a z-score procedure, was then used for further analysis.

A convex optimization algorithm [12] to divide EDA signal into its tonic and phasic components was also applied. From the phasic component, relevant peaks were identified as corresponding to a first derivative with a value higher than 0.01. Eleven features were extracted from the EDA:

- 5 from the whole EDA signal, namely maximum frequency (Fmax) [13], symbolic information entropy (SIE) [14], mean (meanEDA), standard deviation (stdEDA), and slope (slopeEDA)
- 3 from the tonic component, namely mean (meantonic), standard deviation (stdtonic), and slope (slopetonic)
- 3 from the relevant peaks of the phasic component, namely mean (meanampEDR), standard deviation (stdampEDR), and frequency (freqEDR)

E. Statistical analysis

To assess the effect of VR through the physiological parameters, we implemented Linear Mixed-Effects Models (LMMs). LMMs are used when data samples are non-independent, as this case in which a variable number of VR sessions can come from the same individual. We modelled each of the analysed physiological parameters as the outcome variable, obtaining 21 LMMs, the categorical variable identifying the pre-VR-post phase as the fixed effect, setting the pre-VR phase as the reference level, and as random effects, a number identifying the subject and a number identifying the session. A marginal F test was conducted to assess the significance of differences by comparing pre-VR,

VR, and post-VR phases. A p-value lower than 0.05 was considered a significance threshold.

For both signal processing and statistical analysis, we used Matlab 2022b.

III. Results

A. Study population

A total of 27 patients were enrolled in the VR group (14 M, 13 F, age 53.18 ± 12.41), using the VR-HMD for a total of 61 times. From the ESAS results, patients in the VR group showed significant improvement in tiredness, depression, anxiety, drowsiness, and well-being.

For HRV analysis, a total of 28 sessions from 18 individuals (10 M, 8 F, age 54.26 ± 13.17) were analysed, with 25 VR phases lasting 5 minutes and 3 lasting between 3 and 5 minutes. For EDA analysis, a total of 51 sessions coming from 21 individuals (12 M, 9 F, age 53.81 ± 12.70) were analysed, with 44 VR phases lasting 5 minutes and 7 lasting between 3 and 5 minutes.

The different number of sessions for HRV and EDA analysis is due to signal quality issues: it can happen that, as output from the PPG quality check, no pulses were available for further analysis. We built the LMMs for each parameter by maximizing the number of available sessions for the two autonomic signals.

B. Linear Mixed Effects Models

The results from the LMMs are shown in Table 1, while the parameters that significantly changed across different phases are depicted in Figure 2.

Among the HRV parameters, we found that LF/HF significantly decreased both during VR and post-VR phases (pre-VR vs VR p value = 0.0330, pre-VR vs post-VR p value = 0.0364), while the ApEn had a significant increase in the post-VR phase compared to the pre-VR phase (pre-VR vs post-VR p value = 0.0307).

Regarding EDA analysis, we obtained significant differences only by comparing pre-VR and VR phases, with a significant increase of meanEDA (pre-VR vs VR p value = 0.0008) and meanEDL (pre-VR vs VR p value = 0.0006), and a significant decrease of freqEDR during VR compared to the pre-VR phase (pre vs VR p value = 0.0443).

IV. Discussion

We conducted this study whose aim was to assess the physiological reaction to VR in an oncological population in a real-world context.

We found a significant decrease in the LF/HF parameter both during and after the VR use compared to the pre-VR phase. LF/HF represents the balance between sympathetic and parasympathetic systems. A decrease in its value can be seen as a greater activation of the parasympathetic branch than the sympathetic branch. This is in line with a more relaxed state of the participant while and after using the VR, representing a less stressful state [15].

We also observed a significant change in ApEn by comparing the post-VR phase with the pre-VR phase. ApEn is an indicator of the complexity of the heart rate time series. Higher ApEn values mean lower predictability of the time series, which can be seen as representing a system that can be more easily adapted to changes.

Some EDA features have also been found to significantly change. Specifically, variations in meanEDA and meanEDL have the same trend, with a significant increase during the VR phase compared to the pre-VR phase. EDA is influenced solely by the sympathetic branch of the ANS, and a higher value for meanEDA and meanEDL represents the activation of the sympathetic nervous system. This can reasonably be seen as a more aroused state of the subjects when using the VR-HMD [16]. On the other hand, freqEDR, representing the number of phasic component's peaks, resulted to be significantly lower during the VR session compared to the pre-VR phase. The concurrent presence of higher EDA tonic values and lower number of EDA phasic's peaks can be seen as a higher arousal and engagement of the individual [17] given by the VR experience, together with a less stressed state [18]. Finally, the significant changes in EDA features

Table 1 - Results from Linear Mixed-Effects Models

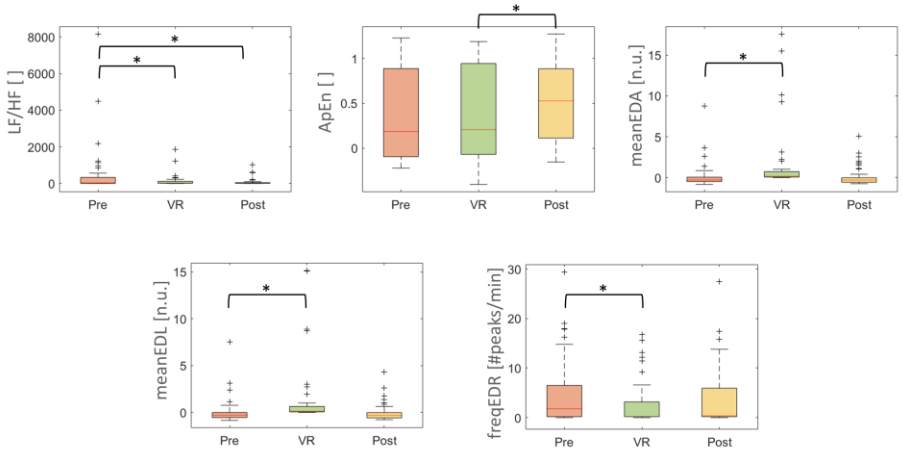

Figure 2 Physiological parameters significantly changed by comparing Pre-VR, VR, and Post-VR phases. * = p < 0.05, ** = p < 0.01

appear only during the VR-phase compared with the pre-VR phase, while they disappear during the post-VR phase. Further studies are needed to assess their behaviour on the long term after the use of VR.

Moreover, a more relaxed state is in line with the output from ESAS questionnaire, filled before and after each VR session. Indeed, it showed significant improvements in anxiety and well-being.

Several limitations need to be highlighted. The first is the limited dataset available for signal processing due to the bad quality of several recordings (45% of PPG recordings have been discarded due to poor quality). Secondly, the VR sessions were performed at different time of the day, so the analysed physiological signals could have been affected by circadian changes.

However, this study represents one of the few attempts in investigating the effects of VR on physiological signals in oncological patients in real-world context, making a step forward to a closer human-machine interaction and the use of VR systems to support therapeutic treatments. Further studies should be conducted on this topic, for example by exploiting physiological signals recordings to adapt the VR scenario to the emotions experienced by the user [19].

Analysis of muscular activity of a cashier during different modalities of human robot collaboration

G. Corvini[1], S. Conforto[1], S. Ranaldi[1], M. Schmid[1] and D. Bibbo[1]
[1] *Department of Industrial, Electronic and Mechanical Engineering, Roma Tre University, Rome, Italy.*

***Abstract*— The effects of siding a collaborative robot (cobot) to a human operator on muscle activity during a scenario simulating a working task (i.e., a supermarket cashier moving cyclically packages) were investigated in this study, by considering different modalities of human-robot collaboration (HRC). Wearable sensors were used to collect kinematic and EMG data, and four different HRC interaction modalities were tested to determine their impact on the biomechanical risk associated with the examined working task. The range, amplitude, and smoothness values of accelerometer data coming from a sensor placed on the trunk, as well as coactivation indexes extracted from EMG data of different relevant muscles were calculated. Without cobot assistance, although a higher smoothness was found in the trunk movement, a high level of prolonged muscular activity was encountered usually associated to a potential increase in the biomechanical risk. In contrast, full assistance from the cobot resulted in the operator developing an intermittent motor control strategy, which reduces the muscular effort but losing smoothness in trunk movements. During two simulated tasks with a medium level of assistance, if the cobot imposed the cadence to complete the task, the required muscular effort remained constantly high, while if the operator was allowed to control the cadence, high smoothness combined with reduced muscular activity resulted. In conclusion, the use of cobots in repetitive tasks can influence the muscle strategy adopted by the operator during HRC. According to the analysis, the most effective approach is to reduce the workload of the operators while allowing them to maintain control over the speed at which tasks are completed.**

***Keywords*—Cobots, Biomechanical risk, Human-Robot Collaboration, surface EMG.**

I. INTRODUCTION

The adoption of cooperative and collaborative robotics in the industrial and commercial framework in recent years has represented and still represents one of the most significant aspects in terms of the renewal of production processes [1]. The interaction between humans and collaborative robots (cobots) produces advantages in the execution of those tasks that are associated with a significant level of biomechanical risk (such as repetitive motion, awkward postures, and lifting tasks) [2]. The HRC, in fact, has the double advantage of combining the potentials of the robotic systems, such as strength and accuracy in the execution of the task and its repetition, with those typical of humans, such as the physical dexterity and the adaptability to unexpected contexts. However, the presence of cobots in work environments leads to a revision of the biomechanical risk assessment paradigms associated with task execution. Biomechanical risk assessment methods known in the literature [3], such as the *level* (intensity of the force during an action), *repetitiveness (*the frequency of the task) and *duration* (the time in which the physical activity is performed) could be not completely adequate because the presence of the cobot could alter the outcome of these measures. Other indexes, such as the Risk index or the OCRA one [4], still do not consider that the cobot could completely remove the object's mass or constrain the task's frequency, yielding in unrealistic risk estimates. To address this problem, an instrument-based approach might play an important role, as it may help predict biomechanical risk values coming from standard methods applied directly to the human operator [5]. For this reason, particular attention has been placed on wearable sensors, such as Surface Electromyography (sEMG) which allows the acquisition of the physiological activity of muscles and Inertial Measurement Units (IMUs), which allow the recording of the kinematics of executed tasks: in fact, thanks to their portability and ease of use, in addition to their small size that does not affect the performed tasks, they might provide good quantitative indicators able to monitor and estimate the biomechanical risk associated to several working activities [6]. This study aims to verify the potentiality of this approach by analysing kinematic parameter and physiological one, extracting the time-varying multi-muscle coactivation index (CI), which can be interpreted as an indicator of the biomechanical risk [7], during the simulation of a specific working task using different modalities of human-robot collaboration. This work is framed in the "BRISK" project, a comprehensive project aimed at studying HRC in working activities through the development of an innovative wearable platform, with the ultimate objective of minimising the biomechanical risks. The data presented in this work are a subset of the whole dataset acquired within the project framework reported in the acknowledgement.

II. METHODS

In the following paragraphs, the experimental setup, the protocols, and the data processing are described.

A. Experimental setup

Tests were performed on a group of 12 male volunteers (right-handed, aged between 25 and 48 years). All volunteers were healthy and had no evident or stated mobility problems. The experiments have been approved by the local ethical committee of Roma Tre University. A specific working task (WT) (i.e., a cashier loading and scanning items for barcode detection) has been simulated considering a setup as reported in Figure 1: the cobot was positioned on the longer side of a 2x1m table with the operator facing it on the opposite side. A scanning area was defined in front of the operator at the center of the table. A set of 1 kg rectangular packages (14x12x5cm), each marked with a barcode on a different side, was used. In the tests, the WT was performed in four different cooperation modalities, in which the cobot cooperated partially, totally, or not at all. A single working cycle consisted of taking the item with the right hand from the departure station (DS), searching for the barcode and scanning it in the designed area, and laying it with the left hand in the arrival station (AS). In one of the four modalities (i.e., *full robot*), the AS is defined in a different

location, as shown in Figure 1. Each package was cyclically replaced in the DS during the task. Each subject was recommended to perform the tests as naturally as possible, without constraining on the gesture's speed (except for the cases in which the velocity constraint was given by the cobot).

B. Protocols

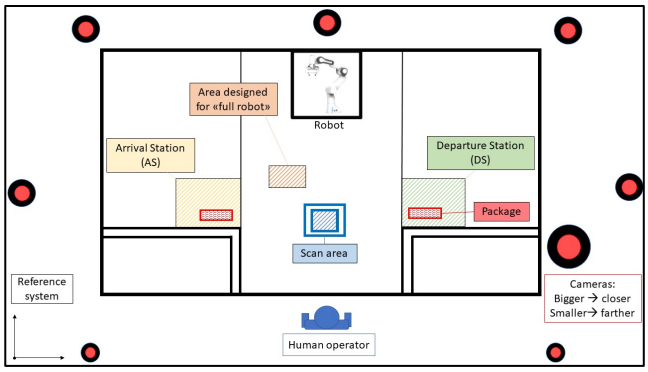

Figure 1: experimental setup for the loading activities simulation

Each test lasted about 5 minutes, in which subjects were asked to perform multiple times the same working cycle (picking, scanning and placing tasks) as naturally as possible, according to one of the following four different collaboration modalities:

a) ***No robot***: the operator picks up the item from the DS, examines it to detect the barcode, scans it in the appropriate area, and finally deposits it in the AS. The execution speed is dictated by the operator.
b) ***Full robot***: The cobot grabs the package and brings it in front of the operator, who takes it to scan the barcode. Then, the package is positioned in a specific area just in front of the operator, as shown in Figure 1, where the cobot picks the item up and moves it to the AS. The execution speed is constrained by the cobot performing all the operations. In this modality, the operator must wait for the execution time of the cobot to complete the working cycle.
c) ***Half robot***: the cobot picks up the item from the DS, brings it in front of the operator, goes back to the DS and picks a new package, without waiting for external output from the operator before starting a new working cycle. The execution speed is constrained by the velocity of the cobot in performing the carrying operation to the operator, return to the DS and grabbing a new item to start a new cycle.
d) ***Half robot touch***: the operator touches the cobot to give the start of the working cycle in the same test. As soon as it has been touched, the cobot picks up the item from the DS, brings it in front of the operator and goes back to the DS waiting for the next touch. At the same time, the operator detects the barcode, scans it and manually places the package in the AS. The execution speed of each cycle mainly depends on the operator touching the cobot, although the cobot, after releasing the package, must return to the DS to grab a new one.

The order of the packages was shuffled each time within the same test to randomize the position of the barcode. The sequential order of the four tests, each corresponding to one of the four different collaboration modalities, was randomized for each participant. This point is quite decisive for the speed of the gesture (constrained or not according to the modality). These collaboration modalities were chosen as they have been associated with different motor control schemes, based on a continuous or intermittent strategy that can lead to a variation in posture or muscular activations [8].

C. Data acquisition and processing

An Inertial Measurement Units (IMU, Shimmer Sensing) was used to acquire kinematic data (sampling frequency fs=102.4Hz) and it was positioned on the trunk.
An optoelectronic system (BTS SMART DX 6000 system with 8 cameras at 2 Mpixel, fs = 250 Hz) was used for the tracking of the body segments kinematics, with a reduced 9 marker set (2 wrists, 2 elbows, 2 shoulders, 2 posterior superior iliac spines and 1 on the neck). These data were mainly used as references for the IMU and for the data segmentation by identifying the beginning of each cycle during a single test. The reference system was fixed on the desk's lower corner at the left of the operator, with the mediolateral axis from left to right and the anteroposterior axis from back to front. The mediolateral coordinate of the left wrist was used to identify the end of each cycle, and thus the beginning of the subsequent one: the minima in the marker position were used to detect when the package was placed in the AS. Finally, physiological signals from muscles were acquired through a sixteen channels EMG system (BTS FREEEMG). Surface EMG signals were recorded using bipolar electrodes with fs=1000 Hz @16 bit. Four pairs of electrodes were placed according to the SENIAM recommendations [9] on the non-focal muscles of the lower and upper limbs. In this study, the following non-focal muscles were monitored: *i)* Upper Trapezius, *ii)* Erector Spinae, *iii)* Gluteus maximus and *iv)* Medial Gastrocnemius.

All data but the IMU were acquired using a common acquisition software environment (i.e., BTS SMART capture), running on a first workstation. For the IMU data, a custom software running on a second PC connected to the BTS workstation by means of a trigger system to synchronize data, was adopted. The different sampling frequencies were considered during the data processing, and data were resampled to a common domain in defining task cycles.

The cooperative activities were performed through interaction with the Franka Emika Panda Advanced Robotic System cobot, an industrial robotic arm with 7 degrees of freedom and a maximum payload of 3 kg. The cobot is equipped with torque sensors on all joints, has a working area of 360° with a maximum extension of 855 mm, and can reach a maximum movement speed of the end effector of 2 m/s.

During all the activities, the accelerometer placed on the trunk has been used to extract compact parameters of trunk kinematics, such as the dynamic range, root mean square value, and smoothness, quantified through the calculation of the log dimensionless jerk as described in equation 1, from the magnitude of the whole acceleration vector [10].

$$smoothness = -\ln\left(\frac{(t_2-t_1)}{v_{peak}^2}\int_{t_1}^{t_2}\left|\frac{da}{dt}\right|^2 dt\right) \quad (1$$

where t_1 and t_2 are the time instants of the window in which the acceleration a and the velocity v are considered. Note that higher values of the log dimensionless jerk correspond to higher value of smoothness.
EMG signals were filtered using a bandpass filter with cut-off frequencies (fc) at 20 and 400 Hz (3rd order of Butterworth). After filtering, envelopes were extracted (full wave rectification and low pass filtering with fc = 5Hz) and they

were segmented according to the length of each cycle (from the DS to the AS). Then, each envelope was normalized to the median value of the maximum peaks extracted from each cycle of the *no robot* trial. Since the length of each cycle was different, envelope signals were interpolated to 1000 points to normalize their length with respect to time. For the graphical representation, the temporal normalization is represented as a percentage of the completed working cycle from 0 to 100% [7]. Subsequently, the time-varying coactivation index, which represents the simultaneous activation of the muscles, was computed for each cycle, and finally, all cycles were averaged to obtain a global coactivation index representing the complete experiment for each subject. For the statistical analysis of the kinematic data, pairwise t-tests were conducted with "collaboration modality" as a grouping factor. To verify whether there is a significant difference in the kinematic parameters among the four modalities, a significance level of $\alpha = 0.05$ was set.

III. Results

The computed average number of packages handled by subjects in the 5-minute duration of the test was: a) n*o robot*: 76±9 packs (15±3 packs/minute); b) *full robot*: 23±1 packs (5±1 packs/minute); c) *half robot*: 66±3 packs (12±2 packs/minute) and d) *half robot touch*: 47±5 packs (9±2 packs/minute).

In Figure 2 the range, amplitude, and smoothness of the signals by the accelerometer on the trunk are displayed. For each collaboration modality, results were averaged among all subjects. The range average value of the n*o robot* trial is the highest among all. In addition, a high value of smoothness is highlighted, due to the absence of the cobot, which allows the subjects to complete the required task at their own velocity. The minimum range and amplitude in the acceleration of the trunk are produced in the *full robot* modality, where the cobot completes both the package loading and unloading phases. *Half robot* and *half robot touch* produce similar results in terms of trunk range and amplitude, but in the latter collaboration modality a greater smoothness is achieved. In the following table results on statistical analysis are reported, considering the paired tests: *no robot* (1) *full robot* (2) *half robot* (3) and *half robot touch* (4). Results show a significative differences for all the parameters in the four modalities, except for the range and RMS parameters between *half robot* and *half robot touch* distributions, and for the smoothness parameter between *no robot* and *half robot touch* distributions.

Table 1 Significance values for pairwise t-tests performed on the kinematic data

Parameter	1 vs. 2	1 vs. 3	1 vs. 4	2 vs. 3	2 vs. 4	3 vs. 4
Range	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	- **($p = 0.09$)**
RMS	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	* ($p < 0.001$)	- **($p = 0.58$)**
Smoothness	* ($p < 0.001$)	* ($p < 0.001$)	- **($p = 0.06$)**	* ($p = 0.03$)	* ($p < 0.001$)	* ($p < 0.001$)

In Figure 3 the coactivation indexes are shown. The coactivation index (averaged among cycles) of each subject is represented with a different color line, while the group mean pattern computed among all subjects together with its standard deviation are identified by the black line and the light grey areas, respectively. On the x-axis, the percentage of completion of the cycle is shown (i.e., zero indicates the initial action of the subject going towards the DS, while 100 indicates

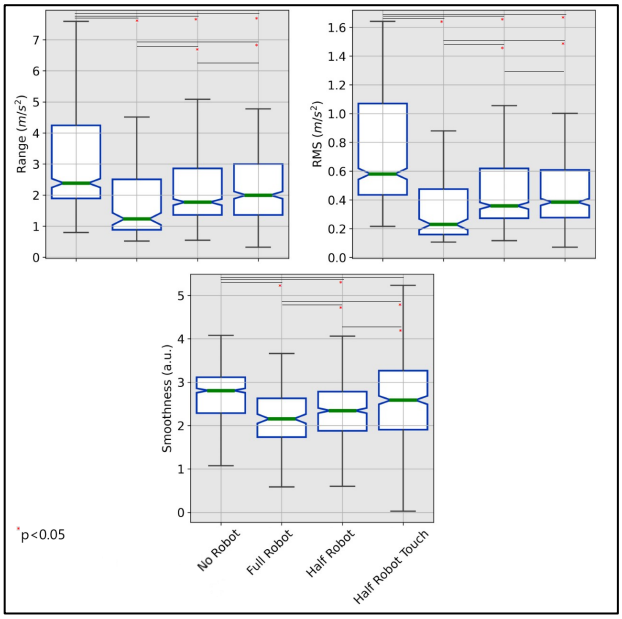

Figure 2 *The analysis of kinematic data extracted from the accelerometer placed on the trunk of the subjects. In descending order, the mean and standard deviations of the range, RMS amplitude, and smoothness are displayed.*

reaching the AS to place the package). The coactivation index of the *no robot* collaboration modality is constantly higher than all the other modalities. It can be noticed that *no robot* and *half robot* have a constant evolution over time indicating a continuous higher coactivation of muscle during the entire time of the trial. *No robot* modality has an increased CI up to 30% at the beginning and then a slow decrease up to 22-25% keeping almost constant values during the package's manipulation phase, and a a small increase to 25% at the end of the cycle. *Full robot* modality produces an great decrease of the CI up to 10% in the resting phase (i.e., when the cobot executes package loading and unloading), and a slower increase in the CI up to 20% during the package manipulation phase similar to those in the other modalities. H*alf robot* always has a constant value of CI around 20%, while *Half robot touch* presents a small peak of CI reaching 25% at the beginning, followed by a rest phase in which the CI reached 15%; from half of the cycle to the CI slowly increased up to 23%.

IV. Discussion and Conclusion

In this study, the working task of a cashier has been simulated with different collaboration modalities provided by a cobot. The objective was to investigate how in a HRC scenario the presence of the cobot induces changes in muscular activity, aiming at a biomechanical risk reduction. It is worth noting that the analysis of muscular activity refers to the involvement of the non-focal muscles characterized by low amplitude since they are mainly devoted to controlling and stabilizing the posture. High levels of trunk acceleration, in terms of amplitude and range, resulted, together with high values of smoothness, when there is no presence of the cobot. This agrees with the analyzed gesture because the working area is entirely covered by the operator and tasks are

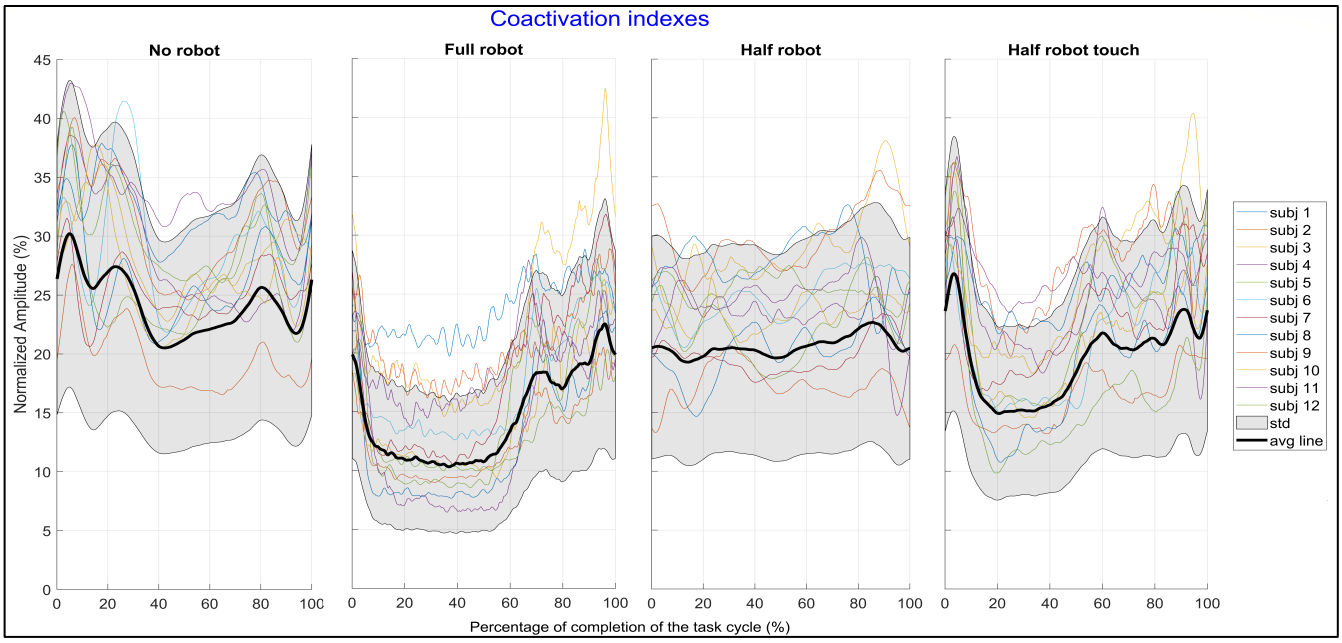

Figure 3 Time-varying Coactivation index computed on the four different trials. In each trial, the CI of each subject is displayed with a different coloured line, while the mean and standard deviations among all subjects are represented by the black line and the light grey area.

performed without any interruptions. In the *no robot* modality, from the analysis of the CI signals, we noticed a continuously high level of CI with increasing values at the beginning and at the end of the cycle, suggesting a continuous posture control to compensate for the packages' loading and unloading phases.

When the cobot cooperates to perform part of the task (i.e., taking the package and bringing it to the scanning station) with a specific cadence (i.e., *half robot* modality), the operator tends to lose control over its own velocity in completing the tasks, because of the inability to predict the timing of the next package to be processed. The result of this effect on the kinematic data is that the operator movement is less smooth, although the range and the amplitude of the acceleration are significantly reduced with respect to all other modalities ($p<0.05$). This modality effectively reduces the range and the amplitude of the movements, because removes the package weight from the loading phase, but the impact of the cobot assistance on the muscular activity is minimum. In fact, although a small decrease in the CI appears with respect to the *no robot* modality, there is still a continuous activation of the muscle throughout the entire duration of the task. This can be explained by a variation of the subject muscular strategy, due to the cobot intervention. Even if the package's loading phase is reduced, this does not help reduce the biomechanical risk, because a continuous muscular effort persists.

In the *full robot* modality, despite a relevant decrease of trunk acceleration, likely due to the higher level of cobot assistance, the operator is, from a theoretical perspective, still not able to predict when the next task will be executed. In practical terms, since the number of managed packages per minute is very low, due to the cobot performance limits, the operator easily and almost immediately seems to adapt their strategy to this specific condition. The smoothness levels are therefore not optimal, as the performed gesture is non-continuous, indicating the use of an intermittent strategy and control of the movement. Because of the increased support by the cobot, and the consequent decrease in the operator's effort, the muscular activity results modified with respect to the other modalities, showing lower average values of coactivation indexes during each cycle. Furthermore, the muscle activation switches from continuous to intermittent, showing different coactivation index values during the manipulation and the waiting phases, respectively.

Similar behavior in the coactivation index can be observed in the *half robot touch* modality, in which the trend oscillates between low values in the resting phase (waiting for the robot to bring the item) and high values in the manipulation one. Nevertheless, the possibility of deciding the beginning of each task (by touching the cobot) helps the operator control the timing of the successive task. This seems to elicit more natural movements, as seen by the significant increase in smoothness.

Therefore, by comparing the four proposed modalities, we could confirm that the introduction of a cobot could efficiently reduce the range and amplitude of the trunk movements of the operator, in addition to producing a lower level of muscle coactivation. Results showed that the collaboration modality can alter the muscle strategy employed by the operator, but it does not necessarily produce benefits, as observed in *half robot*, where the coactivation was maintained constant throughout the whole test. Moreover, it was shown that when the cobot imposes the working cadence on the operator, this produces an increase in the posture stiffness that could be associated with an increase in the biomechanical risk.

In conclusion, the best modality we have found in our analysis is the one where the cobot performs part of the package loading (or unloading) phase, but the operators remain the one that decides the rhythm of the working task.

ACKNOWLEDGMENT

This study is part of the Italian Project BRIC INAIL 2019-ID48 - BRISK: a multi-sensor wearable platform to assess Biomechanical Risk when Interacting with collaborative robotS in worK-related scenarios.

***Abstract*—Optic nerve has been proven to be a valid target for neuroprosthetic implants to restore vision in blind individuals. The optimization of stimulation parameters is crucial for the correct functioning of such implants. Closed-loop stimulation of the optic nerve exploiting the cortical activation pattern as feedback may be a valid optimization strategy. Animal experiments are needed to decode the visual cortex activity in response to simple visual stimuli with a view to testing, in vivo, closed-loop stimulation of the optic nerve. The design of such experiments must take into account the possibility of extending the study to blind human subjects. In this paper, we propose to use machine learning to classify the cortical activation of a mouse, recorded with an electrocorticography (ECoG) array, in response to visual stimuli. The mouse was anesthetized, and 10 different visual stimuli were displayed on a screen positioned 20 cm away from its right eye, while the ECoG array recorded the response of the mouse's left primary visual cortex. We tested 3 classifiers (Random Forest, support vector machine, and multilayer perceptron) and obtained above-chance classification accuracy (47% with 10 classes), showing interesting preliminary results of ECoG and machine learning in terms of visual cortex decoding.**

I. Introduction

Visual prostheses have been under investigation for years [1]. These devices are the last resort for patients suffering from blinding diseases for which no pharmaceutical cure exists and they usually consist of electrode arrays targeting the visual pathway not affected by the disease [1]. There is evidence that the optic nerve is a valid location for a visual prosthesis, which would exploit the ascending visual pathway and be less invasive than a cortical implant [2] [3] [4]. As with other types of neuroprostheses, it is important to optimize the stimulation protocols to elicit the desired visual perceptions [5]. A strategy may be to perform closed-loop electrical stimulation, where the feedback is the evoked cortical activation, that resembles the cortical activation naturally generated by visual stimuli [6]. It has been proven with animal models that optic nerve stimulation can selectively activate the visual cortex [4]. It is now necessary to test the possibility of discriminating simple visual stimuli through the evoked cortical response, a prerequisite for using such response as feedback.

Visual cortex decoding has been widely explored in animals, and research is mainly oriented toward neuronal level decoding [7]. Intracortical probes allow us to record signals with single-neuron resolution, but this information is confined in a limited portion of the primary visual cortex (V1) surface and, due to V1 retinotopic organization, corresponds to a limited portion of the visual field [8]. Moreover, it would be difficult to record single neurons in humans for both technical and ethical reasons [9]. On the other hand, electrocorticography (ECoG)-based visual cortex decoding of visual stimuli has been performed in humans [10] [11] [12], suggesting the possibility to translate these experiments from animal models to human subjects [9]. As another benefit of ECoG, large arrays allow us to record activity from the whole V1, and consequently relative to the whole visual field [8].

In this work, we propose machine learning-based classification of visually evoked potentials recorded with an ECoG array placed on a mouse V1. We delivered visual stimuli with

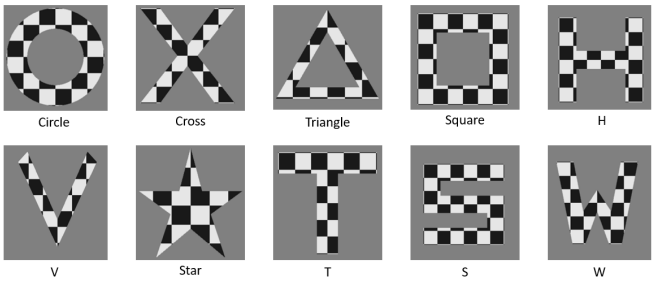

Fig. 2: Shapes displayed on the screen during the experimental session.

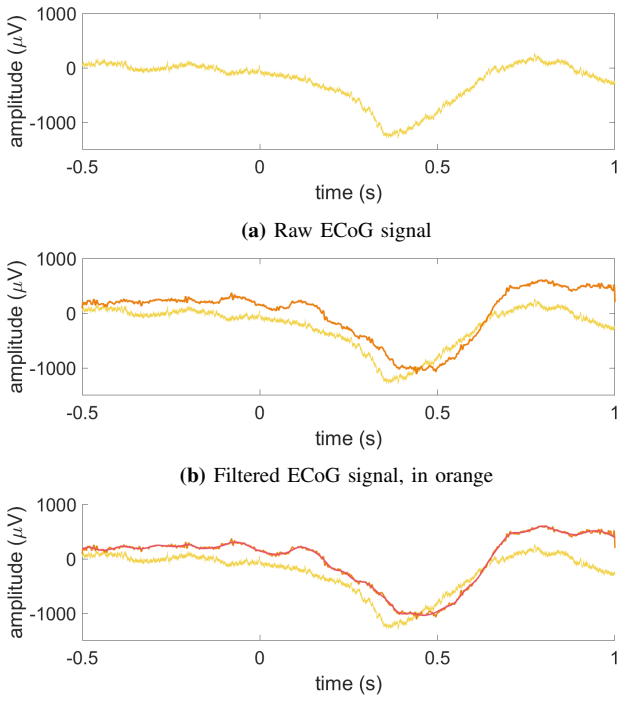
10 different shapes to the animal, recorded its V1 responses, and classified them into the corresponding 10 classes. This allowed us to explore the potential of ECoG arrays combined with machine learning techniques to perform visual cortex decoding, paving the way for *in vivo* testing of closed-loop stimulation of the optic nerve.

II. Materials and Methods

Section II-A describes the visual stimuli and the acquisition of ECoG signals. Data preprocessing and classification are described in Section II-B and Section II-C respectively.



A. Experimental session

Our experiment involved one mouse, which was deeply anesthetized using isoflurane (concentration: 5% induction, 1.5% during surgery) and placed in a stereotactic frame. Craniotomy was performed to expose the left V1 and an ECoG array was placed 3.5mm lateral from lambda, as shown in Fig. 1. The ECoG array was composed of 16 (4x4) platinum sites, spaced of 500 μm (E16-500-5-200; NeuroNexus), and connected to the Neuralynx ERP-27 electrode reference panel.

During the recordings, the mouse was anesthetized using isoflurane (0.8-0.4%) and chlorprothixene 1.5 mg/kg intraperitoneally injected. The visual stimuli consisted of 100 repetitions of 10 different shapes displayed on a screen positioned 20 cm from the right eye of the animal, to elicit cortical responses corresponding to the monocular vision. The visual stimuli, shown in Fig. 2, have the outlines filled with a flickering checkerboard (temporal frequency of 5 Hz, spatial frequency of 0.08 cycles per degree). They were presented in random order after a 500 ms pre-stimulus gray background, lasted for 500 ms, and were followed by 1s of post-stimulus gray background.

B. Data preprocessing

Data preprocessing was performed using the FieldTrip toolbox [13]. The data were divided into segments of 1.5 s, from 0.5 s before to 1 s after the stimulus onset (Fig. 3a). The first step consisted in resampling the data, recorded at 30 kHz, to 1 kHz to improve processing time. A bandpass finite impulse response filter was applied to filter the signal between 0.1 and 200 Hz, and a notch infinite impulse response (IIR) filter was used to suppress the line noise (50 and 150 Hz) (Fig. 3b).

(a) Raw ECoG signal

(b) Filtered ECoG signal, in orange

(c) Wavelet-denoised ECoG signal, in red

Fig. 3: Sample results of signal preprocessing on one of the 16 channels of the ECoG array. The yellow signal in panel **a** is the raw ECoG signal, the orange in panel **b** is the filtered signal, and the red in panel **c** is the wavelet-denoised signal.

After visual inspection, faulty channels (9 and 16) were interpolated exploiting their neighbors. Finally, 5-level wavelet decomposition was performed using the Bior3.3 biorthogonal wavelet function. The level 5 approximation coefficient vectors were reconstructed (Fig. 3c), and a window of interest between 0 and 0.8 s was extracted for each channel and concatenated for each trial. The dataset used to train and test the classifiers comprised 1000 trials of 13104 time samples.

C. Classification

The same training procedure was used to test 3 classifiers, namely a Random Forest (RF) classifier, a support vector

TABLE I: Hyperparameters tested with grid search

Classifier	Parameter	Values
Random Forest	n_estimators	10, 100, 500
	max_features	32, 10, 20
	max_depth	10, 20, 30, 50
	min_samples_leaf	1, 2, 4
	min_samples_split	2,5,10

machine (SVM), and a multilayer perceptron (MLP). Nested stratified cross-validation was performed for hyperparameter optimization. The dataset was divided into 10 folds in the outer loop and into 3 folds in the inner loop. The hyperparameters (Table I) were tuned by performing a grid search and selected according to the best classification accuracy on the validation set.

The metrics used to evaluate the models were the classification accuracy and the area under the receiver operating characteristic (ROC) curves, macro-averaged across the 10 folds. One-way ANOVA test was used to assess the statistical significance between the performance of the 3 classifiers.

All the experiments were performed on a Dell XPS 8940, Intel Core i7-10700 processor, 2.90GHz CPU, NVIDIA GeForce GTX 1660 Ti GPU, 16 GB RAM.

III. Results

The classification performance of the 3 tested classifiers are summarized in Fig. 4. RF classifier performed with an accuracy of 22.70±0.3% and an area under the ROC curve (AUC) of 0.66 (Fig. 4, **A** and **D**), slightly above the chance level despite the low classification accuracy. As shown in Fig. 5, classification performance with the SVM was significantly better ($p < 0.01$), and resulted in an accuracy of 44.20±0.05% and an AUC of 0.86 (Fig. 4, **B** and **E**). MLP outperformed in accuracy both the previous classifiers reaching an accuracy of 47.10±0.05%. The AUC was 0.84, lower than the SVM (Fig. 4, **C** and **F**).

Despite the different performances, there is consistency across the confusion matrices. With all the classifiers, Star and T are well identified, while V and Triangle are difficult to discriminate.

IV. Discussion and Future Work

The optic nerve is a possible target for a neural prosthesis aimed at vision restoration [2] [3] [4] and, as with all other neuroprostheses, a crucial aspect is the choice of the stimulation parameters and their optimization strategy. A viable idea is the closed-loop stimulation of the optic nerve, which exploits the cortical activation pattern as feedback [6]. According to this strategy, the cortical activation following the electrical stimulation of the optic nerve would be compared to and driven towards a certain target cortical activation, corresponding to visual perception. To achieve this, a target cortical activation must be identified in principle, therefore we need to classify the activity of the visual cortex based on the visual stimuli presented to the mouse.

The goal of this work was to investigate the feasibility of visual stimuli classification based on the cortical response recorded with an ECoG array. The stimuli set comprised 10 simple shapes, which were passively presented to the anesthetized animal, in random order. Machine learning was

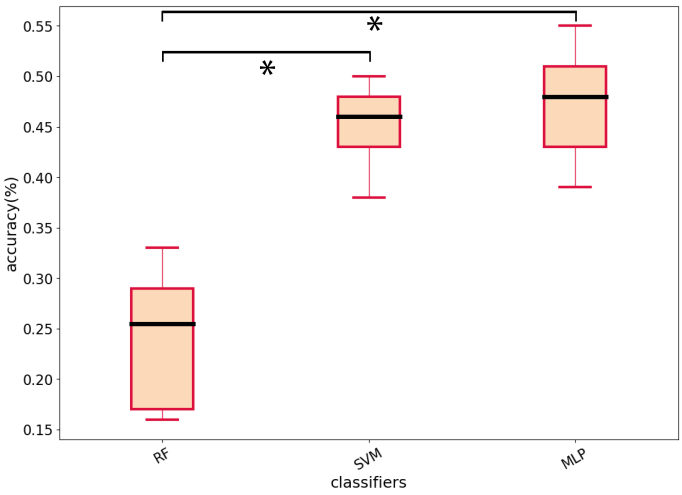

Fig. 5: Comparison of the classifiers' performance. The boxplots show the accuracy of the different classifiers on the test set.

exploited to perform the stimuli classification, and in particular, RF, SVM and MLP classifiers were tested. RF performance was not satisfactory, being above the chance level ($AUC > 0.5$) but not enough to be considered acceptable [14]. Conversely, SVM and MLP classifiers allow significantly better performance, as shown in Fig. 5. More than 40% accuracy has been reached on 10 classes, with AUCs of 0.86 and 0.84 respectively, which indicate good discrimination between classes and classification beyond the chance level.

One potential limitation of our study is that we only used data recorded from a single mouse, which may limit the generalizability of our findings. However, despite this limitation, our results suggest that it might be possible, to a certain extent, to associate a visual stimulus with the corresponding cortical response recorded with an ECoG array. It is important to note that ECoG has a low spatial resolution of recordings, which is likely why, to our knowledge, it has not been previously used for visual stimulus decoding in mice.

On the other hand, the advantages of this technique make it the most suitable for this study. It allows us to record evoked responses from large portions of V1 and consequently of the visual field [8], avoiding information loss. It is possible to record the electrically evoked potential in response to optic nerve stimulation [4], a crucial step for the implementation of closed-loop stimulation. ECoG-based decoding of visual stimuli in human subjects is feasible and has already been done in the literature [10] [11] [12], making it possible to move the study to humans. These advantages are of great importance for the future developments of the study, concerning the closed-loop electrical stimulation of the optic nerve on animal models first, and on humans in the future.

Short-term future steps involve data collection from several animals to investigate the possibility of generalization, the delivery of different visual stimuli to explore the performance of this technique when other areas of the visual field are involved, and the exploration of the closed-loop stimulation of the optic nerve on animal models.

Effects of State Representation on a Reinforcement Learning Based Decision Support System

C. Drudi[1], M. Mollura[1], and R. Barbieri[1]
[1] *Department of Electronic, Information and Bioengineering, Politecnico di Milano, Milano, Italy*

***Abstract*—Reinforcement Learning (RL) methods are increasingly seen as an effective paradigm for providing important solutions in healthcare applications. This is particularly true in critical care, where sequential decision making is closely related to the RL paradigm. However, there are still important issues to be addressed, including the crucial problem of defining an optimal Markov Decision Process (MDP) that best fits the real-world clinical scenario.**
Many proposed approaches to RL in the ICU have used k-means clustering to define the states of the MDP. The k-means algorithm is particularly vulnerable to high-dimensional data, which is needed to account for all possible confounders.
In this work, we use the k-medoids algorithm to define the Markov states. Since this method is more robust to noise and outliers, we investigate the effect of the clustering algorithm on the performance of the RL model.
Data from 20,496 ICU stays of septic patients were included in this study. Two different MDPs were built. The first had its states defined using the k-means algorithm, while the second had its states defined using the k-medoids algorithm. Both MDPs were then solved using an RL technique called policy iteration to obtain the optimal policy. The optimal policies were evaluated using the Weighted Importance Sampling (WIS) estimator.
The policy obtained using k-medoids converged to a 95% confidence lower bound (LB) of 88.67, performing better than the policy obtained using k-means (95% confidence LB of 86.01). This finding suggests that the use of k-medoids in the RL setting could be a key element within an AI-based clinical decision support system, potentially resulting in a lower mortality rate compared to current traditional treatment strategies.

I. INTRODUCTION

In recent years, healthcare research has seen a sharp increase in advanced statistical applications to develop new technologies aimed at assisting clinicians in the treatment of patients. These methodological advances have been fostered by the increasing amount of data available, the collection of which has been made possible thanks to technological advances in the collection, storage and processing of data [1], [2]. Critical care practice consists of a series of sequential decisions to be made, this makes the Intensive Care Unit (ICU) particularly compatible with the Reinforcement Learning (RL) paradigm. RL is able to infer which actions are statistically optimal from the pool of actions commonly selected by clinicians.
Many successful RL applications in the ICU context are available in the literature. Some relevant examples include [3], the authors applied RL to determine the optimal target glycemic level in critically ill patients and managed to reduce the mortality of the cohort from 31% to 24.7%. References [4], [5] managed to optimize the timing of mechanical ventilation (MV), reducing the incidence of reintubation and decreasing the total time under MV, while [6], [7], [8] optimized heparin dosages with RL.
One particular condition in critical care that has gained attention in healthcare is sepsis. Several studies [9], [10], [11], [12] have proposed RL applications to individualize and optimize the hemodynamic treatment of septic patients. Despite being a burdensome condition, there is no common consensus among clinicians regarding an optimal treatment strategy, with agreement on only a few treatment variables [13]. RL applications have shown great potential to fill the knowledge gap in sepsis management, allowing for personalized vasopressor (VP) and intravenous fluid (IV) treatment based on a patient's specific characteristics at any given time.
Despite its great potential, RL has some common limitations that need to be addressed [14], [15]. One of these shortcomings is the choice of state representation in the Markov Decision Process (MDP) definition. It is categorical that the state representation correctly and exhaustively summarizes the information contained in the data. One of the most popular methods to define the states is through partitioning clustering techniques, mainly using k-means algorithm. In general, RL applications require high-dimensional space data to ensure that all possible confounders have been included. High dimensionality is also shown to interfere with the k-means algorithm, which loses performance as the dimensionality of the data increases. Furthermore, [16] suggests that the k-medoids algorithm performs better for large datasets.
In this study, we compare the effect that the k-means and k-medoid algorithms have on the performance of RL agents.

II. METHODS

A. Data and preprocessing

This work considers the "Multi-parameter Intelligent Monitoring in Intensive Care (MIMIC-III) database, which contains data from 53,423 hospital admissions at the Beth Israel Deaconess Medical Center in Boston between 2001 and 2012 [17].

The study cohort consists of patients who meet the Sepsis-3 criteria [18] and excludes patients under 18 years of age, those with undocumented mortality or intravenous fluid administration, or those with treatment withdrawal, including those in palliative care or unrecoverable. Patient withdrawal is defined as death within 24 hours of the end of data collection and no receipt of vasopressor during the last 24 hours of data collection, but having received at least one previous administration. The final study population includes 20,496 unique ICU admissions.

Sepsis was identified using two criteria: the presence of a positive microbiological specimen prior to antibiotic administration or a positive microbiological specimen within 24 hours of prior antibiotic administration. In the first case, the onset of sepsis was defined only if the antibiotic was administered within 72 hours of the microbiological sample. The time of sepsis onset is determined as the time of the earliest event [18].

The data used in this study includes values collected from 24 hours before the estimated onset of sepsis to 48 hours after the estimated onset of sepsis. The data are organized in 4-hour time bins, and when multiple observations for the same variable were available in a given time bin, they were averaged or summed according to the type of variable. The study includes 48 variables such as vital signs, demographics, laboratory values, fluid balance, the Elixhauser comorbidity score, and the treatments of interest: intravenous fluids and vasopressors. The study assumes a baseline SOFA score of zero, consistent with previous work in the literature [19], and variables with heterogeneous units of measure were standardized and the numerical values of the variable are capped at plausible physiological values.

This study addresses data sparsity by using a zero order interpolation approach [20], which is commonly used when dealing with clinical time series and mimics the behavior of medical decision making [21]. Any remaining missing data is imputed using interpolation. The data are divided into a training set (80%) and a test set (20%).

In this study, an MDP is built on the dataset. Each patient is assigned to a state for each time step using a partitioning clustering algorithm. The total number of clusters is 750, and two additional absorbing states are added to represent either survival or death of the patient. A total of two models are built, one using k-means as the clustering algorithm and one using k-medoids as the clustering algorithm.

Five bins are created for each treatment type, with one bin reserved for the null dose and the remaining four bins being bounded by the 25th percentile, median, and 75th percentile. The total number of possible actions is 25. The rewards received by the agent are set to +100 if the MDP ends in the "survived" state and -100 if it ends in the "dead" state, this choice is to ensure that the RL agent tries to maximize the 90-day survival. The dynamic evolution of the MDP is determined by the transition matrix T (s',s,a), which defines the probability of each state-action-new-state (s-a-s') triplet. The transitions that occurred less than 5 times were excluded; this choice is made to force the RL agent to select only actions commonly chosen by clinicians, making the resulting policy safer.

B. Policy iteration and evaluation

The MDP underlying RL was solved using the policy iteration algorithm, which involves starting with a random policy, evaluating it, then updating the optimal action for each state, and repeating until convergence to the optimal policy [22].

The state-action value function $Q^{\pi}(s,a)$ represents the expected sum of discounted rewards from following policy π, given a particular state-action pair (*s,a*), and it indicates how beneficial it is to take action a when in state s.

The policy determined to be optimal by policy iteration is defined as:

$$\pi(s)^* \leftarrow \underset{a}{\operatorname{argmax}}\, Q^{\pi^*}(s,a) \forall s \tag{1}$$

Once the policy π to evaluate is known, the state-value of each state s when following policy π can be computed using the Bellman equation:

$$V^{\pi}(s) = \sum_{a} \pi(s,a) \sum_{s'} T(s',s,a)[R(s') + \gamma V^{\pi}(s')] \tag{2}$$

To determine the performance of the optimal AI policy, a technique called Weighted Importance Sampling (WIS) was used, where π_C represents the policy that generated the data and π_{AI} represents the policy of the AI.

The accumulated importance ratio at time step t is defined as:

$$\rho_{1:t} := \prod_{t'=1}^{t} \pi_{AI}(a_{t'} \| s_{t'}) / \pi_C(a_{t'} \| s_{t'}) \tag{3}$$

the average at time t of equation 3 is $w_t = \sum_{i=1}^{N} \rho_{1:t}(i)/N$, where N is the total number of trajectories.

The WIS estimator for a single trajectory can be defined as:

$$V_{WIS} = \frac{\rho_{1:T}}{w_T} \sum_{t=1}^{T} \gamma^{t-1} r_t \tag{4}$$

the overall WIS estimator is determined by averaging all V_{WIS} over each available trajectory.

III. RESULTS

To evaluate and compare the effects of the two different partitioning clustering methods on the RL agent, we visualized (Fig. 1) the evolution of the 95% confidence lower bound (LB) during the training process.

The performance of the RL agent obtained by performing policy iteration on the MDP with the state representation determined by k-means is shown with a solid orange line, while the solid blue line represents the performance of the RL agent obtained by performing policy iteration on the MDP with the state representation obtained by the k-medoids algorithm. Note that the RL agent obtained by k-means for model number

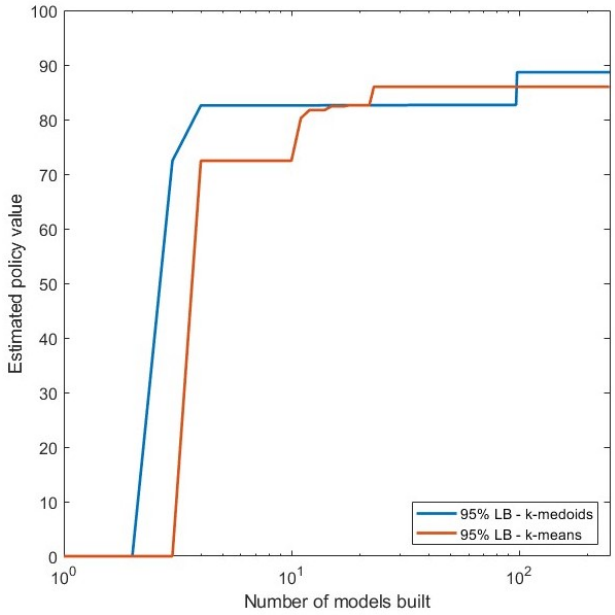

Fig. 1: Evolution of the 95% confidence LB of the *k-means* model and *k-medoids* model over the training of the RL policy

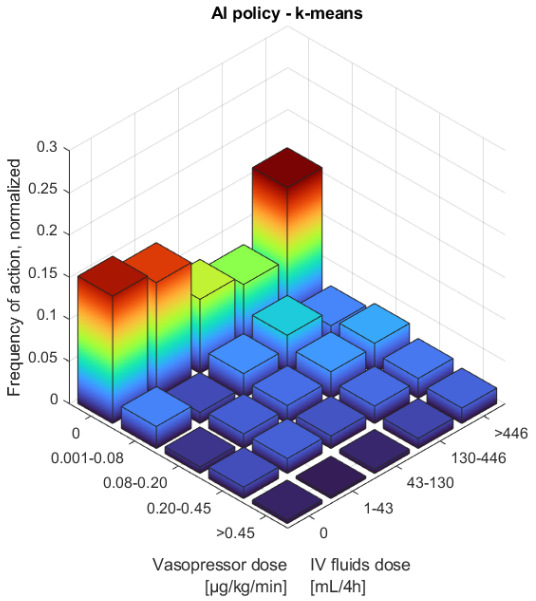

Fig. 2: Histogram of normalized frequencies of the action selected by the *k-means* policy

4 has a 95% LB of 72.45, 80.26 for model number 11, 81.73 for model number 12, 82.42 for model number 15, and 82.62 for model number 18. The improvement of the 95% LB stops at model number 23 and settles at 86.01.
For the RL agent obtained after k-medoids, we have a 95% LB of 72.43 for model number 3 and a 95% LB of 82.58 for model number 4. Two small improvements occur at models 14 and 33 with 95% LB of 82.62 and 82.67 respectively. The model then settles down to a value of 88.67 at model number 98, clearly outperforming its k-means counterpart.

The frequencies of the actions chosen by the k-means policy are visualized in Fig. 2, while the frequencies of the action chosen by the k-medoids policy are shown in Fig. 3.

The numerical results are shown in the tables 2 and 3. The *high* option corresponds to the highest bin (>446 mL/4h for IV and >0.45 μg/kg/min for VP). The k-medoids policy acts more frequently on our patient cohort than the k-means policy, thus less frequently resorting to extreme treatment options and preferring a more moderate treatment strategy.

	No VP	*Moderate VP*	*High VP*
No IV	0.1511	0.0474	0.0043
Moderate IV	0.3011	0.0974	0.0119
High IV	0.1611	0.0862	0.0183

TABLE I: Normalized frequencies of the action selected by the *k-means* policy

IV. DISCUSSION

The objective of this study was to analyze and compare the effect of different partitional clustering algorithms on the performance of the RL model. Two algorithms were compared: the k-means algorithm and the k-medoids algorithm.

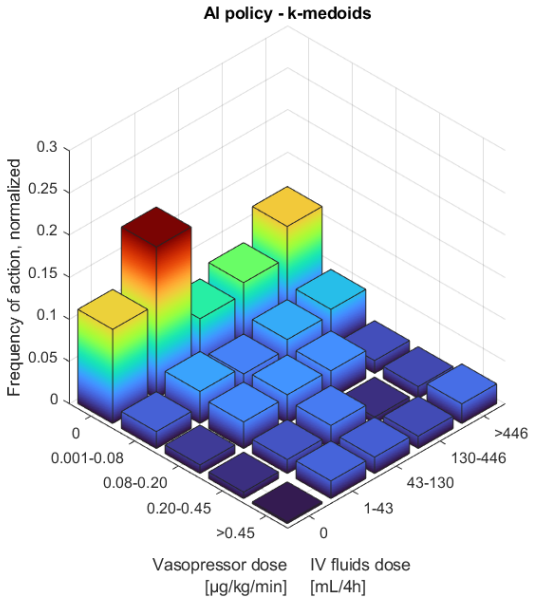

Fig. 3: Histogram of normalized frequencies of the action selected by the *k-medoids* policy

	No VP	*Moderate VP*	*High VP*
No IV	0.1117	0.0379	0.0021
Moderate IV	0.3226	0.080	0.0146
High IV	0.1149	0.0755	0.0233

TABLE II: Normalized frequencies of the action selected by the *k-medoids* policy

When the RL agent was computed using the k-medoids algorithm to define the states of the MDP, we observed a sharp improvement in model performance. This result may be

explained by the improved state representation obtained with the k-medoids algorithm.

This observation is consistent with other works in the literature that claim that k-medoids have some advantage over k-means [16], [23]. It has also been found from experimental results that k-means is advantageous for smaller datasets, while k-medoids tend to perform better for large datasets, a common characteristic of datasets used for RL. It is also shown that k-medoids is more robust to outliers and more resilient to noisy data, one of the common problems of high-dimensional feature spaces used in RL. In addition, the cluster quality is visually more convincing and with less class overlap when using k-medoids.

Finally, the k-medoids policy acts more often on the study cohort with respect to its k-means counterpart, and it is also less extreme. As a matter of fact, the k-medoids policy suggests extreme treatment options less frequently than the k-means policy.

This property might be preferable since extreme treatment dosages are usually used only as a last resort. Thus, the more moderate behaviour of the k-medoids policy may be the reason behind the performance boost of the RL policy and it also more closely reflects the behavior of clinicians who use extreme treatment options more sparingly.

V. CONCLUSION

In conclusion, we have shown that applying a k-medoids clustering algorithm to build the states for the MDP underlying RL leads to an improvement in the performance of the model. In particular, the RL agent obtained by k-medoids achieves a 95% LB equal to 88.67, while its k-means counterpart shows a 95% LB of 86.01. Given this result, it appears that using the k-medoids algorithm instead of the k-means algorithm to build the state representation could be beneficial, leading to a decision support system that minimizes mortality and improves sepsis treatment outcomes.

In addition, it is possible that the actions suggested by the k-medoids policy might be more welcome by clinicians, since they tend to be more moderate and realistic, incurring less often to high dosages.

***Abstract*—One of the main factors contributing to road accidents all around the world is driver fatigue. For safety reasons, it is essential to identify drowsiness episodes as soon as possible. Numerous studies have shown that PERCLOS, i.e. the percentage of eyelid closure over the pupil across time, is one of the most accurate parameters for drowsiness state assessment. The evaluation of PERCLOS is, however, dependent on the lighting conditions because it is normally computed from the visible video of the subjects. The goal of this study is to get around these constraints by assessing sleepy states using inexpensive, high-resolution thermal infrared technologies. Twelve sleep-deprived participants were chosen for the study, which involved an hour-long driving activity on a driving simulator. Thermal camera Device Alab SmartIr640 was used to capture facial skin temperature throughout the trial, along with facial visible videos of the subjects. Relevant thermal features were estimated from facial regions of interest and extracted over a 30 second time span. A data-driven multivariate machine learning approach based on a three-level Decision Tree Classification of the drowsy state (AWAKE class: PERCLOS<0.15, FATIGUE class: 0.15<PERCLOS<0.23, and SLEEPY class: PERCLOS>0.23) was developed. The average classification accuracy was 0.72±0.05 (mean ± standard deviation). These preliminary results point to the possibility of determining drivers' drowsiness based on facial thermal traits, circumventing the limitations associated with lighting and eye detection that are typical of conventional approaches.**

***Keywords*—drowsiness detection; ADAS; thermal infrared imaging; machine learning;**

I. INTRODUCTION

ONE of the most frequent causes of fatal traffic accidents worldwide is driver fatigue.

The National Highway Traffic Safety Administration (NHTSA) estimates that around 100,000 accidents each year involve drowsy driving. More than 1,550 people die in these collisions, and 71,000 people are injured [1]. The scientific community has made various attempts over the past few decades to prevent accidents brought on by drowsy driving. The estimation of three different types of factors can be used to identify drowsiness:1) Vehicle based 2) Behavioural based 3) Physiological based [2]. Among all, one of the most effective methods to assess driver drowsiness is based on the estimation of a behavioural parameter related to the eye blink, i.e., PERCLOS (percentage of eyelid closure over the pupil across time).

PERCLOS is the cumulative eye closure duration excluding the time spent on normal eye blinks. PERCLOS has been shown to be a highly accurate measure for estimating the drowsy condition of the driver (accuracy of 91.6% stated in [3] and 94.58% in [4]). However, PERCLOS is normally calculated from the visible video of the subjects and its evaluation is highly dependent on the lighting conditions.

Given its independence from the ambient lighting conditions, thermal infrared (IR) imaging may provide a remedy for these shortcomings (i.e., applications also over night or in low-light situations). Additionally, it has the significant benefit of being able to assess autonomic parameters (such as respiratory, sudomotor, and cardiovascular functions) non-invasively and with no contact with the participants [5]. So, if compared to methodologies relying on visible imaging, IR imagery is very suitable for drowsiness detection solution especially in contexts of poor lighting/night conditions.

Given the benefits of using thermography for driver condition monitoring, there are a sizable number of scholarly publications in this area of study. The majority of these publications deal with monitoring driver fatigue and sleepiness. Driver drowsiness was examined by Ebrahimian-Hadikiashari et al. [6] by examining the respiratory function as measured by thermography. The authors saw a considerable reduction in the rate of driver breathing as they transitioned from extremely sleepy to awake states. Additionally, Knapik et al. [7] presented a method based on thermal imaging yawn detection for the evaluation of driver weariness. Recently, Cardone et al. [8] presented a preliminary study relying on a support vector classification able to evaluate the driver's drowsiness state. The present work represents an improvement of [8], employing a different classification model based on a decision tree approach.

In this study, supervised machine learning (ML) techniques and IR imaging were used to determine the driver's level of drowsiness. A three-level Decision Tree classification (DTC) of the drowsy state was carried out, relying on the physiological parameter PERCLOS, used as the gold standard, on the basis of key features of thermal signals extracted from peculiar regions of interest (ROIs), indicative of the psycho-physiological state. The PERCLOS relies on eyelid activity, which, as well as the temperature of the body, are both under the control of the autonomic nervous system. So we hypothesized a strict link between the gold standard used as output for the classification model and the input IR thermal features.

The three output classes have been defined using the work of Garcia et al. [9] and PERCLOS evaluation over time (i.e. AWAKE vs. FATIGUE vs. SLEEP). A leave-one-subject-out cross-validation was used to evaluate the model's

generalization capabilities.
The advanced driving-assistance systems (ADAS) technology and, generally, the degree of road security are both significantly improved by the contactless methodology described in this work for the identification of driver sleepy states.

II. MATERIALS AND METHODS

A. Participants

Twelve adults (6 males, age range 25–45 years, mean 32.7 years) were recruited for the experiment. Before each experimental session, participants were widely informed about the purpose and protocol of the study, and signed an informed consent form, explaining the methods and the purposes of the experimentation in accordance with the Declaration of Helsinki. All the participants were asked to sleep up to two hours the night before the experimental session. Additionally, they were instructed to abstain from consuming any stimulating drugs for the twelve hours prior to the experiment, such as tea, coffee, and cigarette smoke.

B. Procedure and data acquisition

Each individual spent 20 minutes in the experimental room prior to the test to allow the baseline skin temperature to stabilize. A thermostat was used to set the recording space's standard temperature (23 °C) and humidity level (50–60%).
The experiment was carried out using a static driver simulator. Three 27-inch monitors were used to show the scene. The stimulation's total video resolution was 5760 x 1080 pixels. The driver and the screen were separated by 1.5 meters. The horizontal view angle of the participant was 150 degrees.
The City Car Driving, Home Edition software (version 1.5) [10] was used to simulate driving. The experimental procedure involved running a driving simulation in an urban setting for 60 minutes. To guarantee monotonous driving circumstances and consistency of the study protocol for all subjects, the experimental conditions were predetermined (i.e., Traffic density: 0%; Traffic behavior: Low density of traffic; Fullness of traffic: 0%; Dangerous change of traffic: Never; Emergency braking of the car ahead: Never; Pedestrian crossing the road in a wrong place: Never; Accident on the road: Never; Dangerous entrance of the vehicle to the oncoming lane: Never).
Both visible and thermal IR videos were taken while the experimental technique was being carried out.
The depth visible camera Intel RealSense D415 (Full HD 1080p (1920 x 1080)) and the thermal IR camera Device Alab SmartIr640 (spatial resolution: 640x480 pixel, thermal sensitivity: < 50 mK) both recorded visible and thermal infrared (IR) videos.

C. Analysis of PERCLOS signals

The proportion of time that the eyelids are closed over the pupil is known as PERCLOS, and tracking facial landmark's position in relation to the eyes region is required for its evaluation. The technique proposed in [11] was applied to track the coordinates of 68 face landmarks over time.
The visible videos were used to extract PERCLOS signals, which were then computed over 30 second time intervals. The Eye Aspect Ratio (EAR) was first calculated with the procedure described in [12]. The ratio of the eye's height to width is known as the EAR. It is nearly constant and equal to one when the eye is open, and it is approximately zero while closing the eye.
When the EAR is lower than 0.8 for a period that is longer than 3 frames (i.e. 0.1 seconds since the acquisition frame rate was 30 Hz), PERCLOS is marked with 1, otherwise it is 0. Then, for each temporal window (i.e. 30 seconds), the occurrence of 1 is evaluated and a percentage value of this signal is evaluated (PERCLOS%). Referring to the classification thresholds defined in [9], three classes were identified as follows:
1. CLASS 0 - awake --> if $0 \leq PERCLOS\% < 15\%$
2. CLASS 1 - fatigue --> if $15\% \leq PERCLOS\% < 23\%$
3. CLASS 2 - drowsiness --> if $PERCLOS\% \geq 23\%$

A gold standard signal was thus produced for each individual and each interval of 30 seconds, serving as the reference (i.e. label output) for the classification model.

D. Analysis of visible and thermal imaging data

Visible and IR videos of the subjects' faces were simultaneously recorded during the driving experiment at an acquisition frame rate of 30 Hz.

Given the availability of computer vision algorithms for visible videos, visible imaging was used as reference for tracking facial landmark features. The visible facial landmark features were transferred to the thermal imagery, estimating the geometrical transformation between the two imaging optical devices. The tracking procedure described in [11] was used to identify the 68 facial landmark on the thermal images over time, relying on the co-registered visible video. Figure 1a shows an example of the 68 feature landmarks identified on a thermal image.

Two ROIs were considered and positioned on facial areas of physiological importance (nose tip and glabella). The ROIs' coordinates were automatically calculated from the location of the 68 landmarks. In this way, the initialization of the position of the ROIs was automatically determined (Figure 1a).
For each ROI, the average value of all the pixels belonging to the ROI was extracted over time (Figure 1b).

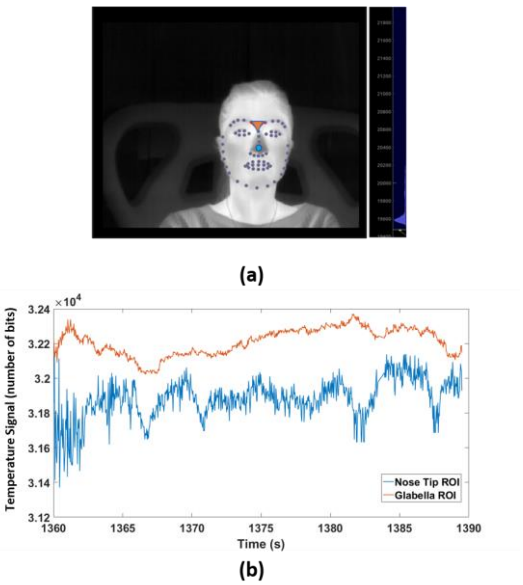

Fig. 1: Thermal signal extraction: (a) Facial landmark identification in the thermal image and ROI identification (nose tip and glabella

showed in orange and blue color respectively), (b) average thermal signals extracted from the ROIs in an exemplificative time window.

Eleven features were computed over successive 30-seconds temporal windows for each of the extracted signals:
1) average value of the raw thermal signals (M);
2) standard deviation of the raw thermal signals (STD);
3) kurtosis of the raw thermal signals (K);
4) skewness of the raw thermal signals (S);
5) absolute value of the difference between the average of the signal in the first 5 seconds and in the last 5 seconds (Δ);
6) 25th percentile of the raw thermal signals (25th P);
7) 50th percentile of the raw thermal signals (50th P);
8) 75th percentile of the raw thermal signals (75th P);
9) 90th percentile of the raw thermal signals (90th P);
10) slope of the raw signal, defined the angular coefficient of the line interpolating the signal (Sl);
11) sample entropy (SampEn).

Importantly, a feature selection based on wrapper approach was employed to consider only the minimal set of features that were relevant for the classification purpose. In this study, a number of 50 random combinations of features was chosen.

E. Application of supervised machine learning

A ML approach based on DTC was employed to classify the drowsy state of the subjects. The eleven thermal features described in Section *II.D* were used to perform a three-level classification of the driver's drowsy state (i.e. AWAKE - FATIGUE - SLEEP). The three classes were defined relying on the threshold defined from the PERCLOS evaluation (Section *II.C*). Cross-validation was employed to assess the generalization capabilities of the procedure. Specifically, a leave-one-subject-out cross-validation was executed.
Furthermore, given the different sample numerosity of the classes, a bootstrap procedure was implemented to test classification performance on balanced classes. The performances of the classification were evaluated by Receiver Operating Characteristic (ROC) analysis.

III. RESULTS

Since the three classes had a different number of samples (797 samples for AWAKE vs. 32 samples for FATIGUE vs. 42 samples for DROWSINESS conditions), a bootstrap procedure was implemented to provide a classification using balanced classes. The average Area Under Curve (AUC) was 0.72 and with standard deviation of 0.05. The distribution of the AUC obtained after the bootstrap is reported in Figure 2 whereas the confusion matrix is reported in Figure 3.

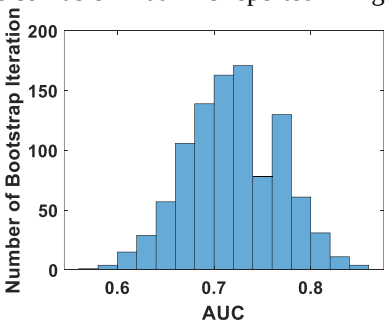

Fig. 2: Results after bootstrap procedure (n_iterations = 1000): distribution of the Area Under Curve (AUC) obtained after the bootstrap procedure.

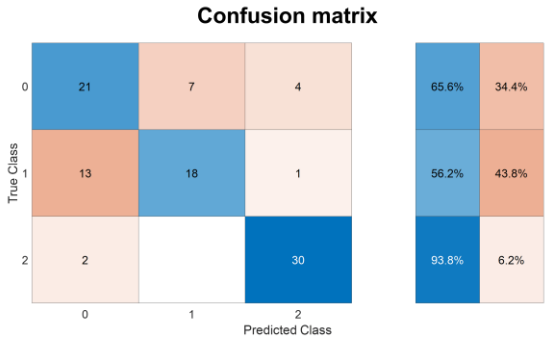

Fig. 3: Confusion matrix for the presented DTC model.

Relying on the confusion matrix, performance parameters, such as specificity and sensitivity were computed for each one of the classes considering the other ones as a unique class. The values of the parameters are reported in Table 1 for each class:

TABLE I: SENSITIVITY AND SPECIFICITY OF THE PRESENTED SVC CLASSIFIER

Standard parameter	***Sensitivity***	***Specificity***
Class 0	0.66	0.76
Class 1	0.56	0.88
Class 2	0.94	0.83
Average -global	**0.72**	**0.82**

Averaging the values reported in Table 1, a global sensitivity of 71.87% and a global specificity of 82.37% were obtained demonstrating a consistent improvement with respect to the authors' previous work [8], which reported a sensitivity of 72.52% and a specificity of 67.69%.

IV. DISCUSSION

This article describes a novel approach to measuring driver drowsiness based on thermal IR imaging and supervised ML. Thermal infrared images and visible videos were captured on twelve sleep deprived participants during an experiment on a driving simulator. In this study, PERCLOS was thus evaluated in consecutive 30-seconds time windows. In the same temporal window, eleven representative features from average thermal signals on two ROIs (i.e. nose tip and glabella) were extracted (Fig. 1). These specific ROIs are reported in literature as the most responsive regions to the autonomic responses and have been already employed to assess stress levels, cognitive workload on drivers. The two ROIs have been also used on drowsiness detection, especially the nose tip area [6],[7]. Using a multivariate ML method based on DTC, a three-level classification of the driver's drowsy state was carried out (i.e. AWAKE vs. FATIGUE vs. SLEEP). A bootstrap approach was used because of the three classes imbalance. The classifier performed well according to ROC analysis, with an average AUC of 0.72 (Fig. 2), a sensitivity of 71.87% and a specificity of 82.37% (Table 1), thus indicating promising performances of the developed model.
It is important to note that the cross-validation and bootstrap procedures tested the model's applicability to a large cohort of

drivers and offered the generalization performances of the model.

The developed method's main advantage over existing literature is its use of supervised machine learning, which is based only on thermal features and ignores any parameters related to the behavior of the driver or the vehicle [13]. This approach achieves performance levels that are comparable with those of more sophisticated methods. Additionally, because the model has already been tested and is ready for use, the established method paves the way for effective real-time implementation of monitoring drivers' sleepy states using simply thermal IR imaging.

However, additional research should be done to broaden the sample. The employed ML approach relied on supervised learning, which is inherently a data-driven analysis. Since data-driven analysis is greatly influenced by sample size, the model's performance could actually be improved by reducing a potential overfitting effect brought on by the small sample size. Another limitation of the study relies on the methodology used for IR features extraction. The IR tracking approach relied on visible imaging algorithms for facial landmark tracking. To benefit from the advantages of using the only thermal IR imaging (e.g. independence from poor/scarce lighting conditions), a completely IR imaging based tracking approach should be developed. The authors want to underline that the main aim of this study was to assess the possibility to develop a model for drowsiness detection based on the only IR thermal features. IR tracking algorithms development is still an open issue to be solved in the future. Finally, the data presented in this work are related to simulated driving scenarios, where factors like direct ventilation or sunlight that affect IR measurements were not taken into account. To broaden the technique's application, it would be necessary to apply the proposed methodology to real-world driving scenarios as well.

For future directions, since the PERCLOS thresholds clearly have an effect on the results, it would be interesting to investigate the ML performance with varying threshold levels and also to compare different typologies of ML classifiers.

V. CONCLUSION

The use of thermal IR imaging and ML algorithms to identify driver drowsiness is presented. The primary goal of the method was to identify the drowsy states of the drivers, overtaking the shortcomings associated with the use of visible cameras to identify indicators of fatigue. The drowsy condition of the individuals while driving in a simulated setting have been classified with a good level of accuracy using a machine learning approach based on thermal features. The presented research reveals that facial thermal traits could constitute a reliable sign of drowsiness in drivers.

Supervised Learning-based Detection of Pressure-induced Failures in Continuous Glucose Sensors

E. Idi[1], E. Manzoni[1], A. Facchinetti[1], G. Sparacino[1] and S. Del Favero[1]
[1] *Department of Information Engineering, University of Padova*

***Abstract*—Continuous Glucose Monitors (CGMs) are minimally invasive sensors that are crucial for the management of Type 1 Diabetes (T1D). Pressure-induced sensor attenuations (PISAs) are common faults that occur in the every-day use of the devices. PISAs result in false low blood glucose readings that can impact the reliability in both real-time and retrospective use of the sensors. In this work, we investigate the detection of PISAs failures using supervised learning techniques. Specifically, 6 algorithms, namely Support Vector Machine, Logistic Regression, k-Nearest Neighbors, Decision Tree, Random Forest and Adaptive Boosting are tested and compared to recognize the failures on a dataset generated in-silico using a state-of-art T1D simulator. Encouraging performance are achieved by some of the algorithms tested. In particular, Random Forest recognized up to 90% of the failures with less than 1 false alarms every 10 days. The results obtained in the simulated scenario paves the way for further analysis on real-data and possible improving for detecting new types of fault of the sensors.**

***Keywords*—Continuous Glucose Monitors, Compression artifacts, Detection, Supervised learning.**

I. INTRODUCTION

Type 1 Diabetes (T1D) is a chronic metabolic disease characterized by the defecting or lacking production of insulin, a hormone that plays a key-role in the regulation of the concentration of glucose in the blood. The lack of endogenous insulin is due to the destruction of the pancreatic β-cells by the immune system, responsible of its secretion, and needs to be compensated with exogenous administration [1]. Even in presence of accurate therapy and management, T1D might lead to glycemic levels higher ($hyperglycemia$) and lower ($hypoglycemia$) than the normal range, possibly causing complications that could affect the vascular system, the central nervous system and organs, such as kidneys and eyes [2]. To avoid these scenarios and to maintain the blood glucose (BG) level inside safe limits, called *euglycemic range*, different strategies have been introduced to guarantee an appropriate glucose monitoring, allowing proper treatment decisions.

In the last two decades, minimally-invasive portable sensors, which can offer real-time "quasi-continuous" glucose concentration measurements at rates of 1–5 min for several days, have been developed and introduced in the market, showing a significantly improving of T1D daily treatment. These devices, that are usually referred to as continuous glucose monitoring systems, have revolutionized the management of diabetes, alleviating patients of the burden of the disease, and are proven to have a strong impact also in the clinical practice [3]. Indeed, CGMs can be used retrospectively by clinicians and caregivers to assess the quality of the treatments by extracting glycemic control metrics or analyzing glucose patterns, and by technicians to evaluate the efficacy of glucose control strategies [4], [5]. Faults in CGMs, even if temporary, can have an impact on the sensors' accuracy, leading to potential adverse effects on treatment decisions when used in real-time by patients and inaccurate analysis and evaluation when used retrospectively by clinicians [6].

A. Compression Artifacts

The sensing capability within minimally-invasive CGM systems relies on the glucose oxidase reaction taking place in an electrode deposited on a needle, that is commonly put on the abdomen or the upper arm skin of the patients. Unfortunately, the occasional mechanical compression of the device can alter the glucose diffusion process, reducing the blood glucose flow in the insertion site and causing an attenuation of the sensor sensitivity that results in an underestimation of the glucose concentration, as shown in Figure 1. This is one of the most common faults of the CGM sensors [7], and it is often referred to as Pressure-induced Sensitivity Attenuations (PISAs).

Thereby, to address the aforementioned issue related to the possible presence of false hypoglycemic events, it is important to develop fault detection techniques to identify these malfunctions and to increase the reliability and trustworthiness of CGM devices.

B. Aim of the study

In this study, we expand upon previous research by investigating the retrospective detection of PISAs in CGMs using supervised classification algorithms. We aim to develop a data-driven fault detection approach for the retrospective recognition of PISAs in order to improve the reliability of CGM sensors. Unlike model-based approaches, which rely heavily on the defined model that is difficult to identify due to inter-subject variability, the proposed algorithms rely solely on the availability of labeled historical data.

Moreover, we employ only the data collected with CGM sensors, excluding all the data that could be potentially useful for the purpose but require other devices (i.e. insulin pump) or the strong compliance of the users to be collected (i.e. meal intakes or physical activity).

II. DATASET

A dataset of 100 virtual subjects is generated using the Padova/UVa T1D simulator [8], an accurate physiology simulator that was approved by Food and Drug Administration

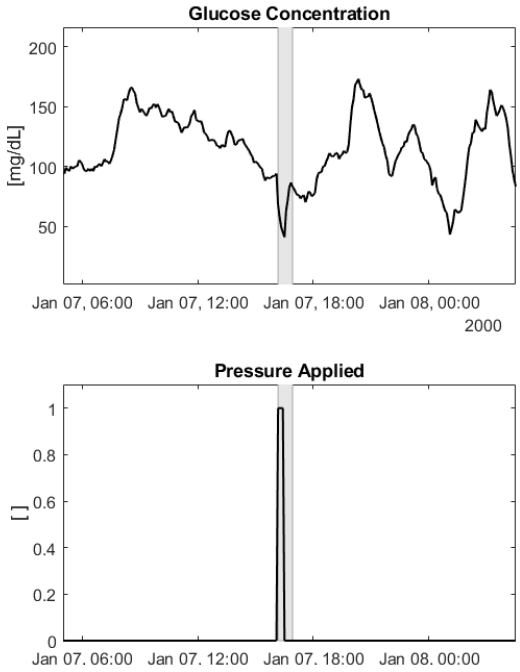

Fig. 1: The first panel shows an example of the compression artifact (highlighted with the gray band) while in the second panel is reported the value of the pressure that causes the fault.

(FDA) as a substitute of animal testing prior to clinical trials on humans. For each of the 100 subjects, a 10-days protocol is simulated with 3 meals per day (breakfast, lunch, and dinner) taking place with uniform probability at $[7.00-8.00]$, $[11.30-13.00]$, $[18.30-20.00]$ and carbohydrates assumption sampled according to the distribution introduced in [9] (namely 58.2 ± 22.5 g for breakfast, 77.7 ± 27.0 g for lunch, 83.9 ± 32.3 g for dinner). It is also considered the possible carbohydrates estimation errors performed by the patient as modeled in [9]. A proportional integral derivative (PID) controller is used as an hybrid closed-loop insulin delivery therapy. BG readings are corrupted with faults in perfectly known position: to simulate the PISAs we used the model described in [10] and validated on CGM time series collected in 72 T1D subjects by the Dexcom G4 Platinum sensor. Moreover, the number of faults in each trace is randomly sampled in accordance with [11]. Finally, the dataset is split in training and test set in a 80-20 proportion.

III. METHODS

The fault detection method's architecture is divided into two main steps. First, the feature extraction is performed by processing the CGM data and computing relevant variables designed to help discriminating normal and abnormal (or $faulty$) data.

Then, different supervised algorithms are applied to the set of features to complete the binary classification in terms of faulty/not-faulty. The performance of the methods tested are presented and discussed in Section IV.

A. Feature Extraction

The upper panel of Figure 1 shows a typical shape of a Pressure Induced Sensor Attenuation. PISAs are characterized by an initial quick dip in BG caused by the pressure applied to the sensor, followed by a subsequent rapid recovery.

Three features are used to highlight the typical pattern in CGM data. These features have already been presented in our previous work [12] and are briefly summarized in this section.

The first feature is defined as:

$$f_1(t) = \frac{1}{2w+1}\sum_{i=t-w}^{t+w} |d'CGM(i)| - \left|\frac{1}{2w+1}\sum_{i=t-w}^{t+w} d'CGM(i)\right|$$

where $d'CGM(t)$ is the first derivative of the CGM signal computed as

$$d'CGM(t) = \frac{1}{T}(CGM(t+1) - CGM(t))$$

with $T = 5$ min the sampling time of the CGM, and w the number of previous and subsequent samples consider (total window length: $2w+1$). The feature $f_1(t)$ is composed of two terms: the first is expected to be large in portions where the signal is rapidly varying, including during a fault, the second represents a correction to remove the possible presence of persistent increase (e.g. after a meal) or decrease, that are not compatible with the shape of the PISA events.

The second feature is obtained applying a moving mask to the CGM signal. This strategy for pattern recognition is frequently applied in biomedical signal analysis [13], e.g. to detect QRS complexes in an ECG trace. The mask looks for a rapid decrease and a subsequent rapid increase. Therefore, the mask focuses on the first derivative of the CGM, in particular its positive and negative components, computed respectively as:

$$|d'CGM(t)|_{>0} = \begin{cases} d'CGM(t) & \text{if} \quad d'CGM(t) \geq 0 \\ 0 & \text{if} \quad d'CGM(t) < 0, \end{cases}$$

$$|d'CGM(t)|_{<0} = \begin{cases} 0 & \text{if} \quad d'CGM(t) \geq 0 \\ -d'CGM(t) & \text{if} \quad d'CGM(t) < 0 \end{cases}$$

The feature $f_2(t)$ consists in the product of two terms $f_2(t) = s_1(t)s_2(t)$ with

$$s_1(t) = \frac{1}{L+1}\sum_{i=t}^{t+L} |d'CGM(i)|_{>0}$$

$$s_2(t) = \frac{1}{L+1}\sum_{i=t+d}^{t+d+L} |d'CGM(i)|_{<0}.$$

The feature f_2 is large if and only if $s_1(t)$ and $s_2(t)$ are simultaneously large at time t, and this happens only if there is a large decrease in the CGM signal followed by a large increase after d samples. The parameters L and d are fixed in accordance to the duration of the failures [10]: $L = d = 3$.

A third last feature $f_3(t)$ is based on the second derivative of the CGM signal $d''CGM(t)$ and is computed as:

$$f_3(t) = \frac{1}{2w+1} \sum_{i=t-w}^{t+w} |d''CGM(t)|. \quad (1)$$

This feature is large in presence of highly irregular data portions with frequent variations of the signal derivative.
An example of the features extracted is reported in Figure 2.

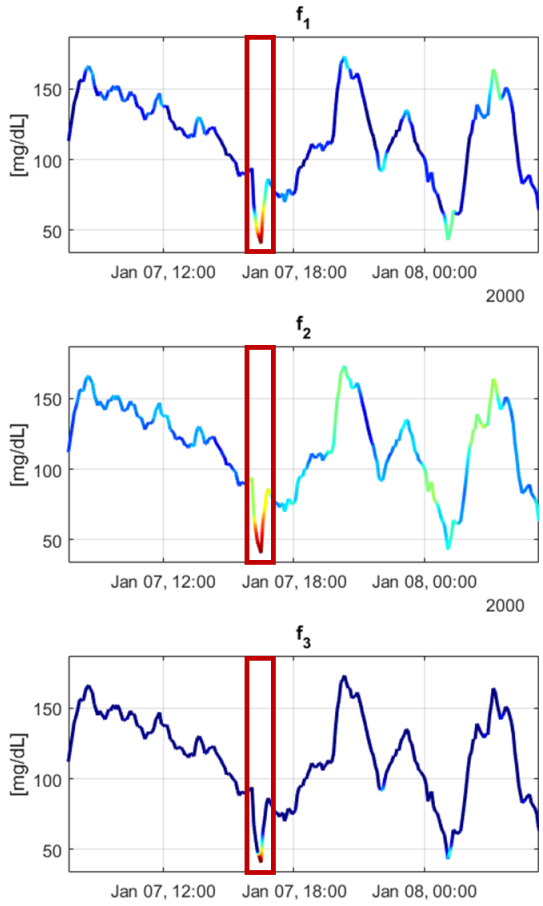

Fig. 2: The CGM trace is colored according to the value of the three features computed. All of them assume high values (corresponding to the red color) when a PISA occurs (highlighted with a red square). Instead, in normal conditions, the trace is colored in blue corresponding to low values of the features.

B. The chosen supervised algorithms

The detection of faulty events was traditionally investigated by employing model-based techniques [14], [15]. However, a significant hurdle of these approaches is the strong dependence on the quality of the model on which they leverage: to achieve accurate models of T1D physiology is a challenging task because of the physiological complexity and the significant inter- and intra-patient variability.

Thus, in this work, we develop a model-free fault detection strategy and we compared the PISA classification performance of several supervised machine learning algorithms: the list of algorithms (implemented in MATLAB2022b) and their parameters are provided in Table I.

TABLE I: ALGORITHMS TESTED

Algorithms	Settings
Logistic Regression	Distribution: $binomial$, probability threshold: 0.5
SVM	kernel: $gaussian$
Decision Tree	Split Criterion: Gini's diversity index
kNN	Distance: correlation, Number of Neighbors: 20
Random Forest	Number of trees: 100, minimum Leaf Size: 1
ADA-boost	Number of ensemble learning cycles: 100

C. Assessment of the algorithms

The performance of the supervised algorithms is evaluated and compared based on their ability to correctly classify instances of PISA faults. The accuracy of the algorithms is determined by comparing their classifications of faulty/non-faulty instances to the ground truth labels, which are known as the faulty events were deliberately added to the simulation in known positions.

In particular, we refer to an $alarm$ when the algorithm assigned a sample to the faulty class. When one or more alarms are raised during a pressure-induced failure, a true positive (TP) is assigned, otherwise the faulty portion is classified as a false negative (FN). Instead, if an alarm is wrongly raised, a false positive (FP) is considered. Moreover, the 25-minutes window after the generation of an alert is excluded by the evaluation, since the faults cause the system to remain in an anomalous state for some time.

To evaluate the algorithm performance and to deal with unbalanced dataset, the FP/day-Recall space [16] is considered. Specifically, we use as evaluation metrics, the number of false alarms per day (FP/day), and the Recall (also known as sensitivity), that represents the capability of the algorithm to effectively detect a fault and is computed as:

$$Recall = \frac{TP}{TP + FN}.$$

IV. RESULTS

The results of the supervised methods tested are summarized and reported in Table II.

In this highly unbalanced dataset, Support Vector Machine (SVM) and Logistic Regression show a limited discriminating power with the lowest number of false alarms generated but also the lowest number of faults recognized.

The best performance is achieved with Random Forest that shows similar results in terms of recall with Decision Tree, but with the half of false alarms generated, and an higher recall with respect to k-Nearest Neighbors, with the same false alarms generated.

An appealing trade-off between recall and FP/day is obtained with Adaptive-boosting algorithm (ADA-boost) that is able to recognize the 80% of the failures without generating false alarms.

TABLE II: TEST SET

	Recall	*FP/day*
SVM	0.29 [0.20-0.50]	0.00 [0.00-0.00]
Logistic Regression	0.50 [0.22-0.71]	0.00 [0.00-0.05]
k-NN	0.75 [0.45-1.00]	0.10 [0.00-0.20]
Decision Tree	1.00 [0.75-1.00]	0.20 [0.05-0.30]
Random Forest	0.90 [0.68-1.00]	0.10 [0.00-0.15]
ADA-boost	0.79 [0.60-1.00]	0.00 [0.00-0.00]

V. CONCLUSIONS

In this work, supervised algorithms were tested to detect compression artifacts (known as PISAs), which are temporary failures that affect the Continuous Glucose Monitors' accuracy by generating anomalous glycemic reading. The performance of the algorithm was evaluated basing on the recall and the number of false alarms generated per day.

Some of the proposed fault detection methods exhibit promising results, particularly Random Forest and ADA-boost which were able to detect the 90% and 80% of compression artifacts respectively, with less than 1 false alarm generated every 10 days.

Since this study is retrospective, one of its main limitation is the intrinsic inability of detecting the malfunctions in real time. This is only related to the features extracted, that benefit from knowing the future glucose concentration measurements in their definition.

Possible future research will expand this approach to real data affected by PISAs, to understand how much the training of the algorithm on simulated faults is affecting the accuracy of the method.

***Abstract*—In this study, we have explored the field of emotion recognition, which has been gaining increasing interest for both the study of emotional control disorders and human-computer interaction. The majority of emotion recognition studies in the literature use visual or audio-visual stimuli, leaving the audio-only component often overlooked. In this study, we analyzed data from an experiment on emotion recognition induced by music. By processing signals from the electrocardiogram, respiration, and skin conductance, we identified features that were highly relevant for separating four emotions (i.e., joy, anger, sadness, pleasure). We then created a machine learning model to classify the four emotions using only three of the most relevant features selected based on a recent feature selection method utilizing a graphical visualization. The results showed an average accuracy of 85% in classifying the four emotions, and more than 90% of accuracy for classifying arousal and valence. This study highlights the potential of using only audio stimuli for emotion recognition and the effectiveness of music as a tool for studying emotional control.**

***Keywords*—Emotions, pshysiological signals, machine learning, music.**

I. INTRODUCTION

The emotional state of an individual plays a crucial part in their existence, acting as an essential aspect that has evolved over time to guarantee preservation and procreation through modifying behaviors in response to the surroundings [1]. Emotions hold a vital place in human conduct, as they regulate the movement of facial muscles and other regions of the body, leading to identifiable physical posture and expressions that mirror the current emotional state of the person.

Research on emotions is attracting a growing level of attention in our society due to its potential applications in a wide range of fields, including the emerging areas of Human-Computer and Human-Robot interaction [2].

The development of effective techniques for eliciting and identifying emotions can significantly aid in the evaluation and quantification of conditions that have a significant impact on human health and well-being.

Even if there is a growing interest in using music in more clinically oriented applications such as monitoring depression, anxiety, stress, chronic anger and mood disorders [3],[4], the emotional aspect of sounds has received comparatively less attention with respect to the extensive research on visual stimuli in the field of emotion recognition from physiological signals [5],[6].

Furthermore, we have recently discovered that sounds can evoke a stronger physiological response, both centrally and peripherally, compared to visual stimuli, and to the combination of auditory and visual stimuli [7],[8]. Building upon these results, we have conducted an analysis on an online dataset of emotion recognition through music, which has received relatively little attention in literature, especially in terms of the physiological changes induced by emotional music. In the field of emotion recognition, most studies tend to overlook the interpretation of features and instead focus on achieving high accuracy rates by using dimensionality reduction methods, calculating a high number of features without specifying which signals and features may be most relevant for creating a framework that can be applied in similar studies. Our aim is to create a simple framework for emotion recognition by investigating the meaning of features in relation to specific emotions and music.

II. MATERIALS AND METHODS

A. Data

The data employed in our study was obtained from the University of Augusta, Germany [9]. The research involved assessing a single individual over a period of 25 consecutive days. The participant was exposed to various musical selections, chosen on a daily basis, to gauge various emotional states: joy, anger, sadness, and pleasure. The aim of listening to these musical pieces was to guide the participant through a sequence of emotional states, starting with joy, moving to anger, sadness, and ending with pleasure. To elicit the intended emotional state, the participant was prompted to select songs that evoked personal memories.

During the listening of the musical pieces, the subject was monitored using biosensors to extract four physiological signals: skin conductance (SC), electrocardiogram (ECG), electromyogram (EMG), and respiration (RESP). After collecting the signals, the subject was given a break of varying duration to allow the parameters to return to their baseline, before proceeding with the next recording. In total, 25 recordings were obtained for each of the four emotions and for each of the signals. The recordings were made throughout the duration of the musical pieces, but were then standardized to 120 seconds from the start of each piece. The ECG was sampled at 256 Hz, while SC, EMG and RESP were at 32 Hz. In light of the advancements in wearable sensors currently available, we

have decided to discard the facial EMG sensor due to its increased invasiveness and lower level of integration. We will instead focus on analyzing only three signals for which there are already integrated sensors available on the market.

B. Data Processing and Feature Extraction

ECG: The ECG signal was first processed through a zero-phase, 4th order low-pass Butterworth filter. R peaks on the ECG signal were identified using a Pan-Tompkins based algorithm [10]. From these peaks, a total of 5 features were calculated. Given the relatevely short duration of songs (i.e., 120 seconds), only features related to the time domain were included. For each emotion five basic features were extracted from ECG: average and standard deviation of normal-to-normal intervals (*AVNN*, *SDNN*), first and second standard deviations and their ratio from the Poincare‘ analysis (*SD1*, *SD2*, *SD ratio*).

SC: The SC signal was first processed through a 2 Hz zero-phase, 4th order low-pass Butterworth filter, and then downsampled to a rate of 8 Hz to eliminate any redundant information. To identify the phasic component, a median filter was implemented by determining the median SC of the neighboring samples in a range of +/- 4 seconds centered on the current sample [11]. The raw signal was then adjusted by subtracting the median SC to obtain the phasic component. Once the peak onsets (amplitude > 0.005 μS) and offsets (0 μS < amplitude) were identified on the phasic signal, a SC peak was detected on the raw signal between each onset and offset occurrence. For each emotion eleven basic features were extracted from SC: the average and standard deviation SC values (*AVSC*, *SDSC*), the quantity of SC peaks (*SC n peaks*), the mean amplitude of the peaks (*AVSC n peaks*), the standard deviation of the peaks (*SDSC n peaks*), the average rise and recovery time of the pekas in seconds (*AVSC rise time*, *AVSC recovery time*) and the average of the integral of the phasic component's envelope (*AVenv*). Then, the SC signal filtered with a 2nd order Butterworth band-pass filter from 0.5 to 1 Hz is used to compute some metrics such as average, standard deviation and maximum of the SC derivative (*AVSC der*, *SDSC der*, *MAXSC der*).

RESP: The RESP signal was filtered by a Zero-phase digital band-pass filtering (1 Hz pass-band cutoff frequency and 1.5 Hz stop-band cut-off frequency)by using the Parks–McClellan algorithm [12]. The signal was then analyzed to identify its maximum and minimum values by applying a thresholding technique. For each emotion two basic features were extracted from RESP: the respiratory frequency (*f RESP*) and the average amplitude of breaths (*amp RESP*), computed as the difference between maximum and minimum of each breath.

C. Statistical analysis

The normality of the data was evaluated using the Shapiro-Wilk test. Since one or more emotions were characterized by a non-normal distribution for each feature, and in order to compare four distributions (one for each emotion) of the same subject on different days, the non-parametric Friedman's test with Bonferroni correction was applied.

D. Classification

A simple emotion recognition models was created using the k-nearest-neighbor classifier. In order to provide a simple and interpretable model, a feature selection method based on a graphical visualization that had already proven useful in this field was applied [13]. In this method, for each couple of statistically significant features, 2D boxplot are created where the center of the boxes is the average of the two features and the sides of the boxes are the 95% confidence intervals for the average estimation. Subsequently, the features that appear most frequently in the pairs where no intersection between the boxes is detected, are selected. Of these, the ones that are less correlated are then chosen.

Since the dataset consists of repeated measures of the same subject on different days, revised leave-one-out cross validations were applied to the entire dataset. In particular, to evaluate whether the influence of different days was negligible in the classification, a leave-5days-out cross validation was applied, where in each iteration, 5 entire days of measurements were left as the validation set. Then, in order to see if the performance persisted even with fewer observations, a leave-1day-out was applied, and finally, a leave-one-out, leaving only one observation in the validation set. The same analysis was repeated with the same three features for binary arousal and valence classification. Arousal represents the level of tension or relaxation associated with an emotion (i.e., high for joy/anger and low for sadness/pleasure) and valence represents the pleasantness or unpleasantness of an emotion (i.e., positive for joy/pleasure and low for sadness/anger) [16].

III. RESULTS

According to the statistical analysis, the majority of features have been found to be statistically significant in at least three out of six comparisons (i.e., joy-anger, joy-sadness, joy-pleasure, anger-sadness, anger-pleasure, sadness-pleasure). In particular, *AVNN*, *RESP f* and *RESP amp* have been the most effective features, obtaining five statistically significant differences out of six (i.e., all except anger-pleasure, joy-pleasure, and sadness-pleasure, respectively). Four statistically significant differences have also been found for *SDSC n peaks* and *MAXSC der* (i.e., all except anger-pleasure, sadness-pleasure). Median and interquartile range for each of the above mentioned relevant features are reported in Table I.

TABLE I: MEDIAN AND INTERQUARTILE RANGE OF THE FEATURES WHICH SHOW AT LEAST FOUR STATISTICALLY SIGNIFICANT DIFFERENCES AMONG THE FOUR EMOTIONS.

	JOY	*ANGER*	*SADNESS*	*PLEASURE*
AVNN [ms]	713 (57)	799 (56)	882 (50)	828 (90)
f RESP [n resp/min]	12.5 (2.6)	22 (3.7)	11 (0.62)	13 (1.75)
amp RESP [a.u.]	0.84 (0.38)	0.50 (0.28)	0.72 (0.35)	0.73 (0.28)
MAXSC der [nS]	7.1 (12.9)	2.8 (3.9)	0.94 (1.4)	1.1 (1.4)
SDSC n peaks	13 (8.5)	6 (4.25)	2 (5)	4 (4)

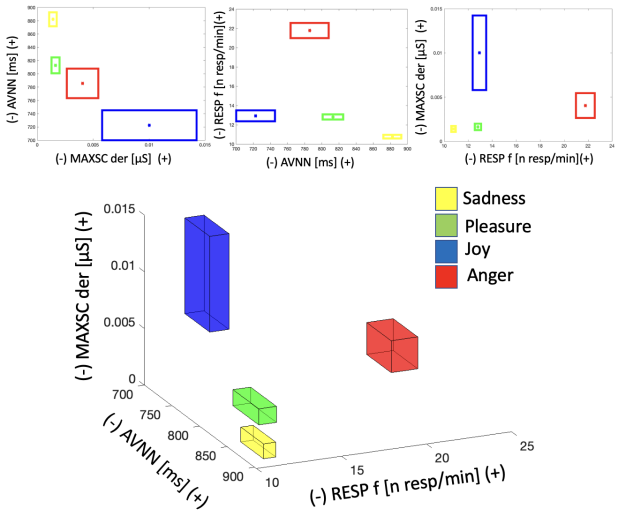

Fig. 1: 3D boxes are displayed, one for each emotion, where the center of each box (i.e., each emotion) is given by the mean of the three features and the length of the sides is given by the 95% confidence limits for the mean estimate. Specifically, the main figure shows the combination of the three most performing features in the space of the four emotions. Above, the projections of the 3D boxes in two dimensions are presented.

Form the feature selection step, *AVNN*, *MAXSC der*, *RESP f*, were the best features selected, able to separate the four emotions in the 2D plane and correlated minimally. A graphical representation is visible in Figure 1, which shows both the projections and a 3D representation of the four emotions in the plane of the most relevant features for the separation. Only these features were included in the following models.

The average validation accuracy in classifying the four emotions and both arousal and valence was calculated and reported in Table II.

TABLE II: KNN ACCURACY AS MEAN (S.D.) OBTAINED FOR FOUR EMOTIONS, AROUSAL AND VALENCE CLASSIFICATION.

	4 Emotions	*Arousal*	*Valence*
leave-5days-out	85 (0.07)	90 (0.03)	92 (0.09)
leave-1day-out	85 (0.17)	92 (0.11)	93 (0.13)
leave-one-out	85 (0.30)	92 (0.27)	93 (0.25)

IV. DISCUSSIONS

A. Feature characterization

Statistical analysis has revealed that SC, ECG, and RESP signals are able to distinguish among the four emotions (see Table I). The effectiveness of this protocol, indeed, lies in the fact that most people have a tendency to associate certain musical melodies with specific emotional states due to their frequent exposure to music throughout their daily lives.

The *AVNN* feature, which is related to the average of normal heartbeats, *RESP f*, and *RESP amp*, were found to be the best performing features, resulting in statistically significant differences in all comparisons among emotions except one.

In general, we can see from Table I and Figure 1 that the features related to the SC are able to separate the emotional dimension of arousal, that is, the emotions with the highest excitement (i.e., joy and anger) from those with the lowest excitement (i.e., pleasure and sadness). It can be noted that higher values are related to higher arousal, which is already widely accepted in literature [17],[14]. The interesting thing to notice is how at the level of excitement, the joy, positive-valence emotion, seems to win over anger. In fact, it seems that all the features related to SC have much higher values in joy than the other emotions, as can be easily seen from Figure 1, where the derivative of the SC stands out in height on the z-axis compared to the other three emotions.

At the cardiac level, we can see how *AVNN* has a very good performance and characterizes joy and sadness very well in an opposite way. These two emotions are, in fact, opposite to the circumflex model used to describe emotions in the dimensions of valence and arousal and, in fact, joy, with high arousal and positive valence, has the highest heart acceleration, while sadness, with low arousal and negative valence, has the highest deceleration.

Regarding the respiratory signal, it seems to be very relevant for the recognition of anger, which shows a much higher average rate than the other three emotions.

From a physiological point of view, summarizing the results, this study suggests that:

-Joy is characterized by a greater sympathetic activation, obtaining, in fact, much higher SC values than the other emotions, as well as a higher heart acceleration.

-Anger, on the other hand, seems to be described very well by respiratory frequency and breath amplitude, much higher and much narrower, respectively, than the other emotions.

-Sadness is the emotion characterized by the lowest responses in terms of respiratory frequency, heart acceleration, and sweating.

-Pleasure, very close to sadness at the physiological level, is characterized by values of all features located in the middle compared to the two emotions with high arousal and sadness.

B. Emotion classification

Regarding the classification part, the problem was addressed by trying to overcome the limitation given by the fact that the recordings are related to only one subject. In order to evaluate the dependence of the classification on time, that is, to see if on different days at the physiological level the emotional responses were different, it was decided to use a leave-one-out cross-validation, leaving in the first case five entire days, in the second case one entire day and in the third case only one observation in the validation set. This has avoided data leakage as for each iteration, the model was not trained on recordings belonging to days present in the validation set. From Table II, it can be seen that the KNN model performed very well. An average accuracy of 85% was obtained in discriminating the four emotions using only three features and very high average

accuracies were found for arousal (i.e., 90%/92%) and valence dimensions (i.e., 92%/93%). Looking at the results related to different leave-one-out models, we can see that time is not relevant in the classification, proving that musical stimuli used are able to evoke a similar physiological response even on different days. It is not the first time that the elicitation of emotions through music leads to very high results in terms of classification. It is indeed the case of Kim and Andre [15], who, by making measurements on three subjects over the course of three months using music as an emotional stimulus, were able to achieve an accuracy of 87% for each subject in discriminating the four emotions used in this study. Despite the fact that music and audio-only stimuli are not commonly used in literature for the study of emotions, it is clear that music can have a great potential in this field, also opening the possibility of extending auditory stimuli to other fields of psychophysiology.

Further studies are certainly necessary, particularly to overcome the limitation of subject-dependent classification. It is necessary to achieve good performance in a subject-independent setting in order to extend the models to real-world scenarios. It is also necessary to use not only music but also real-world sounds to understand if they can evoke emotions with similarly good performance.

V. Conclusion

In this study, we have presented an analysis of a dataset of emotions elicited by musical stimuli during the measurement of physiological signals. Specifically, we have focused on the study of the physiological differences induced by such emotions, with the aim of understanding how our body behaves depending on the emotion evoked. Through a simple machine learning model and using only three features, one for each signal analyzed, we were able to achieve high accuracy both in the four-class problem in separating the emotions, and in the binary problems for separating low/high arousal and positive/negative valence. The temporal variable, given by the fact that the same subject was tested on different days, did not seem to influence the results. Overall, this study suggests that music as a mode of stimulation appears to be effective, opening the door to its use in other fields beyond emotion recognition, such as the study of pathologies such as anxiety and mood disorders.

Quantitative validation of an automatic videoPPG technique during autonomic elicitations

A.C. Palmisciano[1], M. Mollura[1], R. Barbieri[1], and L. Mainardi[1]
[1]*Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milano, Italy*

***Abstract*—The videophotoplethysmography (vPPG) is a technique that allows proxy measurements of blood volume variations in the peripheral microcirculation by detecting the periodical skin color variations during the phases of the cardiac cycle. Therefore, it is also possible to use vPPG signals to evaluate heart rate variability and autonomic modulation of the cardiovascular system. The main advantage of this technique is that it does not require physical contact. We developed and validated an automatic method for the extraction of the vPPG signal, with related HRV descriptors, focusing on different aspects of the vPPG workflow. First, we developed an automatic pixel classifier for the identification and tracking of the region of interest (ROI) and validated it by building a specific validation dataset, with the Dice similarity coefficient as the performance metric. We chose the hand palm as the ROI. Then, we devised an extraction and processing pipeline that can automatically obtain the vPPG signal from the video recording and remove the artifacts. The final step was the extraction of the pulse-to-pulse (PP) series and the pulse rate variability (PRV) parameters. For further validation with respect to contact PPG, we designed an autonomic elicitation protocol for the acquisition of the signals. The PP series and PRV features were evaluated. The strongest correlation ($r > 0.9$) was obtained for the average of the PP intervals (AVNN) while the lowest ($r < 0.75$) was for their standard deviation (SDNN) and the proportion of PP intervals differing by more than 50 ms (pNN50). The Bland-Altman analysis highlighted larger intervals of agreement during the handgrip phases. The sympatho-vagal balance (LF/HF) behaved as expected and its difference between experimental phases was found significant ($p < 0.01$) by a multiple comparison test with Bonferroni correction. Although improvements in the robustness of the algorithm are necessary, this study's results consistently demonstrate that vPPG is a viable technique for extracting blood volume variations and evaluating heart rate variability.**

***Keywords*—videoPPG, autonomic nervous system, HRV, skin detection**

I. INTRODUCTION

The monitoring of cardiovascular parameters is usually performed with recording techniques that require physical contact, such as electrocardiography (ECG) and photoplethysmography (PPG). Skin contact can be a major limitation in many circumstances: typical examples are recordings performed in neonatal intensive care units and vital signs measurements from subjects with damaged or sensitive skin or with autistic spectrum disorders. Videophotoplethysmography (vPPG) overcomes this limitation, as it measures variations in skin perfusion by detecting slight periodical skin color variations through a camera and yields a pulsatile signal similar to PPG. Telemedicine for monitoring chronically ill patients and elderly and non-clinical uses are other possible fields of application of this technique [1], taking advantage of the absence of physical obstructions and the relative simplicity of the required instrumentation. Since it was first proposed [2], many different vPPG techniques have been developed. However, the main stages of the vPPG general workflow [3] can be summarized as follows:

1) *Video recording* of a region of interest (ROI) with a camera. The most common ROIs are highly vascularised skin regions, like the face or the hand's palm.
2) *ROI detection and tracking*, a necessary phase to separate the skin, which is the area that contains the desired pulse signal, from other regions that do not contribute to the signal and may introduce noise.
3) *Signal extraction* is the stage in which a sample of a time series is obtained from each frame of the video.
4) *Signal processing* to obtain a useful pulse signal from the raw one previously extracted, which usually contains unwanted noise.

Heart rate variability (HRV) is an important indicator of health status. HRV descriptors, as listed in [4], are typically extracted from ECG signals. PPG can be employed to measure pulse rate variability (PRV) which can be used as a surrogate of HRV and to obtain the related parameters [5]. Obtaining the PRV parameters without contact would be an important step toward a more agile, continuative, and comfortable health assessment in a wide range of contexts.
In in this paper, we developed an automatic method for the extraction of the vPPG signal from a high frame rate RGB video. The final goal was to exploit vPPG to obtain PRV descriptors to assess the autonomic modulation of the cardiovascular system. We then proceeded to validate the pipeline and the resulting PRV parameters obtained during an experimental protocol devised to elicit specific autonomic nervous system responses. It must be stressed that the validation of the vPPG PRV descriptors against those obtained with contact PPG was a fundamental preparatory step performed before the evaluation of the autonomic modulation of the cardiovascular system.

II. METHODS

A. Experimental setup

Twenty-two (13 females, 9 males) healthy volunteers of different ages (25±2, range 20–31 years) were recruited for this study. Their skin phototypes were in the range II–IV of the Fitzpatrick scale. All subjects signed a written informed consent comprehensively describing the experimental procedure which was approved by the Politecnico di Milano ethical

committee. During the experimental sessions, the vPPG and finger PPG signals were recorded. The considered ROI is the hand palm's skin. The video was recorded with a The Imaging Source DFK-23UM021RGB camera at a resolution of 640×480 and 115 fps frame rate. The environmental conditions during the experiment were controlled in terms of illumination and background. A consumer-level ring light set to daylight color temperature (4500 K) was used as the only source of light. The employed background was dark and opaque. The subjects were asked to remain as still as possible. The finger PPG was recorded with the Thought Technology SA9308M sensor at a sampling frequency of 2048 Hz.

B. Automatic pixel classifier

ROI identification and tracking was performed with an automatic pixel classifier that does not require intervention by a human operator at any processing stage. The training of the classifier is patient-specific and therefore a new training set must be created for each new acquisition. The starting point for an automatic pixel classifier was the method described in [6]. It exploits the K-means clustering algorithm for the unsupervised labeling of the pixels of the first frame, which are assigned to "skin" or "non-skin" clusters. These labels are then used to train a Decision Tree (DT) classifier, which is used to segment each frame by classifying the pixels. In this work, we added a preprocessing stage before the K-means clustering. This stage consists of the conversion of the first frame from the RGB to the HSV color space and then the use of the PCA. The unsupervised labeling is then performed on the first two principal components. The "skin" cluster is identified as the one containing the central pixel of the frame. The DT is then trained on the first frame in the RGB color space using the obtained labels and the trained classifier is then used for the successive frames.

C. Pixel classifier validation

To validate the segmentation procedure, we created a dataset by asking four subjects of the experimental population to record a video of their hand in uncontrolled environmental conditions, specifically with free background and illumination. Then, we extracted four frames from each video and manually segmented them to create an annotated dataset. The manually segmented frames were used as ground truth. The performance of the proposed segmentation method was evaluated and compared to the algorithm described in [6] in controlled and uncontrolled environmental conditions. The chosen performance metric was the Dice similarity coefficient (DSC) [7] defined as in Equation 1, where $|X|$, $|Y|$, and $|X \cap Y|$ are respectively the cardinalities and the cardinality of the intersection of the sets X and Y.

$$DSC = \frac{2|X \cap Y|}{|X| + |Y|} \tag{1}$$

D. Signal extraction and processing

The signal was obtained from the green channel of the segmented video through spatial pooling. This signal may contain artifacts in the form of jumps and a non-linear trend. The latter is common in PPG signals as they are given by the combination of a slowly varying baseline and a pulsatile part [8]. Moreover, the acquired frames were unevenly spaced in time due to the lag of the video recording system. Hence, the signal produced by the spatial pooling was irregularly sampled. Taking these specific artifacts into account, we processed the signal in three different stages:

1) *Jumps correction and detrending*. The jumps were identified by computing the absolute value of the first derivative of the signal, finding its local maxima, and taking these points as breakpoints. Then the signal was dived into one-second-long windows and their extremes were added to the breakpoints vector. Finally, a linear interpolant was computed and subtracted from each interval between two breakpoints, eliminating both the jumps and the non-linear trend.
2) *Interpolation*. The corrected and detrended signal was linearly interpolated to obtain time series with evenly spaced samples.
3) *Filtering*. The signal was finally band-pass filtered with a Hamming filter with cut-off frequencies of 0.03 and 4 Hz obtaining the vPPG signal.

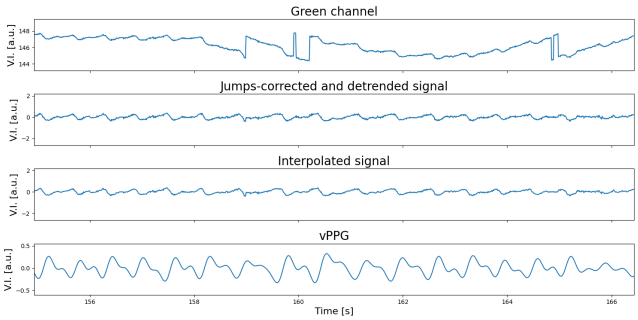

Fig. 1: Signal processing steps.

On the other hand, the contact PPG signal was resampled at 115 Hz and then bandpass filtered with a Hamming filter with cut-off frequencies of 0.03 and 4 Hz.

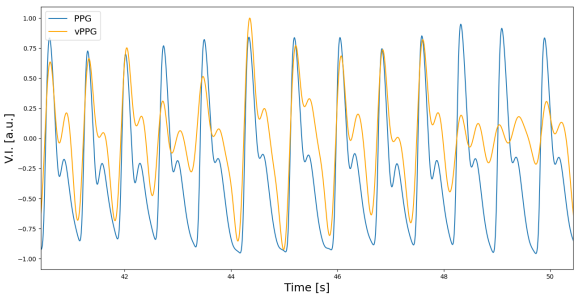

Fig. 2: Comparison of PPG (blue) and vPPG (orange).

E. PP series extraction and validation

Two of the twenty-two acquired signals had to be discarded due to issues in the video recording. Once the signals were obtained, we computed the PRV parameters from vPPG and PPG. The first step was the identification of the fiducial points. We chose the systolic peaks, identified with the Automatic Multiscale Peak Detection (AMPD) algorithm [9]. Then, the pulse-to-pulse (PP) series were computed. The PP series were validated by computing Spearman's correlation coefficient (r) between PP intervals from vPPG and PPG, with the latter taken as a reference. A specific threshold for a minimum correlation was set at 0.65. One more signal had to be discarded due to having $r < 0.65$, therefore the following analyses were conducted on 19 subjects.

F. Autonomic stimulation protocol

We designed the autonomic stimulation protocol as a series of simple tasks to elicit specific responses of the two branches of the autonomic nervous system. The protocol consisted of the following phases, interleaved by rest periods:

- *Baseline*. The subjects had to remain still and relax for 5 minutes.
- *Paced breathing*. The subjects were asked to breathe at the fixed frequency of 10 breaths per minute (6 seconds for each cycle) for 2 minutes.
- *Handgrip*. The subject was given a rubber ball and asked to alternatively squeeze and release it (1-second grip and 1-second release) with the hand not involved in the recording for 30 seconds. This phase was repeated twice.

The paced breathing and handgrip aimed at inducing vagal and sympathetic activation respectively. The instructions to perform the tasks were given to the subjects through animations displayed on an LCD monitor placed in front of them.

G. PRV parameters validation

The selected time domain parameters are the average of PP intervals (AVNN), the standard deviation of PP intervals (SDNN), and the percentage of PP intervals differing by more than 50 ms (pNN50). The chosen frequency domain parameters are the spectral power in the low-frequency range of 0.04-0.15 Hz (LF), the high-frequency range of 0.15-0.4 Hz (HF), and their ratio (LF/HF or sympatho-vagal balance). The vPPG parameters were validated in terms of correlation (with the Spearman's correlation coefficient) and agreement (with the Bland-Altman analysis) with the reference parameters obtained through PPG.

H. PRV parameters comparison among phases

To evaluate the effects of the different stimulations on the considered PRV descriptors, the Friedman test and the multiple comparison test with Bonferroni correction were adopted.

III. Results

A. Pixel classifier

The performance measured with the DSC of the proposed pixel classification algorithm (with preprocessing) and the algorithm in [6] (without preprocessing) are presented in Figure 3. The figure evidences that the proposed algorithm performs better in both conditions while achieving a reduced variability in segmentation capacity.

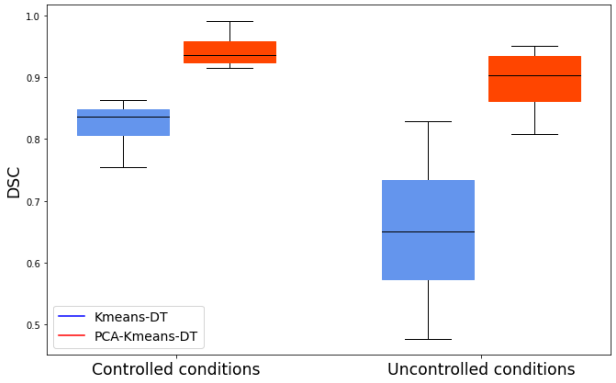

Fig. 3: Performance of the pixel classification algorithms in the tested conditions.

B. PRV parameters

The correlation results between the PRV parameters obtained with the two techniques are summarized in Table I. The highest correlation can be observed for the AVNN parameter ($r > 0.9$) while the lowest for SDNN and pNN50 ($r < 0.75$). The correlation remains high for the frequency domain parameters except for LF/HF during the first handgrip phase. Regarding the Bland-Altman analysis, it was observed that an almost null bias for AVNN during all phases, an underestimation of the LF/HF parameter, and an overestimation of the other parameters by the vPPG. Moreover, the limits of agreement (defined as $mean \pm 1.96SD$ of the difference of the PRV parameter obtained with vPPG and PPG) described a larger interval during the handgrip phases for all parameters, indicating a larger dispersion of errors. As an example, the scatterplots and Bland-Altman plots of PPG vs. vPPG for the sympatho-vagal balance LF/HF are reported in Figure 4 and 5.

TABLE I: PRV DESCRIPTORS CORRELATION

	Baseline	*Paced breathing*	*Handgrip 1*	*Handgrip 2*
AVNN	1.000	0.998	0.995	0.991
SDNN	0.614	0.740	0.707	0.739
pNN50	0.626	0.678	0.596	0.391*
LF	0.975	0.919	0.967	0.933
HF	0.932	0.893	0.840	0.895
LF/HF	0.886	0.804	0.402*	0.700

* indicates correlation coefficients with non-significant *p-value*.

The behavior of the sympatho-vagal balance during the four experimental phases is presented in Figure 6. We can notice the prevalence of HF components during the paced breathing phase while the LF components prevail during handgrip, coherently for vPPG and PPG.

The multiple comparison test revealed that the difference between LF/HF in paced breathing and handgrip phases is statistically significant ($p < 0.01$) in both vPPG and PPG.

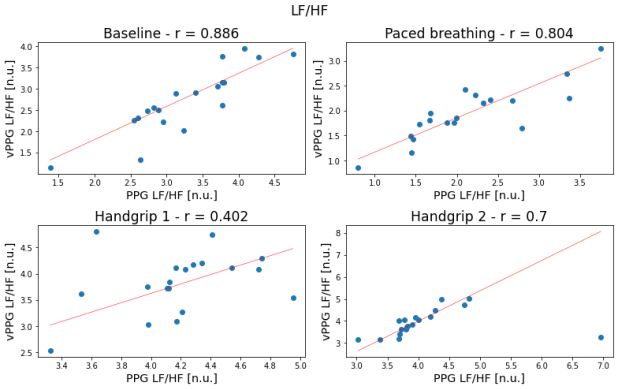

Fig. 4: Scatterplots of LF/HF during the experimetnal phases.

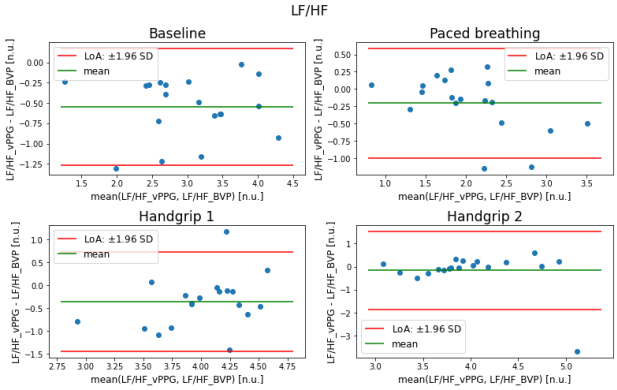

Fig. 5: Bland-Altman plots of LF/HF during the experimetnal phases.

IV. Conclusions

In this work, we developed and implemented an automatic method for extracting and processing the vPPG signal aiming at measuring pulse rate variability parameters. Then, we validated this method. The validation of the proposed automatic pixel classifier for the identification and tracking of the ROI showed improved performance in the considered environmental conditions, indicating the effectiveness of the preprocessing stage.

The correlation and agreement analyses highlighted that vPPG can provide satisfying estimations of the PRV parameters. However, a drop in correlation and larger intervals of agreement must be noticed for all parameters during the handgrip phases. This result is probably due to subjects' movements during this phase, since the vPPG is more prone to motion artifacts. A similar result was observed in a previous study, with weaker correlation and agreement during the stand phase of a rest-to-stand maneuver [10]. Regarding the comparison between experimental tasks, the sympatho-vagal balance presents the expected behavior in both vPPG and contact PPG, with vagal activation during paced breathing [11] and sympathetic activation during handgrip [12].

Further studies are required to improve the method's robustness to movements, and to validate it in conditions closer to those of real-world applications.

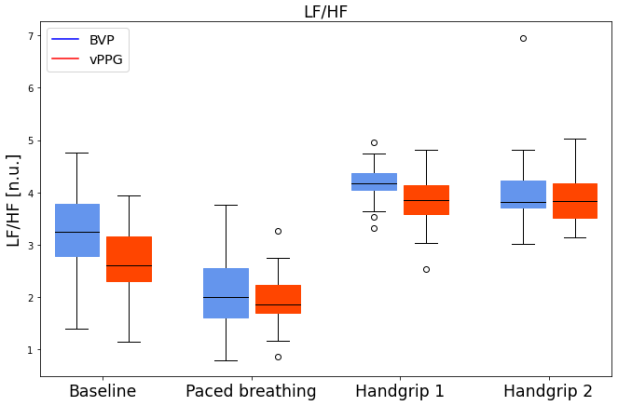

Fig. 6: LF/HF during the experimetnal phases for finger PPG (blue) and vPPG (red).

***Abstract*— Cerebral autoregulation (CA) is a fundamental homeostatic mechanism that maintains cerebral blood flow (CBF) within a constant range despite blood pressure variations. In this work, two different approaches for assessing CA are compared, i.e. the autoregulation index (ARI) and dynamic entropy measures. The arterial pressure and the CBF velocity were acquired on eighteen subjects undergoing coronary artery bypass graft surgery, before induction of general anaesthesia with propofol and during anaesthesia. The ARI-based method confirmed the known result that CA remains unchanged with propofol. Entropy measures led to complementary findings, suggesting an increased dependence of cerebral blood flow dynamics on systemic pressure, probably due to the effect of mechanical breathing during surgery.**

***Keywords*—Cerebrovascular autoregulation, autoregulation index, entropy, linear parametric autoregressive modelling.**

I. Introduction

Cerebrovascular autoregulation (CA) is a critical process in humans for maintaining adequate cerebral blood flow (CBF) values in response to external or internal system disturbances, such as changes in arterial blood pressure (AP) [1]. The assessment of CA can be carried out by measuring changes in CBF in response to slow (static method) [2] or rapid changes (dynamic method) [3] in AP. While the static method requires external invasive intervention to induce changes in AP, the use of the transcranial Doppler ultrasound technique (TCD) allow the non-invasive assessment of dynamic CA through the investigation of the beat-to-beat CBF changes in relation to AP changes occurring spontaneously [4], under the assumption that CBF velocity is approximately equal to CBF [3]. Indeed, the non-invasive characterization of CA is based on the study of the dynamic closed-loop interactions between the mean AP (MAP) and the mean CBF velocity (MCBFV) along the pressure-to-flow link of the closed-loop system, i.e. considering the interactions directed from MAP to MCBFV. CA is defined as the intrinsic control mechanism operating along this reflex and aiming to maintain a constant and stable MCBFV despite beat-to-beat variations of MAP, while preserving some degree of uncoupling between MCBFV and MAP over a range of values of MAP as wide as possible [4]–[6]. Dynamic CA has been evaluated exploiting different methods, such as the MAP-MCBFV closed-loop system transfer function [7], the autoregulation index (ARI) [4], [8], and linear parametric autoregressive models [9], [10]. In particular, the ARI index models the response of MCBFV to changes in MAP by a system of differential equations in which each estimated MCBFV curve, numbered from 0 to 9, represents a different level of CA [4]. The computation of ARI can be carried out by considering three different approaches, i.e. the time domain method (TDM) [11] , the non-parametric method (non-PM) [12] and the parametric method (PM) [9]. Recently, measures of dynamic entropy for bivariate systems [13] have been developed, which are derived from full and restricted autoregressive models and can be exploited to study the dynamic interactions along the pressure-to-flow link.

The present study focuses on the assessment of dynamic CA in patients scheduled for coronary artery bypass graft (CABG) surgery, before and during general anaesthesia with propofol [14]. Two different approaches are exploited to investigate CA mechanisms, i.e. the ARI and measures of dynamic entropy for bivariate systems [13]. Herein, we use the PM to assess CA, consistently with entropy measures which are also based on linear parametric modelling of time series under the hypothesis of Gaussian processes [13], [15]. The parametric ARI and entropy-based measures are compared evaluating their degree of correlation, with the aim to evidence whether the two investigated methods highlight similar or different aspects of cerebrovascular physiology, also allowing to better understand the role of confounding factors in the closed-loop interactions between CBF and AP.

II. Materials and Methods

A. Experimental protocol and series extraction

Eighteen patients (age: 63.8 ± 7.8 yrs, 1 female) scheduled for CABG surgery were enrolled at the Department of Cardiothoracic, Vascular Anaesthesia and Intensive Care of IRCCS Policlinico San Donato, San Donato Milanese, Milan, Italy [14]. Patients signed an informed consent before participating to the study and were examined ahead of surgery before induction of general anaesthesia (PRE) and after intubation of the trachea, during general anaesthesia, before opening the chest (POST). During the PRE session, subjects were breathing spontaneously, whereas during the POST session they were mechanically ventilated with a rate of 12-16 breaths/min. The PRE session was recorded after application of standard premedications including intramuscular administration of atropine (0.5 mg) and fentanyl (100 μg). Anaesthesia was induced by the intravenous bolus injection of propofol and remifentanil. The POST session was recorded when the target plasma concentration of propofol was expected to be around 3 μg/ml based the pharmacokinetic properties of the drug.

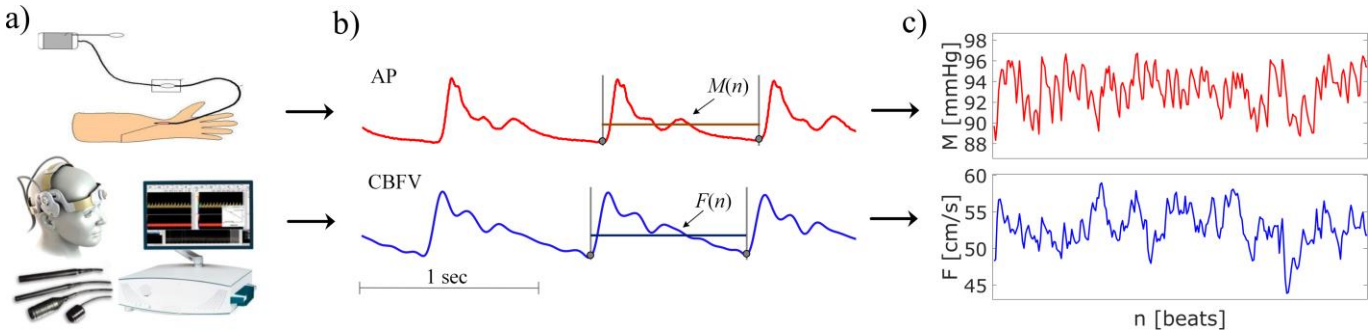

Fig. 1 (a) Schematic representation of the biomedical instrumentation used for data acquisition: (top) invasive measurement of AP by a catheter inserted into the radial artery; (bottom) transcranial Doppler ultrasound (TCD) device with ultrasound probes and adjustable helmet for CBFV acquisition from the middle cerebral artery (right or left). **(b)** exemplary traces of the acquired AP and CBFV signals for a representative subject; **(c)** the M and F time series are extracted respectively by integrating the AP signal within the diastolic pulse interval and the CBFV signal between its two minima within the cardiac period.

Electrocardiogram (ECG, lead II), invasive AP from the radial artery and CBF velocity (CBFV) from the middle cerebral arteries through a TCD device were simultaneously acquired. The acquisition phase in PRE and POST conditions lasted about 6 minutes. After signal acquisition, MAP and MCBFV stationary time series of 250 beats each were extracted by integrating respectively the AP and CBFV signals between two consecutive diastolic points and dividing by the time interval between them. In the following, we refer to MAP and MCBFV time series as M and F, respectively. Further details about the experimental protocol, signal acquisition and series extraction can be found in [14]. The schematic representation of the acquisition system, a representative example of the acquired signals and the extracted time series are shown in Fig. 1.

B. Autoregulation Index (ARI): parametric estimation

The autoregulation index (ARI) allows to assess CA by modelling F through a system of ten ordinary differential equations in agreement with the derivative filter model originally introduced by Tiecks et al. [4]. The Tiecks' model provides a set of ten step responses, in which each predicted F curve ranks the efficiency of CA from 0, i.e. absent CA, to 9, i.e. excellent CA, with ARI values lower than or equal to 4 indicating impaired CA [4]. The ten F curves derived from this model are compared with the F curve estimated from the parametric linear representation of the dynamic F-M relationship. More precisely, an auto and cross regressive model (ARX) is applied to describe the dynamical evolution of F due to beat-to-beat changes of both F and M [8]. After the application of a linear detrending to both series, the sample F_k, where k is the current time instant, is described as the linear combination of p past values of F weighted by the coefficients a_i, with $i = 1,\dots,p$, plus the linear combination of $p - \tau + 1$ past values of M weighted by the coefficients b_i, with $i = \tau,\dots,p$, plus a random unpredictable portion W_k being the sampling of a Gaussian white noise W with zero mean and variance λ^2:

$$F_k = \sum_{i=1}^{p} a_i F_{k-i} + \sum_{i=\tau}^{p} b_i M_{k-i} + W_k, \qquad (1)$$

where p is the model order and τ is the lag of the faster interactions from M to F. By representing the model coefficients in the Z domain as $A(z) = \sum_{i=1}^{p} a_i z^{-i}$ and $B(z) = \sum_{i=\tau}^{p} b_i z^{-i}$, the transfer function from M to F, which provides the coefficients of the impulse response, can be written as:

$$H_{F-M}(z) = \frac{B(z)}{1-A(z)}. \qquad (2)$$

The impulse response was truncated to 31 values taking the cardiac beats from 0 to 30. After integrating the impulse response to obtain the step response, the comparison between each of the ten step responses derived from the Tiecks' model and the data-driven step response was carried out via the normalized mean square prediction error (NMSPE), computed as the mean square value of the difference between the measured and the predicted F curves normalized by the mean square value of the measured F curve [8]. We selected the optimal ARI (i.e. from 0 to 9) as the value corresponding to the minimum value of NMSPE. Further details on the proposed method can be found in [8].

C. Dynamic information measures

Given the bivariate process S = {M, F}, where M is the driver and F is the target process, the framework of information theory allows the study of the dynamic interactions along the pressure-to-flow link by quantifying the information content of the target in terms of predictive information $P_{F|S}$ (i.e., information contained in the target that can be described by the past history of the entire process S). Using the chain rule, $P_{F|S}$ can be decomposed in two different ways [13]:

$$\text{(i)} P_{F|S} = S_F + T_{M\to F};\ \text{(ii)}\ P_{F|S} = C_{M\to F} + S_{F|M}, \qquad (3)$$

where S_F is the self-entropy (information carried by the present state of the target that can be predicted by its own past), $T_{M\to F}$ is the transfer entropy (information carried by the present of the target that can be predicted by the past of the driver above and beyond the part that is predicted by the past of the target), $C_{M\to F}$ is the cross-entropy (information carried by the present state of the target that can be predicted exclusively by the past of the driver), $S_{F|M}$ is the conditional self-entropy (information carried by the present state of the target that can be predicted by its past above and beyond the part that is predicted by the past of the driver) [13]. Under the assumption of joint gaussianity of the observed bivariate process [15], the dynamic information measures introduced above were evaluated using model-based estimators as:

$$S_F = \frac{1}{2} ln \frac{\sigma_F^2}{\sigma_{AR}^2};\ T_{M\to F} = \frac{1}{2} ln \frac{\sigma_{AR}^2}{\sigma_{ARX}^2} \qquad (4)$$

$$C_{M\to F} = \frac{1}{2} ln \frac{\sigma_F^2}{\sigma_X^2};\ S_{F|M} = \frac{1}{2} ln \frac{\sigma_X^2}{\sigma_{ARX}^2} \quad (5)$$

where σ_F^2 is the variance of the target process, σ_{AR}^2 is the prediction error variance of an auto-regressive (AR) model describing the present state of the target from its past values, σ_X^2 is the prediction error variance of a cross-regressive (X) model describing the present state of the target from the past values of the driver, σ_{ARX}^2 is the prediction error variance of an ARX model describing the present state of the target from the past values of the entire bivariate process. The computation of the dynamic information measures in (4) and (5) thus reduces to the estimation of the error variances of full (ARX) and restricted (AR, X) linear regression models, which was performed by solving the Yule-Walker equations [13].

D. Data pre-processing

The acquired M and F time series were first pre-processed to obtain zero-mean series. As regards the computation of the dynamic entropy measures, further pre-processing was performed using an AR high-pass filter for detrending (zero-phase filter, cut-off frequency of 0.0156 times the sampling frequency, the latter assumed to be the inverse of the mean HP for each subject); model identification was performed by setting the model order according to the Akaike Information Criterion (AIC) for each subject (with maximum scanned model order equal to 14). As regards the parametric ARI computation, the model order was set in accordance with [16].

E. Statistical and correlation analysis

The significance of the differences between experimental conditions (PRE vs. POST) was assessed using non-parametric tests, given the small sample size and that normality of the series assessed through Anderson-Darling test was rejected for most cases. Specifically, the paired Wilcoxon signed rank test was used with a significance level of 5%.

Moreover, the non-parametric Spearman correlation coefficient, corresponding to Pearson correlation coefficient computed from rank vectors [17] was used to assess the degree of correlation between the parametric ARI and the entropy-based linear measures. Indeed, given its non-parametric nature, the assumption of Gaussianity is not a necessary condition and thus it is used to compare discrete variables, such as the ARI, with continuous variables, such as the measures of dynamic entropy. In this study, the parametric ARI values were compared with each of the entropy measures (self-entropy, transfer entropy, cross entropy, and conditional self-entropy) for any given experimental condition.

III. RESULTS AND DISCUSSION

Figure 2 shows the distributions across subjects of ARI values obtained with the parametric method (Fig. 2a), transfer entropy and self-entropy (Fig. 2b, c), cross entropy and conditional self-entropy (Fig. 2d, e), evaluated in the PRE and POST experimental conditions. The ARI method evidenced that CA remained intact during the PRE-POST protocol (Fig. 2a), confirming that propofol general anaesthesia does not affect CA [16]. In fact, although propofol general anaesthesia is known to cause autonomic depression, which is a major determinant of CA [18], several studies exploiting the same experimental protocol have confirmed that CA does not vary with the anaesthetic pharmacokinetic properties of propofol [16].

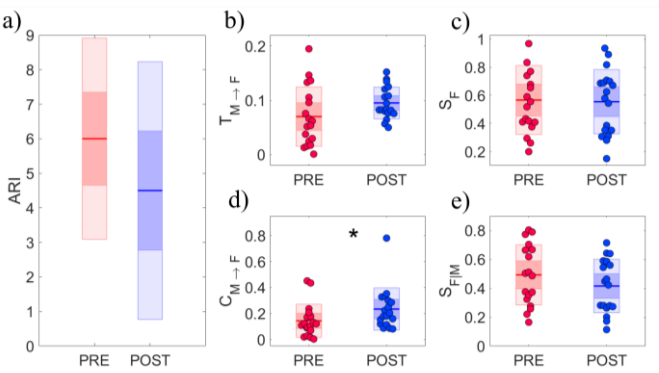

Fig. 2 Results of short-term cerebrovascular variability analysis. Boxplots depict the distributions of **(a)** ARI values computed with the parametric method, **(b)** transfer entropy $T_{M\to F}$, **(c)** self-entropy S_F, **(d)** cross entropy $C_{M\to F}$ and **(e)** conditional self-entropy $S_{F|M}$ in PRE (left boxplots, red dots) and POST (right boxplots, blue dots) conditions. Statistically significant differences (p<0.05): *****, PRE vs POST, Wilcoxon signed rank test for paired data.

Measures of dynamic entropy show different interpretations of how predictable dynamics in the target process are derived from its own past and the past of the driver process. The increased cross-entropy in POST (Fig. 2d, $p = 0.0386$) reflects a higher predictability of CBFV dynamics from AP values, documenting an increased cerebrovascular coupling that might be indicative of reduced cerebral autoregulation (CBFV changes are more dependent on AP variations). However, the finding that $T_{M\to F}$ and $S_{F|M}$ do not vary between conditions (Fig. 2b, c) leads us to suggest that the causal interactions from M to F and the internal dynamics of F may be unaffected by the investigated experimental protocol. Since variations in the cross-entropy can be induced by changes in the direct coupling along both directions of interaction (M→F and F→M in this case) [13], caution should be used in ascribing to a stronger coupling the increased cross-predictability of F given M. Moreover, the simultaneous effect induced by mechanical breathing on M and F during anaesthesia in POST, although not directly investigated, could have generated regular oscillations in both series at the frequency of mechanical ventilation. This would have caused an increased predictability of F from M, which appears when considering $C_{M\to F}$ but not $T_{M\to F}$, i.e. when conditioning also on the past dynamics of F apart from M [19].

Table 1 reports the correlation values between the ARI and each of the dynamic entropy measures, evaluated with the Spearman correlation index (ρ) in the PRE-POST protocol. The weak correlations, confirmed by p values higher than the significance threshold (level of significance of 5%), suggest that ARI and dynamic entropy measures provide different information on the short-term cerebrovascular control and on the functioning of CA in this group of patients.

IV. CONCLUSION

This work aimed to compare different methods for investigating the interaction link from arterial blood pressure to cerebral blood flow (i.e., the pressure-to-flow link), to investigate the physiological mechanisms related to cerebral

autoregulation. The ARI-based method showed that CA remained unchanged with the PRE-POST protocol in patients undergoing CABG surgery, confirming the known properties of propofol on CA maintenance. On the other hand, the statistically significant increase of cross-entropy after the induction of general anaesthesia showed that the dynamics of cerebral blood flow become more dependent on those of systemic pressure, suggesting a possible alteration of cerebral autoregulatory mechanisms. The weak correlation between the two methods confirms that they highlight different aspects of cerebrovascular physiology.

To corroborate the results of this work, future studies should be designed: (i) to investigate cerebrovascular interactions through a closed-loop analysis considering also the effects of cerebral flow variations on arterial pressure; and (ii) to quantify such interactions in the frequency domain separating respiration-related oscillations from effects within the very low frequency (0.02-0.07 Hz) and low frequency (0.07-0.2 Hz) bands during the PRE-POST protocol [6].

TABLE I
SPEARMAN CORRELATION: ARI VS. ENTROPY MEASURES

	PRE		*POST*	
	ρ	*p-value*	*ρ*	*p-value*
ARI vs $T_{M\to F}$	-0.012	0.961	0.447	0.063
ARI vs $C_{M\to F}$	-0.327	0.185	0.254	0.308
ARI vs S_F	-0.224	0.372	0.008	0.974
ARI vs $S_{F\|M}$	-0.012	0.423	-0.114	0.654

Comparison between parametric ARI and dynamic information measures (transfer entropy $T_{M\to F}$, self entropy S_F, cross entropy $C_{M\to F,}$ conditional self entropy $S_{F|M}$) using Spearman correlation index ρ during the PRE and POST experimental conditions. Rejection of the null hypothesis (*p*-value < 0.05) means that the two investigated metrics are significantly correlated.

***Abstract*—Although normative modelling has been recently widely adopted by the neuroimaging community to estimate deviation of cohorts or single subjects, from a reference population's trajectory, it has never been applied on molecular neuroimaging datasets. This is because the typical sample size of molecular imaging datasets of single studies is not adequate for a reliable estimation of population models. Here, we pooled scans from different datasets and compared the performance of common neuroimaging harmonisation techniques when used on molecular neuroimaging data, by measuring the effect of the harmonisation on the deviation scores of the normative model. As harmonisation methods we employed a 3D Gaussian filter and a Bayesian scale and shift estimation method (Combat). By statistically testing the parameters of the deviation-score distribution and inspecting the explained variance map of the model, we selected Combat, trading-off between the two parameters' performance, as the most suitable way to harmonise multi-site/multi-scanner molecular neuroimaging datasets.**

***Keywords*—Normative Modelling, Dopamine, PET Imaging, Multisite Data Pooling.**

I. Introduction

NORMATIVE modelling is a statistical framework increasingly adopted by the neuroimaging community to estimate the "*normal*" behaviour of a measure of interest (e.g., cortical thickness in a region or voxel) in relation with some covariates of interest (e.g., demographical, behavioural or clinical variables). The main characteristic of the methodology is the estimation of a model on a large sample size of a reference cohort (usually healthy controls – HCs), which can be then applied, after validation, to a patient cohort to assess potential deviation from normality at the individual or group level [1], [2]. This method has been applied on magnetic resonance imaging (MRI) data to analyse patterns of tissue loss in bipolar disorders [3], [4], schizophrenia [3]–[5], ADHD [6], and Parkinson's disease [7], but so far, it has never been used with molecular imaging data (i.e., Positron Emission Tomography – PET and Single Photon Emission Computed Tomography – SPECT).

Molecular neuroimaging can provide a unique *in-vivo* view of the biology of the healthy and diseased brain that no other neuroimaging method can provide. By selecting different molecular tracers we can visualize different targets in the brain, i.e., neuroreceptor distribution, synaptic transmission, brain metabolism, enzyme activities, protein synthesis, among others [8]. The application of normative modelling in molecular neuroimaging could prove beneficial in identifying patterns of deviation from normality in psychiatric patients and to develop individualised treatments based on the severity of these.

One of the main problems to apply normative modelling to molecular neuroimaging is the necessity to gather a large enough dataset to capture as much intrinsic variability of the system under investigation as possible. While in structural and functional MRI international collaborations (e.g., ENIGMA [9], UK BIOBANK [10]) are collecting datasets counting thousands of scans of healthy volunteers, in molecular neuroimaging the collection of such extensive datasets is unfeasible for various reasons. First, since molecular neuroimaging requires the injection of a radiotracer, the collection of datasets of HCs with the sole purpose of mapping the human brain could be considered harmful to the participants and therefore unethical. In addition, the acquisition of such datasets with PET would be far more costly than in MRI.

A possible solution to this issue is to gather data of HCs from existing studies. However, when pooling data from various acquisition sites, a harmonisation step is required to clear the data from batch and/or scanner effects before model estimation. Several studies address the issue of harmonisation of neuroimaging datasets [11]–[14], but the most widely used methods are: gaussian kernel smoothing, adjusted residual harmonisation methods (e.g., Combat [11], [12], [15]) and the incorporation of the site effect in the model (i.e., hierarchical models [13], [16], [17]).

In this work, we aim at addressing the issue of multisite harmonisation of molecular neuroimaging data by comparing two of the most widely adopted methods in the neuroimaging field, namely the Gaussian kernel smoothing and Combat harmonisation, evaluating their effects on normative modelling of PET HCs. We applied these methods to two datasets of [^{11}C]-(+)-PHNO and assessed their impact on the single-subject deviation scores of the normative model.

We then tested on an independent larger cohort of HCs acquired with [^{18}F]FDOPA if the method can be generalised to other tracers.

II. Materials and Methods

A. [^{11}C]-(+)-PHNO PET Dataset

We used PET baseline scans of 77 HCs from two existing datasets [18], [19] acquired in the same imaging centre (Invicro, London) using two different scanners (Siemens Hi-Rez Biograph 6, N=54, labelled as PET/CT; Siemens Biograph mMR, N=23, labelled as PET/MR) with [^{11}C]-(+)-PHNO, an

agonist tracer of the dopamine $D_{2/3}R$.

Experimental design, image acquisition, image processing and data analysis was consistent for the two studies and further details are reported in the original publications [18], [19]. Parametric images of dopamine receptor density, measured using non-displaceable binding (BP_{ND}) [20], were obtained using the same MATLAB-based pipeline for the two datasets, using a simplified reference tissue model with cerebellar grey matter as reference region. Final maps were all normalised to the MNI152 standard space prior to harmonisation and normative modelling.

B. *[18F]FDOPA PET Dataset*

6-[^{18}F]-fluoro-L-dopa (FDOPA) PET data of 142 healthy individuals from six different studies, acquired with five different scanners (Siemens Hi-Rez Biograph 6, Siemens Biograph 40 TruePoint, Siemens TruePoint 6, ECAT HR+ 962 and ECAT EXACT 3D) in three different imaging sites (South Korea, Imanet London and Invicro London), were used to check if the harmonisation method withheld the same performances with a different tracer. K_i^{cer} parameter (sometimes indicated as K_i, 1/min [20]) was used as main parameter of interest, quantified with Gjedde-Patlak graphical method using cerebellum as reference region. Acquisition protocol was consistent across sites; all data were quantified and normalised into standard MNI152 standard space with the same in-house developed pipeline (for more details refer to the paper [21]).

C. *Multisite data harmonisation*

To harmonise the data from the test dataset we employed Gaussian kernel smoothing and Combat harmonisation.

Gaussian kernel smoothing (hereafter referred only as smoothing) consists in the application of a 3D convolution filter defined by a gaussian kernel with a Full Width Half Maximum (FWHM) of:

$$FWHM = \sigma\sqrt{8\ln(2)} \cong 2.35\sigma$$

Where σ is the size of the kernel to be found by iteratively searching the best match between the data to be harmonised (PET/MR) and the target (PET/CT), in this case we used as target the PET/CT as it is the technology with the lower resolution between the two under investigation. To smooth the data, we used FSL maths (fslmaths -s flag) with the final kernel size of 3mm, as this provided, after some iterative search, the best visual resemblance between the target group (PET/CT) and the data on which smoothing was applied (PET/MR).

Combat is a Bayesian harmonisation method that estimates site-specific shift and scaling factors. This method, contrary to the Gaussian smoothing, allows to specify some covariates such as demographic variables whose contribution within the data variability is estimated and preserved. These covariates must be specified before the harmonisation, otherwise all variability not attributed to the specified covariates is assumed to be noise to remove during the harmonisation. For this type of harmonisation, we employed the function NeuroCombat from the NeuroCombat python library (version 0.2.10+) to estimate the scaling parameters. During the harmonisation we preserved the effect of the same covariates used in the modelling step, i.e., age, sex and body mass index (BMI) [11], [12], [15].

D. *Normative modelling*

We employed a Bayesian Linear Model (BLR) to estimate the model on HCs with [^{11}C]-(+)-PHNO and [^{18}F]FDOPA. The BLR is a Bayesian extension of the simple linear model where we assume that the response of interest is a linear function of the predictor, and that this relationship will vary normally at any point around the average prediction μ with a consistent standard deviation σ. We can briefly write the assumed data generating model as:

$$Y_{ji}|\beta_{0j}, \beta_{1j}, \sigma \sim N(\mu_j, \sigma_j^2) \text{ with } \mu_j = \beta_{0j} + \beta_{1j}X_i$$

Where β_{0j}, β_{1j} represent the effect parameters of the covariate for voxel j and X_i represents the subject-specific covariates. In our specific cases, we included as covariates only demographic variables (age and sex for both tracers and, additionally, BMI as additional covariate for the [^{11}C]-(+)-PHNO model). The selected covariates were selected from previous in-house analyses of the effects of these covariates on the tracers [21], [22], and from literature [23], [24].

The model is estimated using the PCNToolkit (version 1.20.0) Python library, using the default, weakly informative, prior distributions for the parameters and the Powell optimizer for faster convergence of the model fitting [1]. We estimated voxel-wise models on the 2mm isotropic quantified images, restricting the estimation to the voxels overlapping with a grey matter mask.

To evaluate the in-sample performance of the model, we estimated mean and standard deviation of the model response under k-fold cross validation (k=5). From these estimated metrics we calculated voxel-wise Z-score maps where each voxel is calculated as:

$$Z_j = \frac{Y_j - \hat{\mu}_j(\boldsymbol{X})}{\sqrt{\hat{\sigma}_j^2(\boldsymbol{X})}}$$

Where $\hat{\mu}_j(\boldsymbol{X_i})$ is the estimated mean response and $\hat{\sigma}_j^2(\boldsymbol{X_i})$ is the estimated variance of the response, for voxel j, given the specific set of covariates for subject i.

In addition to the single subject deviation map, we also obtained a voxel-wise map of the explained variance of the estimated model on HCs. This map was visually inspected to weigh the effect of the harmonisation methods had on it.

E. *Statistical analyses*

To assess the best harmonisation method, we first evaluated the effect of this step on the Z-scores by testing the differences of the median and the first four statistical moments of the distribution (mean, standard deviation, skewness, and kurtosis) using Welch two sample t-tests in R (version 4.2.1). In this step the working hypothesis is that, after harmonisation, the distribution of scores should be homogeneous, i.e., there should be no statistical differences between the datasets acquired using the two scanners, in addition the distribution parameters should be close to that of a normal distribution (i.e.,

skewness≈0 and kurtosis≈3).

For re-assessment on the second tracer, we repeated the analyses on the Z-scores by performing an ANOVA on the parameters of the distribution with the anova_test function of the rstatix package in R version 4.2.

III. RESULTS

A. *Muti-scanner [^{11}C]-(+)-PHNO image harmonisation*

From Fig. 1, it is possible to observe a clear scanner effect on the distribution of the Z-scores when no harmonisation is applied; such effect is no longer visible after the application of the harmonisation methods (Fig. 1).

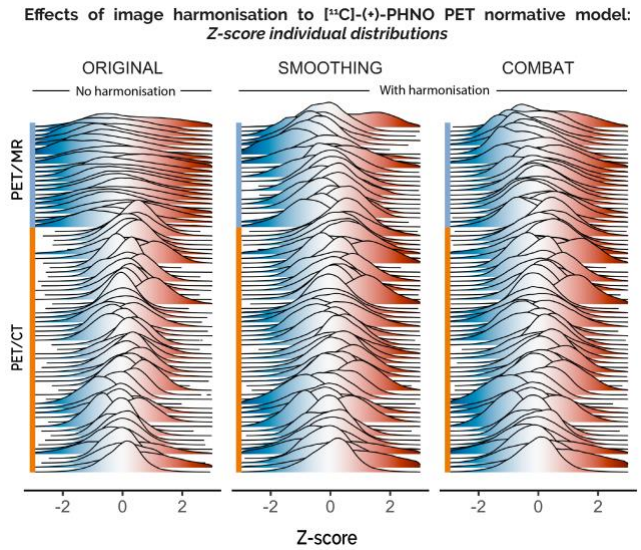

Fig. 1: Effects of harmonisation methods on the Z-scores of [^{11}C]-(+)-PHNO normative model. *The distributions within the ridgeline plots correspond to the Z-score distributions of each subject of the two datasets (PET/MR and PET/CT). While a scanner effect can be clearly seen in the plot representing the original data (on the left), this effect is reduced in both plots representing the scores after harmonisation.*

Quantitatively, the application of harmonisation is not able to remove all the statistical differences due to the scanner type. The difference of mean Z-score distribution between PET/CT and PET/MR is statistically significant for smoothed data (t=2.85, p<0.001), but not for Combat data (t=0.715, p=n.s.). The same trend is visible for the median (original: t=3.21, p<0.01; smoothed: t=3.13, p<0.01; Combat: t=1.53, p=n.s.). In terms of standard deviation, both harmonisation methods reduce the scanner effect, although the difference between methods remains statistically significant with Combat (original: t=-14.59, p<0.001; smoothed: t=-0.40, p=n.s.; Combat: t=-2.47, p<0.01). Considering the higher-order statistical parameters of the Z-score distributions, smoothing outperforms Combat both in terms of skewness (original: t=-4.79, p<0.001; smoothed: t=0.06, p=n.s.; Combat: t=-5.64, p<0.001) and kurtosis (original: t=0.24, p=n.s.; smoothed: t=0.24, p=n.s.; combat: t=3.32, p<0.01).

In addition to the deviation scores, we visually inspected the map of explained variance by the normative model. The model, both with harmonised and un-harmonised data, explains up to 30% of the variance of the data. However, in the map of the explained variance estimated with the original data and with the smoothed data, we can observe what appears to be a spill-over like artifact in the insula which is increased with smoothing and almost disappears with Combat (Fig. 2).

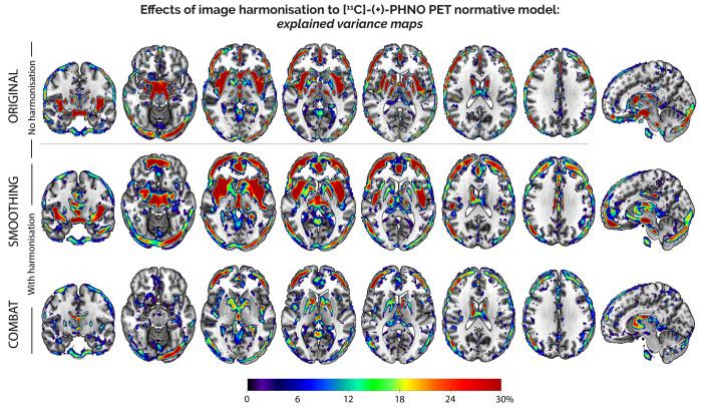

Fig. 2: Effects of harmonisation methods on explained variance of [^{11}C]-(+)-PHNO normative model. *Each row represents the explained variance by the BLR estimated with original, smoothed and Combat harmonised data. In the first two rows there is a visible spill-over like effect in the insula, which almost disappears in the last row.*

B. *Muti-scanner [^{18}F]FDOPA image harmonisation*

Based on the results from the [^{11}C]-(+)-PHNO model, we applied Combat harmonisation to a wider cohort of HCs acquired with 5 different scanners using [^{18}F]FDOPA to determine if the harmonisation yielded similar results with a different tracer.

One-way ANOVA on the first statistical moments to test the effect of different scanners on the Z-score distributions shows no statistical difference in the mean (F=0.12, p=0.98) and median (F=0.098, p=0.983) distribution. Furthermore, no statistical difference in the skewness was found (F=0.351, p=0.843), although there was a residual effect of scanner in the standard deviation (F=3.306, p<0.05) and kurtosis (F=11.01, p <0.001), consistently with the [^{11}C]-(+)-PHNO PET results. Post-hoc analyses highlighted that the differences in skewness are driven by the two scanners with the least number of scans (ECAT HR+ 962, N=12 and ECAT EXACT 3D, N=7).

IV. CONCLUSION

The aim of this work was to find the most suitable method for multi-site/ multi-scanner image harmonisation for normative modelling in the context of molecular imaging.

We applied two of the most used harmonisation methods to a dataset of [^{11}C]-(+)-PHNO PET data and found that Combat shows a reduction in the difference between datasets in term of mean, median and standard deviation, a visual harmonisation of the deviation scores and a reduction of spill-over like effects visible in the explained variance map, suggesting its better suitability for the harmonisation of this type of data.

The results given by Combat are upheld also in a wider cohort of controls, acquired with a different tracer, composed by 5 different datasets of [^{18}F]FDOPA PET, gathered with the same number of scanners. Some differences between groups

remain in standard deviation, skewness and kurtosis, possibly by non-linear contribution of some covariates, which are not fully removed with the linear harmonisation method (Combat) but are eliminated with smoothing. With Combat we can harmonise data in a more meaningful and robust way compared to simple smoothing, which would require an iterative search of the kernel size for any new scanner, even though the harmonisation is not perfect.

In future works additional methods for data harmonisation of multi-scanner PET data should be explored, like non-linear versions of Combat (e.g., Combat-GAM) or the incorporation of the scanner-effect directly in the normative model with the use of hierarchical models, which has been shown to be more robust than Combat, but it demands a higher computational power [16].

In this work we showed that Combat can be used not only to harmonise MRI data, but also for PET scans acquired in different centres/scanners to be used for normative modelling. This will allow the neuroimaging community to gather cohorts of HCs from past studies and different centres and estimate normative models of molecular systems.

***Abstract*—Cardiotocography (CTG) is a widely way to assess foetal well-being status, both in antepartum and intrapartum period. Automatic computerized analysis was introduced to overcome limitations of visual analysis of CTG traces. The present study extended a software previously developed for the calculation of foetal heart rate signal (FHR), floatingline (FL) signal and uterine contractions signal introducing the extraction of five novel statistical parameters from signals mentioned. Dataset contained 580 signals acquired during daily routing foetal monitoring. A univariate statistical analysis was used to compare spontaneous deliveries from caesarean deliveries; an analysis of variance, and a post-hoc test was performed to distinguish the week of gestation (WG) in which the CTG trace was recorded. The results demonstrated that, whereas decelerations features were not able to classify CTG signals, accelerations features were. In particular, kurtosis of FHR accelerations (*p*-value=0.0029) was able to distinguish between CTG corresponding to caesarean and spontaneous delivery. Furthermore, by considering accelerations computed by the FL, their mean (*p*-value=0.034), standard deviation (*p*-value=0.032) and variance (*p*-value=0.011) were useful in discriminating among different WG classes. These are important and promising results because it is the first time that novel features are employed in CTG classification.**

***Keywords*—Cardiotocographic signals, foetal heart rate, uterine contractions, statistical analysis.**

I. Introduction

Cardiotocography (CTG) is a continuous electronic recording of foetal heart rate (FHR), uterine contractions (UC) activity obtained both in antepartum and intrapartum period [1] by means two probs placed on women's abdomen. Nowadays, it is well known that FHR monitoring is an important indicator of foetal health state, mainly about a correct blood oxygenation and a proper autonomous nervous system (ANS) work [2]. Some parameters which indicate a well-being foetal status are FHR variability; accelerations, which indicate ANS reactions to internal and/or external stimuli; the basal level of FHR signal, a running FHR average which, in absence of cardiac arrhythmia, is confined in some intervals dependent on week of gestation (WG) and, at the term of pregnancy, decelerations of FHR, which can be physiological or suspicious, mainly according to their shape and time-correlation with UC.

In clinical practice, visual analysis of CTG traces depends on clinician's experience, noting a variability both between observers and within the same observer. For this reason, visual analysis has been often substituted by computerized analysis of CTG traces [3], [4], which takes advantage of a reproducible and objective quantification of parameters not easily detected by the human eyes [5], [6]. Computerized CTG systems are not yet fully used in clinical fields, since results are not fully satisfying [6]. These techniques try to calculate the parameters usually detect by clinician's eye inspection for diagnosis such as, for example, presence of accelerations, decelerations, baseline trend, and then to add other characteristics, for example, morphological, or outcome of so-called nonlinear analyses, in order to provide physicians with a wider gamma of parameters on which rely their evaluation [7].

Due to their importance in foetal monitoring, this work focused on accelerations and decelerations events. Accelerations and decelerations were assessed both from FHR signals, for preserving the superimposed variability, and from floatingline (FL), for highlighting their shape. Moreover, for CTG traces recorded during the labour also UC were analysed.

In particular, the aim of the current study was to calculate statistical features in order to characterise in a novel way (for this research field) these events and verify if they might be able to distinguish the WG in which the CTG trace was recorded (expression of ANS maturation), and to discriminate CTG of spontaneous deliveries and CTG of caesarean sections.

Indeed, it is worth remembering that, in some countries, the CTG has recognised as a clinical report with legal value; so that the capability to understand if a caesarean section is necessary is still an important research topic.

II. Materials and Methods

A. Data set

CTG traces used in the present study are a subset of a database populated by signals acquired in medical contexts, during daily routine foetal monitoring consisting of 580 traces. All CTG signals last a minimum of 20 minutes from women being in a rest position. Sonicaid or HP-135x cardiotocographs were used to acquire CTG signals. In both cases, as it is known, FHR signals are recorded by an ultrasound Doppler probe while the UC signals by external pressure transducers.

B. Signal pre-processing and classical analysis

After the acquisition of CTG signals, it is useful/necessary to carry out a pre-processing phase whose main purpose is to select only FHR signals which can be considered of good quality. To be labelled of "good quality", signals included in the study matched the following requirements:

- a percentage of signal loss and outliers lower than 10%

and 5% respectively,
- acquired from singleton pregnancy,
- absence of complications during caesarean and spontaneous deliveries,
- correspondence with a healthy new-born, i.e., Apgar at least equal to 7 at the 1st minute,
- birth weight appropriate for gestational age.

Further, as detailed in previous works [8], [9], [10] the pre-processing software makes FHR and UC signals comparable and available for the analysis regardless to the acquisition device. The pre-processing software also provides a quality signal to identify "good" and "bad" quality signal tracts.

The estimation of the relevant clinical parameters in foetal monitoring was carried out with a software previously developed in MATLAB [11].

The software is able to give as outcome:
- baseline and FL, that is the median line of an FHR signal
- detected accelerations and decelerations, with their main features (e.g., time-duration and amplitude)
- detected uterine contractions
- some time and frequency characteristics (such as short-term variability, and power content of the different frequency ranges of FHR PSD)
- other more in-depth analyses (results of dynamic analysis, sample entropy, etc).

Clinical parameters calculation is based both on FIGO guidelines [12] and literature indications [13], [14], [15].

An example of FHR and UC signals are shown in Figure 1.

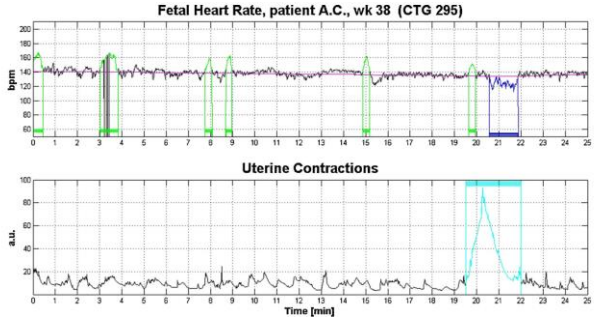

Fig. 1. Foetal heart rate and uterine contractions signals. By using different colours are identified accelerations (green), decelerations (blue) and uterine contractions (light blue).

C. Statistical features extraction

In the current study, the authors extended the above-mentioned software to add new information (listed below). MATLAB functions for statistical features extraction from detected CTG events (accelerations, decelerations, and contractions) were implemented. The functions need as input the following signals and parameters: asset (time axis expressed in s), FHR, FL, UC; plus, for each signal, number of events, time-start and time-end of the events. Of course, not all the signals are simultaneously necessary. The output returns a matrix with all the parameters calculated.

To have a synthetic indicator for each CTG trace, the values of statistical features, calculated for each event identified, were averaged over the number of events of the same type. The mean, min and max number of accelerations, decelerations and UC were respectively: 8.96, 0, 94 (accelerations); 0.12, 0, 7 (decelerations); 2.42, 0, 89 (UC).

Assessed statistical features are the most employed:
- mean
- standard deviation (sd)
- variance
- skewness
- kurtosis.

Statistical features were extracted from accelerations and decelerations of FHR signals, accelerations and decelerations of FL, and UC. The final matrix was 580 x 25 in which the rows represent CTG signals, and columns statistical features, above listed (5 related to: accelerations of FHR, accelerations computed on the FL, decelerations both on FHR and FL, UC).

For the post-processing, CTG were grouped based on the WG in which were recorded. Specifically, 27th-30th week that represents the antepartum period; 31st-35th week for considering preparatory contractions; and 36th-42nd week that represents the term period of a pregnancy.

D. Statistical analysis

Statistical analyses were performed using MATLAB software. The Anderson-Darling test was employed to evaluate the normality of statistical features previously calculated. For normally distributed data a *t*-test for independent sample was used, otherwise a Mann-Whitney test was performed. The univariate statistical analysis was conducted to try to classify CTG corresponding to spontaneous deliveries from CTG corresponding to caesarean ones.

An analysis of variance was also computed to try to distinguish the WG in which the CTG trace was recorded (27th – 30th week, 31st – 35th week or 36th – 42nd week). The same procedure as for the previous analysis was applied to assess the normality of statistical features. Specifically, one-way Anova test was employed for normally distributed data, while its corresponding non-parametric test, Kruskal-Wallis, for not normally distributed ones. Finally, when one-way Anova test or Kruskal-Wallis test was significant, a post-hoc analysis, Turkey test, was conducted to uncover differences between the three groups. The significance level for all statistical tests was fixed at $\alpha<0.05$.

III. Results

Statistical distributions, in terms of means ± sd, of 25 considered features are listed in the footnote[1].

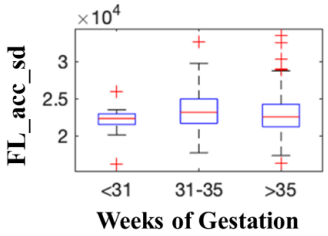
A. Univariate statistical analysis

Univariate statistical analysis tried to classify CTG of spontaneous deliveries from CTG of caesarean sections based

[1] Mean of FHR acc. (146.03 ± 15.01); sd of FHR acc. (21738.81 ± 3721.87); variance of FHR acc. (539.12 ± 968.83); skewness of FHR acc. (-0.30 ± 0.39); kurtosis of FHR acc. (2.59 ±1.58); mean of FL acc (151.04 ± 8.17); sd of FL acc. (22895.60 ± 2491.10); variance of FL acc. (19.13 ± 11.38); skewness of FL acc. (-0.36 ± 0.23); kurtosis of FL acc. (2.15 ± 0.43); mean of FHR dec. (96.03 ± 32.14); sd of FHR dec. (10272.92 ± 5745.91); variance of FHR dec. (1713.16 ± 1604.19); skewness of FHR dec. (-0.86 ± 1.40); kustosis of FHR dec. (4.49 ± 5.35); mean of FL dec. (123.46 ± 10.45); sd of FL dec. (15349.23 ± 2646.55); variance of FL dec. (30.00 ± 22.30); skewness of FL dec. (0.21 ± 0.62); kustosis of FL dec. (2.65 ± 0.82); mean of UC (36.08 ± 14.79); sd of UC (1574.73 ± 1444.37); variance of UC (248.85 ± 352.17); skewness of UC (0.12 ± 0.69); kustosis of UC (2.55 ± 2.92).

on all 25 extracted statistical features. Before carrying out the classification, as above mentioned, a test for checking the normality of data was executed. According to the Anderson-Darling test, all the tested features resulted non normally distributed, except those one related to decelerations computed on the FL. About the separation between spontaneous deliveries and caesarean sections, the significance was reached by the variable kurtosis of accelerations of FHR signal with a *p*-value equal to 0.0029. This is in line with our expectations since grater accelerations generally represent a healthy foetus.

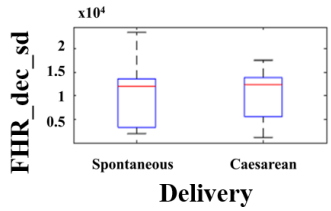
B. *Variance statistical analysis*



Analysis of variance is a way to compare CTG traces recorded in several WGs, among the 27th-30th week, 31st-35th week and 36th-42nd week considering the whole set of 25 extracted statistical features. The normality Anderson-Darling test showed that all variables were not normally distributed and consequently the Kruskal-Wallis test was applied for the whole analysis. Table I illustrates significant test variables.

TABLE I
KRUSKAL-WALLIS TEST RESULTS

Feature	*p-value (α<0.05)*
FL_acc_mean	0.034
FL_acc_sd	0.032
FL_acc_variance	0.011



Abbreviations: FL=floatingline; acc=accelerations; sd=standard deviation

Mean, sd and variance of accelerations on FL signals were indicators of a difference among the three groups. This result is also relevant because accelerations increase in number and are better characterized as the progress of pregnancy. An example of the results is shown in Figure 2.

Abbreviations: FL=floatingline; acc=accelerations; sd=standard deviation
Fig. 2. Box plot of standard deviation of acceleration of floatingline signals.

It is worth highlighting, vice versa, that, a significant result on deceleration events of FHR signals would have been anomalous as they are absent in the first two WG groups, unless there are pathological situations or premature births; situations that were beyond the scope of this preliminary study. Figure 3 is an example of what mentioned above.

Abbreviations: FHR=foetal heart rate; dec=decelerations; sd=standard deviation
Fig. 3. Box plot of standard deviation of decelerations of FHR signals.

Based on Kruskal-Wallis test results, a post-hoc analysis was performed. The results are shown in Table II.

TABLE II
TURKEY TEST RESULTS

Group 1	*Group 2*	*p-value (α<0.05)*	*Feature*
31st-35th week	*36th-42nd week*	0.048	FL_acc_mean
31st-35th week	*36th-42nd week*	0.046	FL_acc_sd
27th-30th week	*31st-35th week*	0.032	FL_acc_variance
27th-30th week	*36th-42nd week*	0.029	FL_acc_variance

Abbreviations: FL=floatingline; acc=accelerations; sd=standard deviation

Specifically, mean and sd of accelerations of FL signals were significant comparing 31st-35th week and 36th-42nd week.

However, it is worth noting that the significance was not so good (*p*-value near to 0.05), this is due to the fact that the accelerations into the two groups, usually, have similar features; indeed, around the 30th week, the ANS is anatomically formed and, generally, a healthy foetus react to stimuli with accelerations of HR.

The variance of accelerations of FL signals were significant both for 27th-30th week and 31st-35th week and for 27th-30th week and 36th-42ndweek. In these cases, the *p*-value was lower, i.e., slightly more significant, according to a not yet complete maturation of the ANS in the WG from 27th to 30th [16].

It is worth highlighting that sd and variance give different results. In our opinion, this is due to the difference enhancement related to squaring.

IV. DISCUSSION AND CONCLUSIONS

CTG signals continue to be badly interpreted even though efforts are being made to overcome the problem using computerized systems for automatic analysis in diagnosis of foetal status. As it is well known, computerized CTG analysis has several benefits, one of which is the objectivity in FHR reading. Additionally, a proper pre-processing can enhance the quality of signals. Again, many computerized systems can evidence suspicious signals and provide a warning. Since computerized CTG is becoming increasingly important, different examples of software for automatic CTG analysis have been shown in literature.

For instance, let us cite the Dawes/Redman analytical criteria, the first ones proposed and which the Sonicaid Fetal Care system is rely on [17]. The SisPorto 2.0, the most recent iteration of a program for automatically analysing CTG traces developed at the University of Porto, which involves accurate analysis of the baseline [5], [18]. Finally, the 2CTG2 system that assesses other characteristics such as, for example, the sample entropy [19]. In this prospective, in previous works [8], [9], a software for CTG automatic analysis was developed.

This paper describes an extension of this software, calculating statistical parameters from events assessed on FHR, UC and FL signals. Statistical analyses were performed to classify different types of deliveries and to distinguish the WG in which the CTG were recorded.

Preliminary results obtained were quite interesting. The authors noticed the importance of kurtosis of acceleration events of FHR signals, which was a significant variable useful

for the classification of CTG related to spontaneous deliveries or caesarean deliveries as well as parameters extracted from the accelerations of FL tried to distinguish the WG. Furthermore, the post-hoc test emphasised among which WGs there is a statistically significant difference, as reported in Table II.

In summary, the obtained preliminary results represent an improvement in the study of CTG signals. On the one hand, although using a different methodology, the results confirmed known concepts; for example, that decelerations cannot be used as predictor events if CTG are recorded early during the pregnancy, or that accelerations change their features (not only the number) as the pregnancy as advances. These findings encourage us about the potential efficacy of the proposed methodology that can be usefully further developed. On the other hand, preliminary results and observations confirmed the importance of computerized CTG. Indeed, parameters here evaluated cannot be computed by naked eyes.

Once the proposed methodology is established, the preliminary results described above provide evidence that it could be useful to include a range of parameters (statistical and/or morphological) to improve the CTG classification; for example, by setting a threshold about mean, sd and variance of accelerations, calculated on FL signals, to assess if the CTG signal is proper for the WG or other diagnostic examinations are necessary. Furthermore, the same analysis techniques could be applied to variables extracted from pathological CTG signals to distinguish reassuring from non-reassuring traces. Finally, an additional development could be the introduction of machine learning algorithms, widely adopted for in different medicine fields for classification purposes [20], [21], [22], [23], [24], for the analysis of CTG traces [25], [26], [27].

***Abstract*—In the last decades, it has become clear that functional interactions between brain regions are crucial for understanding brain's functioning. These interactions can be assessed through functional connectivity approaches that characterize statistical dependencies between time series obtained by time-resolved neuroimaging techniques. Nevertheless, these techniques provide information about brain activity at the scale of brain regions with an extent in the order of several millimetres that constitute a functional unit and are constituted by multiple voxels. To apply conventional bivariate connectivity metrics, the signal of voxels in a brain region (a multi-dimensional set) is usually reduced to a single signal per brain region with a potential loss of information. To overcome this limitation, we have developed a family of "multi-dimensional connectivity" methods that take direct advantage of the multi-dimensional nature of the data. Here, we present a collection of these methods and show, in simulations, that they outperform the approach based on dimensionality reduction and non multi-dimensional connectivity methods.**

***Keywords*—Electroencephalography, Magnetoencephalography, Functional connectivity, Multi-dimensional signals.**

I. INTRODUCTION

In the last decades, neuroimaging research has shown that the characterization of functional interactions between brain regions (i.e. functional connectivity) are crucial for understanding brain's functioning. Functional connectivity is inferred by assessing statistical dependencies between time series associated with regions of interest and obtained by time-resolved neuroimaging techniques (e.g. functional Magnetic Resonance Imaging -fMRI, Electroencephalography - EEG or Magnetoencephalography - MEG). Different bivariate methods for estimating this dependency have been developed (e.g. [1-7]). However, one aspect is often ignored: the fact ROIs are typically composed of multiple voxels, thus ROI signals are typically multi-dimensional and are usually reduced to a representative one-dimensional time series [8] before functional connectivity estimation, with a potential loss of information. To overcome this limitation, "multi-dimensional connectivity" methods have been recently developed to take advantage of the multi-dimensional nature of the data from various neuroimaging techniques: fMRI (e.g. [9,10]), EEG (e.g. [11]) and MEG (e.g. [8]). Here, we present a collection of frequency domain methods we developed to assess different properties of interactions between multi-dimensional signals as, for exampling, linear and non linear coupling as well as directed or undirected coupling.

II. METHODS

A. Multi-dimensional connectivity methods

All the multi-dimensional connectivity metrics we developed are based on assessing functional connectivity as phase coupling of neuronal oscillations exhibited by pairs of multi-dimensional ROIs. We focus on phase coupling metrics [12] given that phase coupling of neuronal oscillations is a putative mechanism for inter-areal communication, and that our methods are mainly intended to be used on MEG and EEG data which are ideally suited to extract neuronal oscillations from the measured signals.

The methods that we developed and tested are listed in Table I together with their properties in terms of the type of phase-coupling they can detect (i.e. coupling between oscillations at the same frequency or coupling between oscillations at different frequencies), as well as in terms of their ability to assess not only the coupling between two ROIs but also its directionality (i.e. directed or undirected).

TABLE I: MULTI-DIMENSIONAL CONNECTIVITY METHODS

Method name	*Coupling type*	*Directionality*
Multivariate Interaction Metric (MIM) [11]	Same frequency Linear	Undirected
Multivariate Phase Slope Index (MPSI) [8]	Same frequency Linear	Directed
Multivariate Antisymmetric Cross Bispectra (MACB)	Different frequencies Non linear	Undirected

In this paper, we will restrict ourselves to linear methods that allow to detect phase-coupling at the same frequency. Specifically, let $x_I(t) = (x_{i1}(t), \dots, x_{iN}(t))^T$ and $x_J(t) = (x_{j1}(t), \dots, x_{jM}(t))^T$ be the multivariate time series for the *N*-dimensional signals *I* and the *M*-dimensional signals *J*, where T denotes the transpose operator. Let also $X_I(f)$ and $X_J(f)$ be the corresponding vector Fourier transforms. The cross-spectral density matrix between $x_I(t)$ and $x_J(t)$ at a given frequency *f* is defined as

$$S_{IJ}(f) = \langle \mathrm{X_I(f)}\, X_J^H(f) \rangle = \begin{bmatrix} S_{II}(f) & S_{IJ}(f) \\ S_{JI}(f) & S_{JJ}(f) \end{bmatrix} \quad (1)$$

where $(\cdot)^H$ denotes the Hermitian conjugate of a matrix. The elements of $\mathrm{S_{IJ}(f)}$ are the cross-spectra between all the pairwise combinations of univariate time series of I and J.

Based on Eq. (1), the multi-dimensional connectivity methods are defined as:

1) Multivariate Interaction Metric- MIM

$$MIM_{IJ}(f) := Tr\left((S_{II}^{R}(f))^{-1}(S_{IJ}^{I}(f))(S_{JJ}^{R}(f))^{-1}(S_{IJ}^{I}(f))^{T}\right) \quad (2)$$

where the superscripts R and I denote the real and imaginary part of the complex-valued cross-spectral density matrices, $(\cdot)^{-1}$ and Tr $(\cdot)$ are the inverse and transpose operators, respectively. MIM does not lead to artefactual phase coupling detections due to artificial zero-lag correlations between the two ROIs. Furthermore, MIM is invariant under invertible and static linear transformation, such as rotations of the physical coordinate system [11].

2) Multivariate Phase Slope Index - MPSI

$$MPSI_{IJ}(f) := 4\sum_{f\in F} Tr\Big(\left(S_{II}^{R}(f+df) + S_{II}^{R}(f)\right)^{-1}\left(S_{IJ}^{I}(f+df)\right)\left(S_{JJ}^{R}(f+df) + S_{JJ}^{R}(f)\right)^{-1}\left(S_{JI}^{R}(f)\right) + \left(S_{II}^{R}(f+df) + S_{II}^{R}(f)\right)^{-1}\left(S_{IJ}^{R}(f+df)\right)\left(S_{II}^{R}(f+df) + S_{II}^{R}(f)\right)^{-1}\left(S_{JI}^{I}(f)\right)\Big) \quad (3)$$

where df and F denote an incremental step in the frequency domain and the frequency band of interest, respectively. MPSI detects the directionality of phase-lagged coupling; a positive value of MPSI indicates that the vector-signal I leads the vector-signal J, while a negative value indicates the opposite. Moreover, similarly to MIM, MPSI is invariant under invertible and static linear transformations, and thus it is independent on rotations of the physical coordinate system [8].

Simulations

We assessed the ability of these metrics to outperform non multi-dimensional metrics by simulating sets of multi-dimensional timeseries corresponding to the signals of two ROIs (*A* and *B*) in which the dimension of each ROI data space was set to N_A=N_B=3 and in which a directed multi-dimensional coupling was generated by introducing a time delay between the two multi-dimensional time courses.

Each set of multidimensional timeseries is written as follows:

$$X_A = \left(x_1, \ldots, x_{N_A}\right)$$
$$X_B = \left(x_{N_A+1}, \ldots, x_{N_B}\right) \quad (4)$$

with

$$x_i(t) = \sum_{i=1}^{N_A}\sum_{k=1}^{P} a_{ijk}\, x_j(t\text{-}\tau_k) + \xi_i(t), i = 1, \ldots, N_A$$
$$x_i(t) = \sum_{i=N_A+1}^{N_A+N_B}\sum_{k=1}^{P} b_{ijk}\, x_j(t\text{-}\tau_k) + \sum_{i=1}^{N_A}\sum_{k=1}^{P} c_{ijk}\, x_j(t\text{-}\tau_k) + \xi_i(t), \quad i = N_A + 1, \ldots, N_A + N_B \quad (5)$$

In addition, N_A+N_B= 6 noise sources were simulated with a temporal evolution given by:

$$y_i(t) = \sum_{k=1}^{P} d_{ik}\, y_i(t\text{-}\tau_k) + \varepsilon_i(t), i = 1, \ldots, N_A + N_B \quad (6)$$

In Eq. 5 and 6 a_{ijk}, b_{ijk}, c_{ijk}, d_{ik}, ξ_i and ε_i are realizations of independent Gaussian random variables of zero mean and a standard deviation equal to 1=10.

The final multidimensional signal is thus given by:

$$Z = (1\text{-}\gamma)\frac{X}{\|X\|_F} + \gamma\frac{Y}{\|Y\|_F} \quad (7)$$

where $X = [X_A\ X_B]'$ is the signal of interest and likewise for the noise , and γ is the noise weight as explained below.

In this model, each of the generated time courses has a length of T = 76200 data points, which, sampled at 254 Hz, corresponds to 5 min of continuous EEG/MEG data. The model order P is equal to 5. We used 20000 pairs of multi-dimensional time series obtained as the sum of a signal term and the noise term weighted by a factor γ in the range from 0 (i.e., no noise) to 0.9 (i.e., 10% signal and 90 % noise) with an incremental step of 0.1, thus leading to 2000 pairs for each γ value. Finally, to calculate the average and standard deviation of the performance indicators (number of right detections, of wrong detections, of not significant detections) of the methods, the generated signals were divided into 20 sets of 100 pairs for each γ.

In the following, we will present the results for the MPSI metric, defined in Eq. 3. Nevertheless, the results for the non-directed multi-dimensional simulated data and the MIM, as defined in Eq. 2, feature a similar behaviour when compared to the corresponding non multivariate version, i.e., the imaginary part of coherency [5] on the first principal component of the multivariate time series.

III. RESULTS

A. Results for the MPSI

In Figure 1, we shown the results obtained by the MPSI and compare it to the results obtained by first applying Canonical Correlation Analysis [13] to reduce the multi-dimensional signals to scalar timeseries, and then using the non multi-dimensional version of the Phase Slope Index [14]. The latter approach is referred to as CCAPSI in Figure 1.

It is evident (Figure 1, left panel) that the percentage of correct detections obtained by MPSI is always higher than the corresponding percentage obtained by CCAPSI for each proportion of signal and noise in the multi-dimensional data. Of course, for higher proportion of signal in the data, both approaches perform better than for the lower proportion of signal but the performance of CCAPSI are still low featuring only about 25% of correct detections for the best case. Conversely, MPSI features about 80% of correct detections for the best case.

Importantly, this effect is only marginally due to CCAPSI making less wrong detections as this percentage is very low and even lower for MPSI (Figure 1 middle panel). The main

reason for the lower number of correct detections featured by CCAPSI comes from its inability to statistically significantly assess if the simulated signals were coupled or not (Figure 1, right panel).

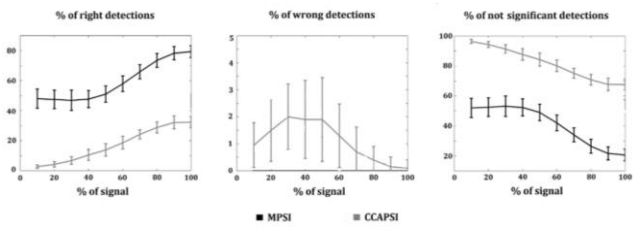

Fig. 1: In this figure the performance over the 2000 simulations for each percentage of signal in the multi-dimensional timeseries is shown. Left: Percentage of correct detections (average and standard deviation) for the MPSI (black) and percentage of correct detections for the CCAPSI (grey). Middle: Percentage of wrong detections for the MPSI (black) and percentage of wrong detections for the CCAPSI (grey). Right: Percentage of no responses (not significant detections) for the MPSI (black) and percentage of wrong detections for the CCAPSI (grey).

IV. Conclusion

In several neuroimaging applications, we do rely on information about brain activity at a meso- or even macro-scale (brain regions with an extent in the order of several millimetres). Usually, these activity is reduced to one signal per region to reduce the complexity. This is especially true when we aim at assessing functional connectivity, i.e. statistical dependencies between brain regions, where for N brain regions at least (N x N/2-1) connectivity values must be computed. Nevertheless, reducing multi-dimensional timeseries to a single one might results in an important loss of information about brain interactions since the regional brain signal is itself multi-dimensional. The development of multi-dimensional methods is thus crucial to avoid this information loss. Also, it must be noted that the difference between the multivariate methods and the corresponding bivariate approach increases for shorter the data length, or for higher the dimension of the single data space.

Here, we presented the definitions of the linear methods we developed in this framework, and the simulation results for the MPSI. In addition, it is important to notice that a similar approach can be applied to non-linear (i.e., cross-frequency interactions) methods, leading to the derivation of the multivariate antisymmetric cross bispectra (MACB). MACB performance can also be proven to be significantly higher than those obtained by antisymmetric cross bispectra after on the first principal component.

Enhancing Safety in Industry 4.0: The Use of Passive Brain Computer Interfaces for Vigilance Monitoring

E. Cinquetti[1], I. Siviero[1], G. Menegaz[1] and S.F. Storti[1]
[1]*Dept. of Engineering for Innovation Medicine, University of Verona*
silviafrancesca.storti@univr.it (corresponding)

***Abstract*—In the context of Industry 4.0 and human-robot interaction, ensuring the safety of operators by avoiding collisions and human errors is crucial. One important aspect of this is monitoring vigilance decrement in order to limit safety risks and improve productivity. While existing solutions for this problem rely on passive brain computer interface (BCI) based on electroencephalography (EEG) recordings, there has been limited exploration of their use in industrial environments. The presented study proposes a new experimental protocol for predicting vigilance degradation using EEG data. The dataset was acquired from five healthy volunteers observing a robotic arm performing three different movements for 23 minutes. The EEG power spectrum over time was computed using the continuous wavelet transform (CWT) and its increment was examined using a linear regression model. The results of the study show that there is an increasing α power band over the parietal brain area, while the vigilance of the operator is decreasing. The first order polynomial regressed to the time variant power spectrum had positive angular coefficients (values between 0 and 0.4) for all subjects. The findings suggest that monitoring vigilance degradation in Industry 4.0 is crucial to prevent accidents and reduced performance in repetitive human tasks.**

***Keywords*—Brain computer interface, electroencephalography, vigilance, industry 4.0.**

I. INTRODUCTION

The manufacturing industry is increasingly embracing heavy automation, with human workers playing a role in cooperating with and monitoring machinery such as robotic arms. While this has led to an increase in productivity, it also has the potential to negatively impact task performance and introduce safety risks and accidents. Performing repetitive tasks can result in a decrease in the operator's attention [1], with potential negative effects on both the operator's health and the quality of the final product.

A brain computer interface (BCI) is a system that acts as direct communication pathways between the brain and an external device exploiting the brain's electrical activity. Passive BCI is primarily used to track or assess brain activity employing signals involuntarily generated by a user to decode the cognitive state, attention, and intentions mainly using the electroencephalography (EEG) [2]. Current applications involve the clinical field, education, entertainment, driving, aviation, and also Industry 4.0 [3]. EEG is a cost-effective, non-invasive and portable way to monitor the operator's mental state, thanks to a headset connected to an amplifier which captures the electric potential differences produced by brain activity. EEG may be used to monitor vigilance, the ability to sustain attention over a long period of time under monotonous stimulus [2]; vigilance is critical in contexts such as plant surveillance, driving, and air traffic control [1], and its absence can lead to potential accidents [4], making it a crucial mental quality to track in Industry 4.0 workplaces. In EEG-based vigilance detection, power spectrum of different frequency bands and their ratios have been used extensively, with the most interesting being θ (4-8 Hz) [5] and α (8-12 Hz). Indeed, the α power spectrum can decrease or increase in response to a stimulus, with increased activity called event-related synchronization (ERS) and decreased activity called event-related desynchronization (ERD) [6]. ERD in the α band is associated with visual stimulation, and is related with activation of cortical areas related to information processing, selective attention and motor preparation. On the other hand, ERS is associated with inhibition of brain activity and may indicate a resting or idling cortical area in which no information is currently processed [7]. The α band activity is also influenced by increased mental fatigue [8]. Mental fatigue refers to a state that occurs when subjects are performing repetitive and monotonous tasks for a prolonged period of time, which is mirrored by loss of vigilance. Growing mental fatigue, and thus vigilance reduction, is characterised by an increase in power of α oscillations [2].

To evaluate the potential of EEG analysis within an industrial setting, we conducted an innovative experiment that aimed at gradually increasing subjects' mental fatigue over time. By closely monitoring EEG activity, we aimed at detecting patterns and trends in brain activity that could indicate changes in subjects' vigilance states as they performed repetitive supervisory tasks. This approach allowed to assess the feasibility of using EEG analysis to monitor vigilance within an industrial context and to identify potential markers of mental fatigue.

II. MATERIALS AND METHODS

A. Participants

The study involved five healthy subjects recruited on a voluntary basis (average age 26.6 $\pm$ 1.34 years, all males). Participants were asked to give informed consent before taking

part in the study. Data were collected according to protocols approved by the local ethics committee of the University of Verona (Comitato di approvazione della ricerca sulla persona [CARP]: protocol n. 2.R1/2022). The study design and data collection took place in the Industrial Computer Engineering (ICE) Laboratory, a research facility of the University of Verona (https://www.icelab.di.univr.it/) [9]. Participants completed a variation of the NASA task-load index questionnaire after the study [10], scoring on a subjective scale from 1 to 20 the perceived pace of the task (temporal demand), how much effort they had to put in the task (effort), and how frustrating it was to them (frustration).

B. Experimental Setup and Paradigm

The EEG was recorded using the portable BeMicro EEG amplifier (EBNeuro S.p.A, Firenze, Italy) and a cap providing 21 Ag/AgCl electrodes positioned according to a 10/20 system (impedance was kept below 10kΩ). The cap has the reference placed anteriorly to Fz, while the ground is posterior to Fz. EEG data were acquired at a sampling rate of 256 Hz and stored using the software Galileo (EBNeuro S.p.A, Firenze, Italy).
The experiment was conduced using a robotic arm KUKA LBR iiwa 14 R820, composed of 7 joints, a flange, and a GIMATIC electromechanical gripper at the end for grabbing small objects. All participants were seated in a comfortable armchair in front of a workbench, where they observed the movement of the robot. The protocol consisted of 3 different movements performed by the KUKA robot, as depicted in Fig. 1. The movement began with the robot picking an object of 2x4 cm from position 1 and moving it to position 2, then moving the object to position 3; the process was repeated 40 times. At each iteration, there were two different positions the object could be placed, marked as a tick or a cross in Fig. 1. The probability of success for the tick position was 80%, while it was 20% for the cross. The reaction times (RT) were measured using a keyboard, with a index finger press of the space-bar button (tick position) or the enter button (cross position), to minimize muscle EEG artifacts. Participants reacted the moment they assessed the position.

The visual vigilance task lasted 23 minutes and consisted of 40 trials. Each trial was a sequence of 3 movements of the KUKA robot, and lasted 33 s. Each sub-trial (individual robot movement) had a duration of at least 11 s, with a small time overhead caused by computation of the arm's trajectory. As shown in Fig. 1, at the start of the movement, the robot would be stationary in the middle of the workbench; after 1s, the robot would grasp the small object; at $t = 4s$, the small object would be moved to a different position. The RT were typically in the time interval around $t = 5s$. In addition to the task, two minutes of EEG with eyes open were recorded in a resting state before the task and a video was recorded to capture any failures or movements.

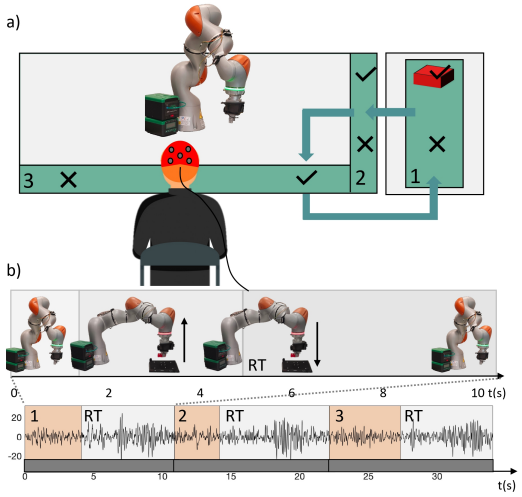

Fig. 1: Representation of the experimental procedure and signal acquisition. a) Robot workspace in which 3 different movements are continuously repeated (i.e., from position 1 to 2, from 2 to 3, from 3 to 1, etc.). b) Timing schedule of the robot movements and an example of processed EEG data acquired during an experimental trial. The RT are also reported.

C. EEG data analysis

EEG data were analyzed in Matlab (R2022a) using EEGLAB (https://sccn.ucsd.edu/eeglab/index.php). The EEG data were filtered by a 3-th order Butterworth band-pass filter with a pass-band frequency between 4 and 30 Hz. The raw EEG data were re-referenced to common average reference (CAR) and baseline corrected. Independent component analysis (ICA) was applied to remove residual artifacts.
We used a Continuous Wavelet Transform (CWT) to extract patterns from EEG signals [11], specifically using the Morlet wavelet, a commonly used method in EEG analysis. We estimated the power spectrum over time for both rest and task conditions from all EEG recordings on the θ and α frequency ranges.

The task is composed of 120 sub-trials. Data analysis was performed in two different ways: on each sub-trial (i.e. 11 s) and on the complete EEG signal (i.e. 23 min). In the first case, the analysis focused on time-variant power spectrum behavior along different phases of a sub-trial [Fig. 2]. Power signal trend following RT was obtained by a linear regression model. In the second case, we analyzed the time-variant power spectrum of each channel in the α frequency band in order to evaluate changes over the entire task recording. The obtained power spectrum was smoothed using an exponentially weighted moving average (EWMA) filter to reduce the variability inside the sub-trials, and then a linear regression model of the first order was used to evaluate increment or decrement over time.

III. Results

A. Sub-trial analysis

The sub-trial analysis for a representative subject (no. 1) is presented in Figs. 2 and 3. Fig. 2 illustrates the average of the power spectrum over sub-trial in the α frequency band

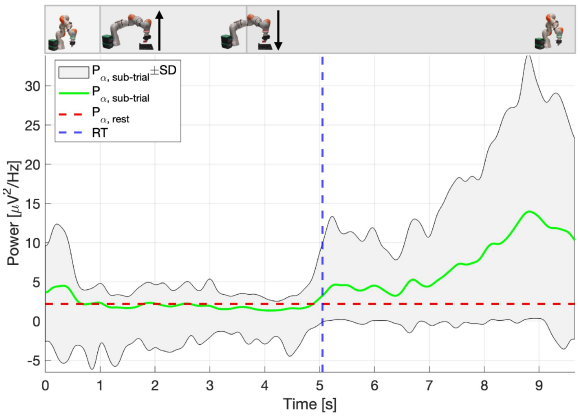

Fig. 2: *Sub-trial analysis*: Time-variant average power spectrum in the α frequency band across sub-trials of a parietal channel ($P3$) for subject 1 (average $P_{\alpha,sub-trial} \pm SD$ [light gray region], average $P_{\alpha,sub-trial}$ [green], average $P_{\alpha,rest}$ [red] and the average RT [blue]).

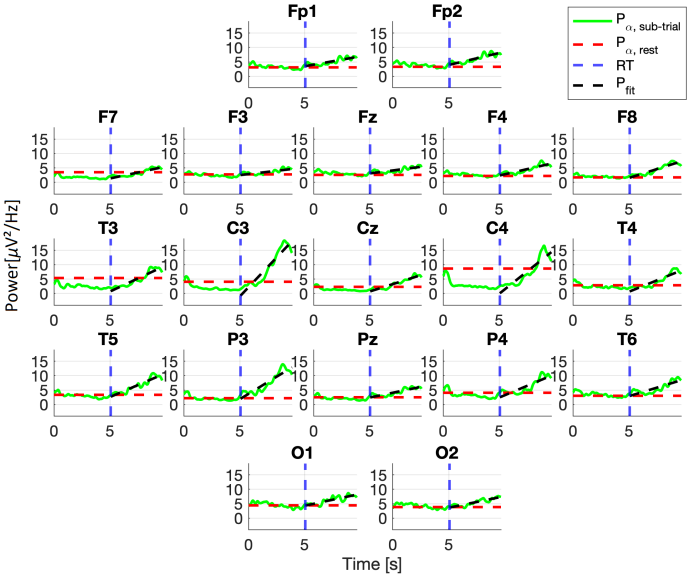

Fig. 3: *Sub-trial analysis*: Time-variant average power spectrum in the α frequency band across sub-trials of all channels for subject 1 (average $P_{\alpha,sub-trial}$ [green], average $P_{\alpha,rest}$ [red] and the average RT [blue]). Data fitted starting from RT (black).

for the channel P3, as well as the power calculated during a resting EEG and the average RT. The average power decreases when the robot grasps the small object, for at least 3 s, and then increases after the RT. Fig. 3 shows the power for each EEG channel and the fitted line, obtained with the linear regression model starting from RT. A positive trend is confirmed, coherent with the ERS behavior triggered by the subject's relaxation. The slope is higher for the channel C3, C4, P3, and P4. This trend has been observed in the other subjects as well. The slopes of the fitted lines for each sub-trial were averaged over each sub-trial and then over subjects, and the results are shown in Table I. The findings confirm that α power spectrum increments primary affect the centro-parietal brain areas.

TABLE I: *Sub-trial analysis*: The slopes of sub-trials computed following RT, averaged over subjects. The higher six values are reported. Despite high SD values, no single subject reports negative slopes. P-value of slope parameter is significant for all subjects ($p < 0.05$).

Ch	*Mean*	*SD*	R^2
C3	1.25	±1.46	0.63
P3	1.00	±0.77	0.66
T5	0.89	±0.59	0.61
C4	1.07	±1.05	0.62
P4	0.68	±1.09	0.60
PZ	0.60	±0.76	0.59

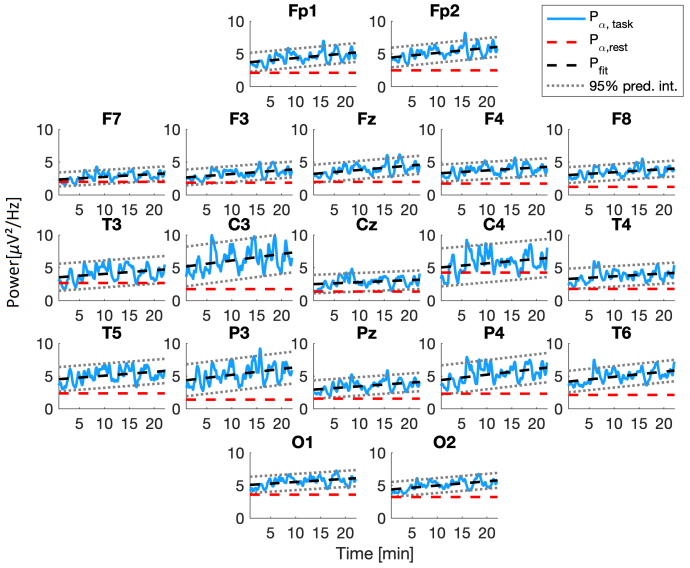

Fig. 4: *Overall EEG signal analysis*: Power spectrum in the α frequency bands over the entire acquisition for subject 1 (smoothed $P_{\alpha,task}$ [light blue], average $P_{\alpha,rest}$ [red], fitted line [black] and the 95% prediction interval [gray]).

B. Overall EEG signal analysis

The results of the experiment show that the mental fatigue increased in all subjects. Fig. 4 illustrates an example for the α frequency band, showing a growing trend in each channel linear regression, especially in centro-parietal areas. The 95% confidence interval is also reported, and a significant relationship between time and the increase of $P_{\alpha,task}$ was found (F-statistic: $p < 0.05$).

Additionally, Fig. 5 shows the slopes of the fitted line over $P_{\theta,task}$ and $P_{\alpha,task}$, both θ and α frequency bands for all the brain areas of interest, confirming a positive trend in α band and, in a reduced way, for θ band too. Subject 5, being the one with higher slope, is also the one having the higher combination of effort and frustration, as shown in Table II, hinting that the task was particularly tiresome to him. Conversely, subjects 1 and 4 reported the minimum degree of frustration possible, and their computed slopes are the lowest

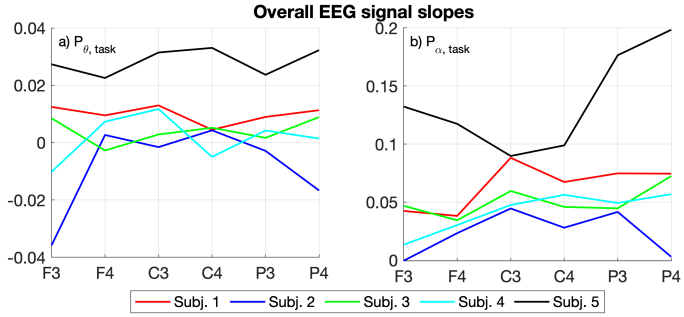

Fig. 5: *Overall EEG signal analysis*: Slopes of the fitted line over time-variant power, computed for each subject. Frontal and centro-parietal channels are reported for: a) θ band, b) α band.

two. Table II also reports the fact that subjects made errors only in the second half of the task, reinforcing the idea that they indeed became more tired over time.

TABLE II: Subjects' mistakes and self-evaluations.

Subject	*Mistaken Trials*	*Temporal Demand*	*Effort*	*Frustration*
1	no errors	2	15	1
2	85, 102	3	3	19
3	no errors	6	1	14
4	109	1	4	1
5	71, 105	3	15	14

IV. Discussion

In this study, a new experimental protocol was designed to assess the feasibility of using EEG-based passive BCI in an industrial context. The study aimed to capture the subjects' vigilance degradation while observing a robotic arm in a laboratory setting that mimicked an industrial production line. Results showed that the spectral power in the α frequency band increased with mental fatigue, making it a potential marker of the user's alertness state [7] during the execution of monotonous and automized tasks. The highest increment was found in the centro-parietial brain areas, as it is known from neurophysiological knowledge [1]. θ band was also characterized by increasing behaviour; this promising result calls for further analysis.

Despite the growing interest and research in EEG-based BCI, with recent methods including connectivity studies and machine learning applications [12, 13, 14], the focus on using BCI technology in Industry 4.0 is still limited, and is mostly confined to academic research labs. This experiment lays the foundation for potential monitoring applications that could greatly benefit operators by reducing risks and human errors, especially during long supervision tasks, without the need of any additional effort from the user. The limitations of this pilot study are the small sample size, which does not allow for significant aggregate data to be obtained, and the lack of a calibration phase. Additionally, the data can vary between individuals, and EEG frequencies should be analyzed carefully as similar spectral power patterns could be associated with different mental states. Despite these limitations, this study provides a proof of concept for using EEG-based passive BCI in industrial settings and highlights the need for further research in this area.

V. Conclusion

The use of EEG-based passive BCI technology in Industry 4.0 has the potential to enhance productivity, reduce safety risks, and improve decision making. This study proposes a new experimental protocol for capturing subjects' vigilance degradation while observing a robotic arm in a laboratory setting simulating an industrial production line. The results show that increased spectral power in the α frequency band is a potential marker of mental fatigue and thus lack of vigilance, which can lead to reduced performance and accidents in repetitive human tasks.

***Abstract*—Image segmentation is an important branch of modern image processing, especially in biomedical or microscopy image analysis. Novel optical imaging techniques such as Light-Sheet Fluorescent Microscopy (LSFM) allow the reconstruction of massive biological samples with micron-scale spatial resolution. In this context, image segmentation is challenging due to the high variability of LSFM images. This article describes the optimization of an automatic segmentation pipeline to identify the cardiac tissue in LSFM-based high-resolution 3D reconstructions of five murine hearts, previously cleared and stained with Wheat Germ Agglutinin (WGA). We address the challenge using Trainable WEKA (Waikato Environment for Knowledge Analysis) Segmentation, a plug-in of Fiji software. Three different training sets were generated by means of a manual ground truth combined with two additional feature selection algorithms included in WEKA: CorrelationAttributeEvaluator and InfoGainAttributeEvaluator. To speed up the computational time, we also defined a reduced training dataset selecting only common features between the two sets: median diffusion, mean, anisotropy, and entropy. We trained four different classifiers for each of the three training sets in order to identify myocardium tissue from the background: RandomForest, J48, NaiveBayes, and MultilayerPerceptron. The performance of the classifiers was evaluated for each training set and we found that the RandomForest is the more accurate and stable model over different datasets with a Dice similarity coefficient of 0.895, 0.895, and 0.892, respectively. Results highlight the reliability of RandomForest to address high-resolution image segmentation, allowing the generation of 3D whole-heart reconstruction useful to investigate, in the future, structural features in pathological mouse models.**

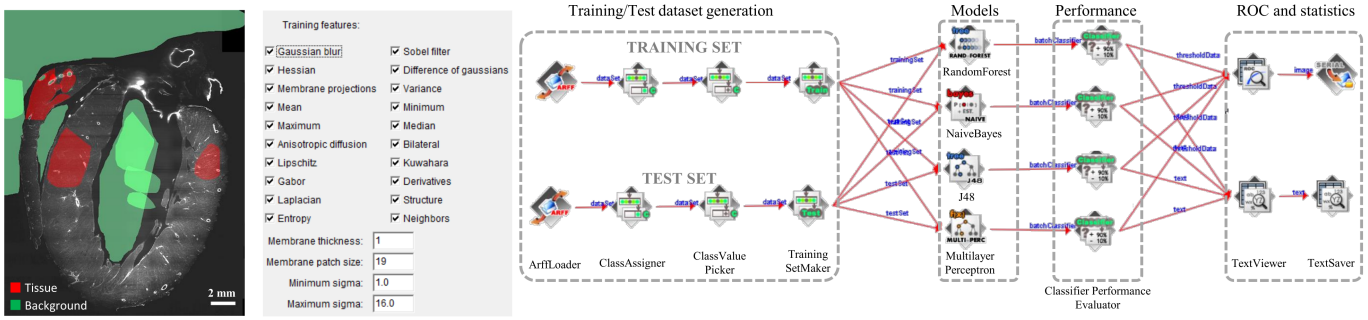
I. Introduction

The World Health Organization (WHO) estimates that 17.9 million people worldwide die of cardiovascular disease (CVD) every year [1]. Research in recent years has made many advances in this field to improve diagnosis, treat these diseases better, and reduce CVD mortality [2].



Several imaging modalities can be applied to studying the heart, including echography, CT, coronary angiography, PET, and MRI [3], [4]. All of these techniques are characterized by insufficient spatial resolution and the inability to detect fluorescence-marked particles usually used in biomedical research [5], [6], [7]. On the other hand, due to the intrinsic opacity of the cardiac tissue, conventional microscopy techniques have the disadvantage of requiring the use of small working distances, or a mechanical slicing of the sample, thus introducing the consequent risks of modifying sample dimensions, preventing a reliable three-dimensional (3D) reconstruction. Light Sheet Fluorescence Microscopy (LSFM), combined with novel advanced tissue-clearing techniques, overcomes these limitations [8], [9].

LSFM consists in illuminating the transparent sample with a single thin sheet of light orthogonally oriented to the detection path so that only the excited optical plane of the tissue is detected. The sample is then moved in an axial direction to perform a tomographic scan, imaging the volume section-by-section, and thus creating a 3D model after a post-processing step [10], [11], improving image contrast and allowing high speed and precise monitoring of cells or tissues combined with fluorescent multi-labeling within a complex and dynamic environment such as the cardiovascular one [12], [13]. LSFM image segmentation lacks fully automated techniques because of the inherent variability of images obtained with this imaging technique. New deep-learning techniques are emerging and showing good results, but currently manual segmentation remains the gold standard in terms of reliability. Naturally, automatic classification overcomes the problems associated with manual segmentation, which is time-consuming and sensitive to high inter- and intra-operator variability [3].

In this study, we optimized a system capable of automatically segmenting cardiac tissue in LSFM reconstructions of cleared adult murine hearts. To this aim, we adopted a plug-in from Fiji, Trainable Weka Segmentation (TWS), to perform a two-step optimization: first, we identified the most significant features to discriminate the tissue from the background with two different algorithms; then, we trained four models on the different training datasets to perform a real segmentation, finally comparing their performance. The ultimate goal of our project is to generate a 3D model of the heart anatomy, thus correlating, in the future, structural features between heart remodeling and electrical heart dysfunctions in pathological murine models.

II. Material And Methods

The present investigation is applied to five three-dimensional reconstructions of cleared hearts of control mice of 6 months (C57BL/6J). The experimental protocol was approved by the Italian Ministry of Health (protocol number 647/2015-106 PR). All the animals were provided by ENVIGO, Italy. Samples reconstructions were obtained by

Fig. 1: a) Representative longitudinal view of a cleared mouse heart reconstruction generated with light-sheet microscopy by staining cellular membranes (pixel size: 20.8 µm). A manual classification of *tissue* (red) and *background* (green) is superimposed on the image as an example of ground truth. b) Features selected to generate the training test using the Trainable Weka Segmentation (TWS) plugin. c) Scheme of the training/test workflow implemented using the tool *KnowledgeFlow* included in TWS. The main parts are highlighted with dashed gray lines.

performing a three-step imaging protocol: tissue clarification with CLARITY method optimized for the cardiac tissue [14], [15]; staining of cellular membranes with Wheat Germ Agglutinin (WGA) conjugated with Alexa Fluor 633; imaging by tiles with a custom-made light-sheet microscope [16] with an original voxel size of $0.65\,\mu m \times 0.65\,\mu m \times 2\,\mu m$ in x, y and z axis respectively. Final reconstruction was obtained by stitching tiles with custom-made software [17]. In this paper, three-dimensional (3D) images are downsampled to an isotropic pixel size of $20.8\,\mu m$.

Cardiac tissue segmentation is performed frame-by-frame in two-dimension (2D) using the plugin TWS, included in the image analysis software Fiji [18], [19], evaluating different classification models on three different sets of features.

A. Preliminary dataset and ground-truth

The preliminary dataset used to identify key features for prediction consists of ten images at different depths from the reconstruction of a single control mouse heart. By starting the TWS plugin, the two classes of interest "Tissue" and "Background" were defined. Ground truth was generated by manually classifying different regions of interest (ROIs) (Figure 1a) in all 10 frames. In the "Settings" tab, all features offered by the WEKA software were selected (Figure 1b) to generate as many features as possible from the images. Next, dimensionality reduction was performed using two different selection algorithms.

B. Feature extraction

Dimensionality reduction was performed using the "Select Attributes" tool in Weka Explorer. This is based on the joint action of an attribute evaluation algorithm (Attribute Evaluator) and a search algorithm (Search Method). The first evaluates each attribute in the data set in relation to the desired classification; the latter determines the most meaningful combination of attributes for the classification. Among the algorithms for attribute selection supported by Weka, we selected:

- CorrelationAttributeEvaluator: calculates the correlation between each attribute and the output variable: attributes are the more significant the closer the correlation values are to 1.
- InfoGainAttributeEvaluator: calculates the entropy of each attribute in relation to the output variable: attributes are the more significant the closer the entropy values are to 1.

In the present study, both evaluation algorithms described above were used, generating two different sets of features (defined as *Correlation set* and *InfoGain set* for simplicity). A set of the common attributes between the previous two sets was also considered and defined as *reduced set*.

C. Classifiers

The tool *KnowledgeFlow* presents a "data-flow"-inspired interface for Weka. Users can select Weka components from a toolbar, place them on a layout canvas, and link them together to form a "knowledge flow" for data processing and analysis. Here, the following classifiers were tested:

- RandomForest: this is the default algorithm when implementing a classifier in Weka;
- J48: characterized by a fast learning process;
- NaiveBayes: the Bayesian classifier is generally reliable and compact;
- MultilayerPerceptron: a classifier widely used in imaging, based on a supervised learning technique called *back-propagation*.

To compare these classifiers, we generate the KnowledgeFlow shown in Figure 1c.

D. Training set and test set

The training and the test datasets were generated by first selecting randomly 40 and 30 images from the five different reconstructions, respectively, and then manually labeling tissue and background on these images. Then we extracted from labeled images the three different sets of features derived through Weka Explorer: Correlation set, InfoGain set, and reduced set, thus generating three versions of training and test datasets. Exploiting the workflow shown in Figure 1c, the four

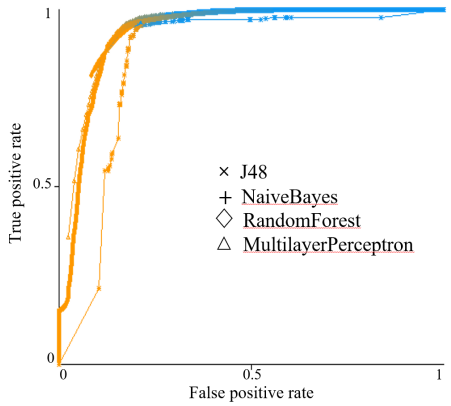

Fig. 2: ROC curve of the four models tested on the *reduced set* of features.

TABLE I: Dice similarity coefficient

Classifier	Correlation set	InfoGain set	Reduced set
J48	0.869	0.889	0.879
NaiveBayes	0.881	0.880	0.888
RandomForest	0.895	0.895	0.892
MultilayerPerceptron	0.872	0.893	0.865

different models were trained on the same training set and then used to classify the test set. Finally, the performance of each model was assessed by the "ClassifierPerformanceEvaluator" module, generating numerical statistics and plotting the Receiver operating characteristic (ROC) curve.

III. Results

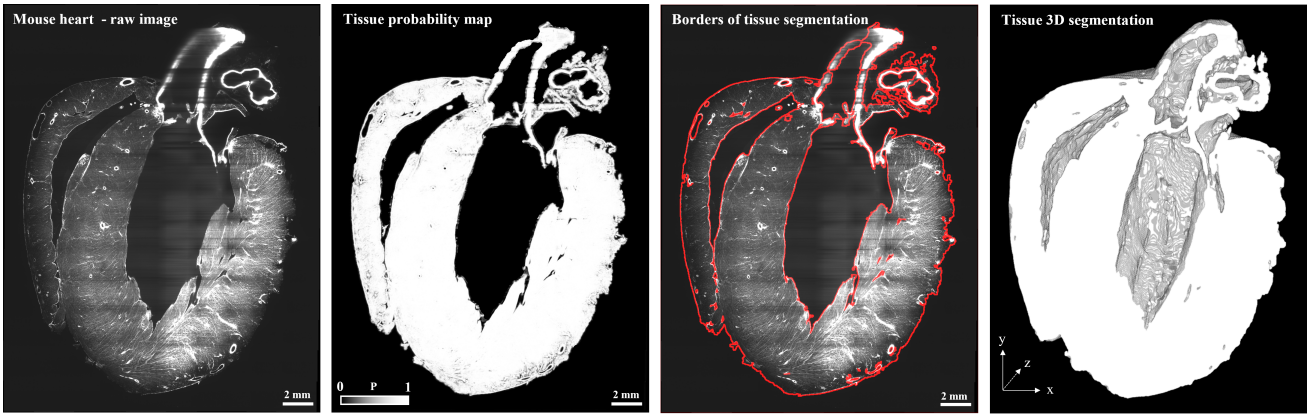
Feature selection was performed using two different algorithms: the CorrelationAttributeEvaluator and the InfoGainAttributeEvaluator. In both cases, we defined the selection threshold as the correlation value obtained using the original image as a feature, without extracting any statistical index or morphological operator. In the first case, the correlation of the original image was 0.474554. The following features, having a correlation value larger than 0.474554, were selected: median, mean, anisotropic diffusion, entropy, membrane projection, Gaussian blur, and minimum. These were defined as *Correlation set*. With the second approach, the correlation of the original image was 0.53931, and the algorithm then identifies as fundamental those features with a correlation value larger than 0.53931, namely: median, mean, anisotropic diffusion, entropy, variance, and maximum, that were defined as *InfoGain set*. We defined also a *reduced set* of features, composed of the subset of features in common with the previous two sets: median, mean, anisotropic diffusion, and entropy.

The four models were trained and tested using these three different sets of features. The Dice similarity coefficient values for the 4 models and for the three different feature sets (Correlation, InfoGain, and reduced sets respectively) are shown in Table I.

The model with the best performance is the RandomForest for all the feature sets, and the error of this model is less variable than the other models over the different feature sets. Using the reduced set of features, the ROC curve of the four models is generated and shown in Figure 2, and the main metrics of the selected model (RandomForest) are reported in Table II.

TABLE II: RandomForest Performance

Class	TP Rate	FP Rate	Precision	Recall	F-Measure	ROC Area
Tissue	0.975	0.211	0.837	0.975	0.901	0.940
Background	0.789	0.025	0.966	0.789	0.869	0.940
Weighted Avg.	0.887	0.123	0.898	0.887	0.886	0.940



Finally, a tissue segmentation was performed on an entire mouse heart reconstruction (Figure 3a shows a representative frame of the sample classified). The 3D image was segmented frame-by-frame using the RandomForest trained with the reduced set of features. This model assigns to each pixel a probability $\mathbf{p} \in [0, 1]$ of belonging to the "tissue" class (Figure 3b). The final binary segmentation can be obtained by applying an arbitrary threshold on that probability map (here, the threshold is set $p = 0.5$, Figure 3c). A 3D segmentation is shown in Figure 3d. The model was able to correctly segment the myocardial tissue also in the regions affected by a low fluorescence signal intensity, without being affected by the variability of the background brightness.

IV. Discussion and Conclusion

This work aimed to optimize a software pipeline for cardiac tissue segmentation in LSFM reconstructions of cleared whole murine hearts. This aspect is important for the investigation of cardiac functioning [20], allowing in the future to correlate structural cardiac tissue remodeling with electrical dysfunctions of the heart detected by novel optical mapping techniques in murine hearts [21], [22]. The work was articulated in three phases: first, we manually segmented the cardiac tissue from the background frame-by-frame in 2D with a plugin of Fiji, TWS, then we extrapolated the most significant attributes exploiting two different feature selection algorithms included in WEKA and finally, we tested different models to evaluate their accuracy on two different ROIs: tissue and background. The optimized pipeline applied to the 3D reconstruction of the hearts showed a good functioning of our system providing a good approach for automatic segmentation of LSFM images. It could be interesting to perform the same test with more powerful processors, using a larger dataset. The main limit was connected to the resolution of the images and the reduced dataset. An improvement of the work could be to use a larger data set and involve images with a higher spatial resolution. The proposed method, applied to reconstructions of hearts of control and pathological models, will allow the extraction of anatomical features, enabling the quantification of the structural remodeling occurring in pathological hearts.

***Abstract*— This study aims to compare two methods for the identification of anatomical and mechanical motor unit (MU) properties through the integration of high-density surface electromyography (HDsEMG) and ultrafast ultrasound (UUS). The two approaches rely on a combined analysis of the firing pattern of active MUs, identified from HDsEMG, and tissue velocity sequences of the muscle cross-section, obtained from UUS. The first method is the spike-triggered averaging (STA) of the tissue velocity sequence based on the occurrences of MU firings. The second is a method based on spatio-temporal independent component analysis (STICA) enhanced with the information of single MU firings. We compared the capability of these two approaches to identify the regions where single MU fibers are located within the muscle cross-section (MU displacement area) *in vivo*. HDsEMG signals and UUS images were detected simultaneously from biceps brachii in ten participants (6 males and 4 females) during low-level isometric elbow flexions. Experimental signals were processed by implementing both STA and STICA approaches. The medio-lateral distance between the estimated MU displacement areas and the centroid of the MU action potential distributions was used to compare the two methods. We found that STICA and STA are able to detect MU displacement areas. However, STICA provides more precise estimations to the detriment of higher computational complexity.**

***Keywords*— high-density surface emg, ultrafast ultrasound, motor unit, averaging, independent component analysis**

I. Introduction

HIGH density surface electromyography (HDsEMG) and ultrafast ultrasound (UUS) provide complementary information about electrical and mechanical muscle properties. Both techniques have been proven successful in characterising single motor unit (MU) properties, opening exciting fronts in studying the neural control of muscle contraction from different perspectives. While HDsEMG decomposition enables identifying the firing pattern of individual MUs and assessing the characteristic MU action potentials (MUAP, electrophysiological information) [1], [2], the analysis of cross-sectional tissue velocity sequences extracted from UUS [3] can provide anatomical and mechanical characteristics of MU fibers [4]–[6].

Recently, these two techniques have been combined to exploit their complementarity and provide a comprehensive description of the neuromechanical MU properties [7]–[10]. This integration uses single MU firing instants, identified from HDsEMG decomposition, to isolate the corresponding muscle tissue mechanical response from UUS tissue velocity sequences (Fig. 1). In this way, it is possible to assess movements in the physiological cross-sectional area of the muscle associated with the excitation of single MU (hereafter referred to as *MU displacement area*) and their twitch characteristics. In this regard, two possible approaches can be implemented. The first one is the spike-triggered averaging (STA) of the tissue velocity sequence based on the occurrences of individual MU firings, as proposed for single MU analysis of mechanomyograms [11]. The second one, recently proposed by our group, is to decompose the tissue velocity sequences with spatio-temporal independent components analysis (STICA) [12] and use the firing information from HDsEMG to select, among the identified components, those associated with MU activity [7].

Previously, we used an electromechanical computer model to test the capability of the two methods to correctly identify single MU displacement areas in simulated contractions with different degrees of neural excitation (i.e., the number of active MUs) and different levels of MU synchronisation (i.e., degree of dependency between firing instants of different MUs) [13]. These variables and the duration of both EMG and ultrasound time series are potentially critical factors impacting both methods. Indeed, we showed that the performance of both approaches was negatively affected by the number of active MUs and synchronisation levels. However, STICA provided a more robust estimation of the MU displacement areas under all the tested conditions.

This study aimed to test whether these *in-silico* results extent to experimental conditions during isometric elbow flexions. Since the location of the MU fibers within the muscle cross-section is unknown in experimental data, we quantified the agreement between the HDsEMG amplitude distribution of the MUAP and the location of the corresponding MU displacement area identified by applying STA and STICA to UUS image sequences.

II. Methods

Ten participants (mean ± SD, 29.2 ± 4.6 years, 6 males and 4 females) with no history of neurological or musculoskeletal impairments or disease were enrolled. The study was conducted in accordance with the Declaration of Helsinki and the procedure approved by the Regional Ethics Committee. Informed consent was obtained from all participants after receiving a detailed explanation of the study procedure.

A. Experimental acquisitions

HDsEMG signals and UUS images were detected simultaneously from the biceps brachii for 8 seconds of low-

level (5% of maximum voluntary contraction) isometric elbow flexions (Fig. 1A). The details of the experimental protocol are reported in [7].

A 64-electrode matrix (8 rows by 8 columns with 10 mm inter-electrode distance) designed to allow the simultaneous acquisition of HDsEMG and ultrasound from the same muscle region [14] was placed over the muscle belly. Monopolar EMG signals were detected, conditioned (Bandwidth 10-500 Hz, gain 46 dB), and sampled at 2048 Hz with 16-bit resolution using a wireless HDsEMG acquisition system (MEACS, LISiN, Politecnico di Torino, Turin, Italy) [15].

Radiofrequency (RF) data were acquired using Verasonics Vantage 128 (Verasonics, Inc., Kirkland, WA, USA). Plane-wave data were obtained at a frame rate of 2500 Hz. The L11-5v probe (7.8125 MHz center frequency) was placed over the muscle to obtain cross-sectional scanning between the fourth and fifth rows and was cantered with respect to the columns of the EMG matrix (Fig. 1A).

A rectangular pulse provided by an external generator (StimTrig; LISiN, Politecnico di Torino, Italy) was used to start the ultrasound acquisition and was concurrently acquired by the HDsEMG system to synchronize EMG-ultrasound acquisitions [16].

B. Data analysis

Experimental signals were processed by implementing both STA and STICA approaches. The two approaches rely on a combined analysis of the firing pattern of active MUs and the tissue velocity sequence estimated from HDsEMG and ultrafast ultrasound imaging, respectively (Fig. 1). Spike trains of individual MU were decomposed from HDsEMG data using a validated method based on convolution kernel compensation (Fig. 1B) [17]. Displacement velocity images were estimated from the RF data using 2D autocorrelation velocity tracking, as in [18], to obtain a sequence of tissue velocities (Fig. 1C). After cropping the images at a depth of ~ 20 mm (outside the maximum EMG range), the sequence resulted in 19976 frames of 70 × 128 pixels.

1) Spike-triggered averaging (STA) approach

The STA of the tissue velocity sequence was performed using the discharge times of the MU identified from HDsEMG decomposition. For each MU, windows of 125 ms centered on each firing instant were averaged to obtain a short sequence in which the contribution of the considered MU might be emphasized over the others. A single image was extracted from this averaged sequence as follows: (i) the time sample at which the maximum velocity occurred was identified, and (ii) the sequence was averaged across ± 10 frames around the maximum time sample (20 frames in total). A global thresholding at 70% of the maximum was applied to the obtained image, providing the single MU displacement area.

2) Spatiotemporal independent component analysis (STICA) approach

STICA was applied to regions of interest (ROI) of the tissue velocity sequence of 35 × 35 pixels spanning the whole field of view with a shift of 5 pixels in both directions. The details of the method are reported in [7]. Here, a synthetic description is provided. Briefly, the algorithm extracted 50 components for each ROI, optimizing the independence over space and time. The components comprised a temporal signal and a spatial map. For each MU decomposed in HDsEMG, the convolution between its firing discharges and a synthetic waveform, representing the velocity of contracting fibers in the superficial-deep axis, was computed. This convolution produces what we refer to as the train of MU velocity twitches. The cross-correlations between these trains and the temporal signals of all UUS components were computed. For each ROI, the component with the maximum correlation within a ± 20 ms time lag was selected. This procedure provided a set of correlation coefficients for all considered ROIs for each decomposed MU. A group of adjacent ROIs with correlation values > 50% of the maximum of all ROIs was retained. The

B) Example of a firing pattern of active MUs decomposed from HDsEMG signals. C) Estimated image sequence of the displacement velocities of the muscle tissue. D) Combined analysis of the MU firing pattern and tissue velocity sequence with two approaches, one based on the spike triggered averaging (STA) and one based on spatio-temporal independent component analysis (STICA). E) Output of the algorithms: images of muscle tissue displacement areas related to a single MU activation.

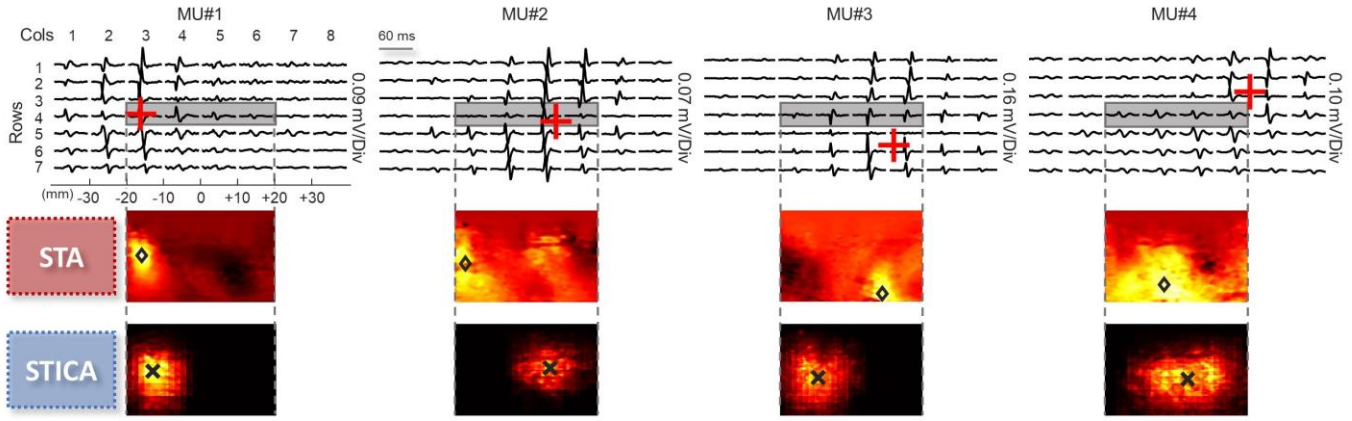

Fig. 2: Four examples of MUs (column wise) decomposed from HDsEMG and the corresponding identified region of displacement. First row: template of the motor unit action potential (MUAP) in single differential derivation along the rows of HDsEMG grid. Red + represents the centroid of the MUAP template distribution as calculated in [7]. The grey rectangle shows the region where the ultrasound probe was placed to scan the muscle cross-sectionally. Second row: images obtained with the spike triggered averaging (STA) approach representing the region of displacement of the corresponding MU. ◊ indicates the centroid of the tissue velocity image. Third row: final images of the approach based on the spatio-temporal independent component analysis (STICA) representing the region of displacement of the corresponding MU. × represents the centroid of the tissue velocity image. The figure shows from left to right: a well-detected MU (low centroid-to-centroid distance between EMG and ultrasound) for both approaches; a MU displacement area correctly identified only by STICA; a MU displacement area correctly identified only by the STA approach; a wrong MU displacement area identification for both STA and STICA.

spatial maps of the ROIs corresponding to the identified group were summed to obtain a single image. A global thresholding at 70% of the maximum was applied to the obtained image, providing the single MU displacement area.

C. Comparison of STICA and STA approaches

The centroids of the MU displacement areas obtained from STA and STICA were computed and compared with the centroids of the amplitude distribution of the MUAP of the corresponding MU (i.e., the MU whose firings were used as input to STA and STICA algorithms). The comparison was performed by computing the centroid-to-centroid (EMG-ultrasound) distance in the medio-lateral direction.

The two algorithms were processed considering the entire 8 s of acquisition and only the first 2 s of acquisition to evaluate the effect of the signal duration on their performance.

D. Statistical analysis

The effect of the factors “method” (STA and STICA) and “duration” (2 s and 8 s) were tested with a 2-way ANOVA on the centroid-to-centroid distance. Post-hoc assessments were conducted using the Bonferroni test whenever a main effect was verified. The significance level was set to $p < 0.05$.

III. Results and Discussion

The HDsEMG decomposition provided 180 MUs (mean ± SD, 18 ± 8 MUs per participant).

Fig. 2 shows the identification of the MU displacement areas of four representative MUs using the combined analysis of HDsEMG data and UUS images. The figure depicts, in the upper panel, the spatial distribution of single differential MUAPs computed longitudinally (i.e., along the fibers’ direction), the regions of displacement in the ultrasound identified with STA (middle panel) and with STICA (bottom panel), respectively. The examples reported in Fig. 2 show four different outcomes of the two algorithms in terms of spatial agreement between the MU displacement area in UUS and the EMG amplitude distribution. Specifically, MU#1 showed a good spatial match for both STA and STICA (as shown by the horizontal distance between the symbols ‘+’ in EMG, ‘◊’ for STA and ‘×’ for STICA). MU#2 and MU#3 showed a good match only with STICA and STA, respectively, while the MU displacement area identification seemed to fail for both STA and STICA in MU#4.

Fig. 3 shows the boxplots of distances between EMG and ultrasound centroid for all the considered MUs for both STA (red) and STICA (blue) when 8 seconds and 2 seconds of signal duration are considered. STICA approach provided lower distances for all the tested durations, as demonstrated by statistically significant differences with respect to STA ($p < 0.001$). Although not significant ($p = 0.054$), a trend associated with signal duration can be appreciated in both STA and STICA and to a larger extent for STA.

The distances obtained for STA and STICA were in the range [0–53 mm] and [0–37 mm], respectively and confirmed the results obtained in simulated conditions, with STICA providing lower distances. As expected, these values are larger than those obtained in simulated conditions where distances always lower than 20 mm were obtained by both methods and for contractions up to 20% MVC. Thus, although we considered lower contraction levels (5% MVC), the performance of both methods degraded in experimental conditions considerably. Besides the obvious differences between experimental and simulated conditions (e.g., the effect of connective tissue affecting the transversal force transmission between fascicles), this result can be explained by the fact that the in the experimental analysis, our reference for the “true” medio-lateral location of MU displacement area was the centroid of the MUAP distribution, that can be identified with a relatively low spatial resolution (inter-electrode distance), thus affecting the estimation error.

Concerning the effect of signal length, both approaches were expected to be affected by the duration of the EMG and ultrasound time series. However, our results suggest that STICA may provide better estimations of MU displacement

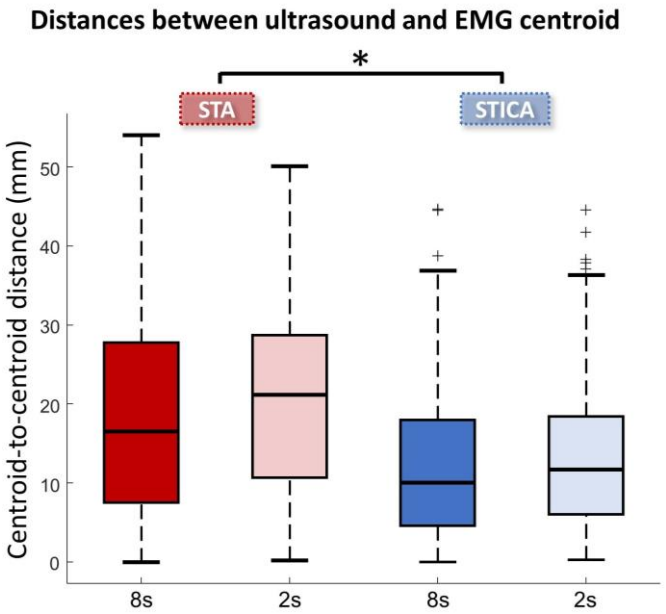

Fig. 3: Boxplots of distances between EMG and ultrasound centroid for all the considered MUs for both STA (red) and STICA (blue) when considering 8 seconds (dark color) and 2 seconds (light color) duration of the acquisition. *p<0.001

areas when short duration acquisitions are performed (light color boxes in Fig. 3). This can be an important advantage considering the large amount of data associated with the detection of sequences of high frame rate ultrasound images. Moreover, the capability to obtain good displacement area estimations for small signal epochs could allow the implementation of STICA-based algorithms exploiting the temporal segmentation of the detected signal to improve the estimation, e.g., by providing a repeatability index of the identified area across the contraction. On the other hand, the low computational complexity of STA may be preferable for applications where the computational time is relevant.

IV. Conclusion

This study compared two approaches (STA and STICA) to identify individual MU properties by combining HDsEMG and UUS. We showed that both STICA and STA can be used to detect regions of muscle tissue displacement whose location is associated with the representation of the MU electrophysiological activity (i.e., MUAP distribution). Although wrong estimations occurred for both methods, STICA provides more precise estimation of the MU displacement region location, to the detriment of higher computational complexity. The higher reliability in the assessment of the MU territory provided by STICA may be explained as a result of the decomposition of the sources' location and temporal information, while STA uses the global interfering signal. Our results expand those of our previous simulation study, providing new qualitative evidence on the suitability of the two proposed approaches for anatomical identification of individual MU using the combination of HDsEMG and UUS analysis. By providing electrophysiological, anatomical and mechanical information on active MUs, these multi-modal approaches are relevant to improve our understanding of the underlying mechanism of muscle contraction, from the neural command to the force production, with applications ranging from basic research to motor rehabilitation.

***Abstract*— Tensor-based morphometry (TBM) is a powerful analysis method to detect subtle morphological alterations in the brain from the statistical analysis of deformation field derived metrics. In this study, we used TBM to characterize longitudinal volumetric changes of non-brain soft tissues (especially muscles), exploiting an accurate registration procedure of different tissues across individuals. With the proposed approach, TBM could be a candidate prognostic tool for certain diseases, such as glioblastoma or sarcopenia, related to head muscles morphological alterations.**

***Keywords*— tensor-based analysis, morphometry, masticatory muscles, MRI**

I. Introduction

Brain morphometry (or computational neuroanatomy) based on MRI aims at statistically identifying and characterizing neuroanatomical differences due to development, aging or disease among populations [1]. Many approaches to detect differences in shape and tissue density across brains have emerged, and all of them require linear and/or non-linear transformations of the brain images to match structures of individual subjects with similar intensity patterns to a population-specific template (this procedure in known as normalization). One way to classify these approaches is to broadly divide them into those that deal with differences in the local composition of brain tissues, after discounting macroscopic shape differences, and those that deal with differences in brain shape (e.g., volume, length, area, or location). The former, known as voxel-based morphometry (VBM) techniques, use deformation fields for group-specific spatial normalization and compare images on a voxel basis to identify regional differences in the density of a particular tissue (e.g., grey or white matter [2], [3], [4]). The latter, so called deformation-based morphometry (DBM) approaches, use the above deformation fields to map any individual brain onto a standard brain template to identify regional displacements in the neuroanatomy [5]. Deformation fields encode the relative positions of different brain structures, but local shapes (such as volumes, lengths, and areas) are encoded in their gradients (Jacobian matrices) and various functions of these tensor fields can be used to characterize shape differences. These techniques are more properly referred to as tensor-based morphometry (TBM) [6]. For example, the Jacobian determinant of the deformation field represents the volume of a warped unit-cube and therefore is useful in studies posing specific questions about whether volume growth or loss has occurred. Particularly, in longitudinal studies, it could be possible to detect local relative volume changes over time: since the Jacobian measures the volume of the deformed unit-cube after time t, the rate of variation of the Jacobian (i.e., its temporal derivative) is the rate of the local volume change [6].

Longitudinal analyses are of particular interest in morphometrics, e.g., to monitor the progression of a disease [7], abnormal development [8], or to characterize brain features associated with pathological conditions, compared to a healthy population [9]. The analysis of longitudinal data requires a customized processing, that considers the characteristics of intra-subject analysis. While cross-sectional data images can be processed independently for each subject, longitudinal data require an additional registration to a baseline image (or mean image) for each subject. Furthermore, the deformation field for spatial normalization is estimated only for the baseline image and then applied to all images. Indeed, any coregistration technique that is not symmetric with respect to the multiple time points might potentially introduce false positive differences [10], [11], [12].

A seminal study [10] showed how the combination of symmetric diffeomorphic modelling of MRI structural images, used to optimize longitudinal data coregistration, with TBM, was able to reveal a pattern of atrophy, typically occurring in aging and dementia, in a subject with mild cognitive impairment. Furthermore, outside the brain, age-related skin thickness decrease has been observed [13], suggesting that this method could potentially be used to characterize anatomical changes of non-brain tissues.

In this work, TBM was used to analyse the effects of intensive mastication exercise, under controlled chewing rate, on volumetric properties of both brain and non-brain soft tissues, taking advantage of an optimized longitudinal registration procedure as well as a group specific spatial normalization approach [14]. Of course, we did not expect any alteration in brain tissues and the corresponding analysis were used as a control condition for our procedure. To the best of our knowledge, no previous study applied TBM to characterize morphological alterations of non-brain soft tissues (e.g., muscles) which could be useful in many clinical scenarios where they represent a prognostic biomarker [15], [16], [17], [18].

II. METHODS

A. Participants

Data from sixty healthy volunteers (18 female) aged 22.83 ± 2.70 (mean ± standard deviation), partly included in a previous study [19], were used in this work. All participants gave their written informed consent to participate in the study in line with the European general data protection regulation (GDPR). The study was approved by the local ethic committee and conducted according to the principle of the Declaration of Helsinki.

B. MRI Acquisition

Brain images were acquired using a 3T MRI scanner (Siemens MAGNETOM Skyra, Siemens Healthcare, Erlangen, Germany), equipped with a head and neck 20 channel radio-frequency coil. Participants underwent two identical acquisition sessions on the same day interleaved by ~1-hour mastication task outside the scanner (see Section II.C and reference [19] for additional details). Both scanning sessions included a 3D Pulsed Arterial Spin Labeling sequence (not used in this work) and a 3D T1-weighted Magnetization Prepared Rapid Gradient Echo (MPRAGE) sequence for anatomical acquisition. The MPRAGE sequence was acquired with the following parameters: repetition time (TR) = 2,400 ms, echo-time (TE) = 2.25 ms, resolution = 1 × 1 × 1 mm^3, matrix size = 256 × 256, number of slices = 192, anterior-posterior phase encoding direction, generalized auto-calibrating partially parallel acquisitions (GRAPPA) factor of 2 in phase-encoding direction, and total acquisition time of 5.25 min.

C. Experimental design

After the first scanning session, half of the participants (mastication group, MAS group) were asked to chew a gum on one side of the mouth for 1 h maintaining a rate of at least 1 bite per second. The mastication side was chosen pseudo-randomly, distributing homogenously subjects masticating on the preferred side and subjects masticating on the opposite side (see reference [19] for further details). Within the MAS group, 14 subjects were assigned to the right-side chewing task, whereas the remaining 16 subjects to the left-side chewing task. Furthermore, contact electrodes were placed on the skin to record the electromyography (EMG) signal from the masseter muscles (left and right) with a sampling rate of 1024 Hz. The EMG electrodes were connected to a computerized 2-channel electromyograph (I-330-C2+, J&J Engineering, Poulsbo, WA, United States) and custom software written with LabView (National Instruments, Austin, TX, United States) provided an acoustic alert if no bites were sensed for more than 1 s. This ensured that all participants maintained the approximate rate of (at least) 1 bite/s for the entire exercise. The other half of the participants rested without chewing (no mastication group, noMAS group). The mastication or the resting period was followed by a second MR scanning session.

D. MRI morphometric analysis

The analysis of the structural data was performed using SPM12 toolbox (Wellcome Trust Centre for Neuroimaging, London, UK; http://www.fil.ion.ucl.ac.uk/spm) and Matlab 2020b (The MathWorks, Inc., Natick, Massachusetts, United States, www.mathworks.com). Both anatomical scans of each subject were first segmented using SPM to obtain separate tissue class volumes for grey matter (c1), white matter (c2), cerebrospinal fluid (CSF, c3), bones (c4), non-brain soft tissues (c5), and image background (c6). Then, deformation fields to warp native images in the Montreal Neurological Institute (MNI) standard space [20] were obtained using SPM longitudinal coregistration pipeline, which is based on pairwise inverse-consistent alignment between the first and second scan of each subject, and incorporates a bias field correction step [10]. This procedure resulted in a single image for each subject, named mid-point image, which was used as input for the subsequent non-linear normalization step, performed using the Diffeomorphic Anatomical Registration using Exponentiated Lie Algebra (DARTEL) approach [21]. DARTEL normalization typically begins by creating a mean volume from the mid-point images of each subject, which is used as an initial group template. Deformations from this template to each of the individual mid-point images are computed, and the template is then re-generated by applying the inverses of the same deformations to the images and then averaging. This procedure was iterated 6 times and the last originated template was used to compute the diffeomorphic transformation of each individual image to the standard MNI space. All tissue class images were used to create the DARTEL group template to ensure good correspondence of all tissue compartments across subjects after the normalization.

Two different approaches were followed for the subsequent analyses. First, a standard VBM was used to test the difference in grey matter, white matter, and non-brain soft tissues between MAS and noMAS groups, as well as longitudinal volume changes and group-time interaction, to ensure the absence of any alteration in tissue compositions in our experimental groups that could have biased the interpretation of the subsequent analysis. For this analysis, images c1, c2 and c5 of both time points were normalized to MNI space using the DARTEL procedure with intensity modulation (i.e., the intensity of the initial image was rescaled based on the amount of the applied warping to preserve the original tissue density) and smoothed with a 6 mm full width at half maximum (FWHM) Gaussian kernel. The SPM flexible factorial model was applied to the data for the statistical analysis, including group and time as predictors, whereas age, sex and intra-cranial volume (ICV), the latter computed using SPM, were added as confounds.

Second, a TBM approach was used to investigate possible subtle morphometric changes between MAS and noMAS groups. The divergence of the velocity field that parametrizes the diffeomorphic transformation was here employed as a measure of volumetric variation, as it encodes the volumetric expansion rate required to achieve alignment of the images, according to the diffeomorphic registration model, similarly to the Jacobian determinant. The divergence is computed by summing up the diagonal elements of the Jacobian matrix of the velocity field. One advantage of working with the divergence operator, rather than the Jacobian determinants, is that these are linear functions of the velocity fields and can be better treated numerically [6], [5], [22]. Using the longitudinal

coregistration pipeline, the divergence rate maps describing the rate of volumetric expansion/shrinkage over time at each voxel were obtained by computing the difference between the divergence of the velocity field of the diffeomorphic transformation between both scans and the mid-point average image, divided by the interscan time. Divergence rate maps of each subject were normalized using DARTEL transformations with no intensity modulation and smoothed with a 6 mm FWHM Gaussian kernel. Then, a flexible factorial model was built in SPM to evaluate group effect, including age, sex, and ICV as confound predictors. For statistical comparisons, family-wise error (FWE) correction with an alpha level of 0.05 was applied to all analyses, together with a cluster extent threshold of 50 contiguous voxels [23].

E. EMG analysis

The absolute EMG signal from both channels was integrated and down sampled to 16 Hz. The mean signal value from both chewing sides and a heuristic estimate of the number of bites were derived from the signal integral and used for post-hoc analysis. For the latter, a peak detection algorithm using MATLAB function '*findpeaks*' was run on the chewing-side signal integral: the mean value on the signal integral was used as initial threshold for the peak detection, and the minimum allowed distance between two peaks was empirically set to 4 or 6 samples (i.e., 4/2.7 bites/s) to best fit the subject's average chewing speed. The results of the peak detection were visually inspected to correct for false detections and remove bad signal periods (e.g., due to amplifier saturation or bad contact of the electrodes).

III. RESULTS

A. MRI morphometric analysis

No significant volume differences were found between MAS and noMAS groups and no significant group-time interactions in the VBM analysis of the white matter, grey matter, and non-brain soft tissues.

In the TBM analysis, a cluster of significant difference was found after FWE correction ($p<0.05$) considering the group contrast MAS vs. noMAS (height threshold: $t(55) = 4.81$; cluster-level: $p_{FWE-corr} = 0.003$; peak-level: $p_{FWE-corr} = 0.004$, $t(55) = 5.62$) located in the left temporalis muscle area (Fig. 1).

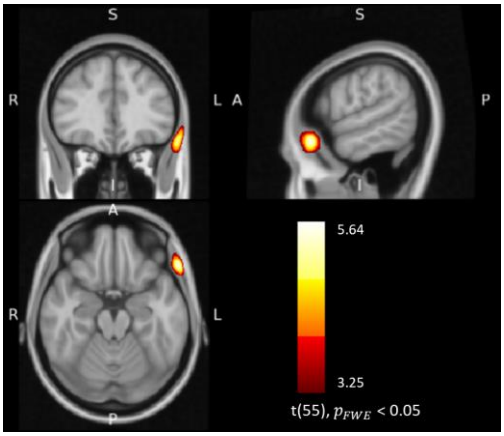

Fig. 1: TBM analysis results. Contrast t-map MAS vs. noMAS group after FWE correction ($p<0.05$).

Clusters of significant differences appeared bilaterally in the same anatomical area when lowering the statistical threshold to $p=0.001$ uncorrected (height threshold $t(55) = 3.25$; left cluster: cluster-level $p_{FWE-corr} = 0.035$, peak-level $p_{FWE-corr} = 0.004$, $t(55) = 5.62$, right cluster: cluster-level $p_{FWE-corr} = 0.251$, peak-level $p_{FWE-corr} = 0.35$, $t(55) = 4.07$) .

Indeed, the mean divergence rate maps of the two groups revealed an opposite pattern in that region, with the MAS group having positive divergence rate values, indicating an expansion trend over time (Fig.2).

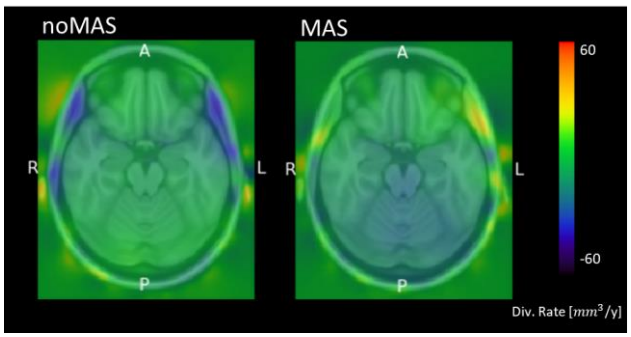

Fig. 2: Mean divergence rate maps for MAS and noMAS group (axial view in MNI space, z = -20).

Fig. 3 describes the distribution of the probability values at each voxel within the left FWE-corrected significant cluster for the membership to each tissue class as originally obtained in the image segmentation step (considering the average tissue probability maps after MNI normalization).

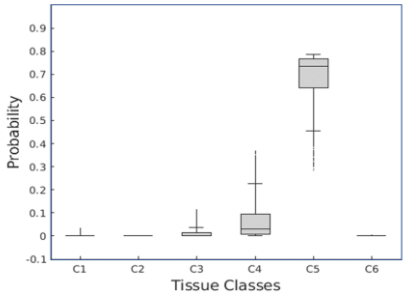

Fig. 3: Tissue probability distribution of the FWE significant voxels. C1 = grey matter, C2 = white matter, C3 = CSF, C4 = bones, C5 = non-brain soft tissues, C6 = image background.

All voxels of the FWE significant cluster were reliably labelled as non-brain soft tissues ($p<0.001$, Wilcoxon signed rank one-tailed paired test performed between C5 probability values and the probability values all other tissue classes).

However, the post-hoc analysis of the MAS group on the EMG-derived metrics revealed no significant correlation between the estimated number of bites, the mean EMG peak amplitude measured on the assigned chewing side, the mean EMG signal values from both channels, and the mean divergence rate value computed within the cluster located in the left side.

IV. CONCLUSION

TBM allows the localization of regions where local volume expansion or shrinkage occurs by measuring the rate of local

volume changes, improving the power to detect volumetric alterations within the limits of the accuracy of the registration algorithm. An advantage of this technique over the classical MRI-based volumetry (e.g., techniques that need the segmentation of the structure of interest at different time points) is that it does not require a priori knowledge of the region of interest to perform the morphological analysis, therefore it is suitable for explorative analysis where no hypothesis about the location of the possible volumetric change is available.

In this work, the combination of an accurate approach for longitudinal coregistration and normalization (that avoids asymmetry biases [24]) and TBM based on divergence rate maps allowed the detection of subtle volume enlargement in the temporalis muscles after 1-hour of intensive mastication exercise. Our results are in line with previous studies showing temporalis muscle hypertrophy due to bruxism, dental malocclusion or excessive chewing gum and trauma [25], and, more in general, increased workload of the masticatory muscles [26]. Temporalis muscle volume (in particular, temporalis muscle thickness, TMT) alterations have been found in migraine patients [27] with respect to healthy control. TMT has been previously proven to have a prognostic role in different diseases: for example it showed a high correlation with overall survival in patients with brain metastasis from melanoma, breast, and lung cancer, as well as in patients with progressive glioblastoma and sarcopenia [15], [16], [17], [18]. TMT is usually manually delineated from MR images or other imaging techniques (e.g., computer tomography or ultrasounds) [28], whereas the use of TBM for an automatic detection of temporalis muscle morphometric alterations could be in principle a more sensible and robust prognostic tool.

***Abstract*— Functional connectomics studies the way different regions of the brain are *functionally* connected by means of time-series correlation of functional magnetic resonance imaging data (fMRI) based on Blood Oxygen Level-Dependent (BOLD) contrast. Typically, it is based on resting-state fMRI, which is meant to measure the effect of the spontaneous neural firing in absence of external stimuli. In this scenario, there is an effort in the scientific community to retrieve a "pseudo-resting" state from task-based fMRI and a need of a methodological consensus among task-state connectivity studies.**

This work takes place within this context and investigates whether a task-free "resting-state" connectivity can be inferred from task-fMRI and examine its impact upon behavioural traits on a clinical context, namely in the comparison of Typical Readers and children with Developmental Dyslexia.

Connectomes are derived with several processing options from the two administered tasks, namely the Sinusoidal Gratings and Coherent Motion detection, and analysed by means of classification experiments. The "pseudo-resting" state connectomes, derived from the regression of the task design information, were able to discriminate between the two tasks. Both "task" and "pseudo-resting" state connectomes successfully allows the discrimination between children with Developmental Dyslexia and Typical Readers (accuracy > 70%). Group discrimination seems to be driven by task-related features, independently from the processing pipeline.

Taken together, our results suggest that regression of task-fMRI signals does not lead to a reliable "pseudo-resting" state connectivity. Task based connectomics can still be used to highlight alterations in connectivity underpinning the different behavioral traits.

***Keywords*—fMRI, task-fMRI, functional connectivity, data processing.**

I. Introduction

Functional connectomics has gained attention in the neuroscientific community in the investigation of cognitive behaviours of the brain. Connectivity from fMRI time-series retrieves functional associations among brain regions, represented by nodes, as synchronization maps of their correlation with each other, represented by an edge. Functional Connectivity (FC) from healthy subjects (i.e., controls) and subjects with some neuropsychiatric disorders could be compared in sight of the detection of some functional biomarkers. Typically, FC is based on resting-state fMRI data [1] and measures connections due to spontaneous neuronal firing [2]. Yet, long scan durations are required to obtain reproducible quantitative connections free from spurious fluctuations of non-neural activity. Thus, many studies do not collect enough resting-state data [3] and seek to infer a "pseudo-resting" state by task-modulated data [4], [5]. "Pseudo-resting" state fMRI is meant to analyse the task-evoked fMRI signal in a resting-state processing approach accounting for the activation due to the task [4], [5].

A recent work shows that cognitive tasks related to the skill of interest amplify the trait-relevant individual differences in functional connectivity patterns [6], thus the removal of the task-related content from fMRI signal in the computation of FC might uncover the neuropsychological context. However, little is discussed about the processing of task-evoked functional data to inspect differences in brain functional organization to human behaviours and cognition.

The aim of this work is two-fold: (i) to perform an evaluation of the "pseudo-resting" condition inferred from task-fMRI examining the feasibility of removing the task information from the signal, and (ii) to explore the optimal processing of task-fMRI connectivity in view of subsequent analysis of differences in behavioural traits.

II. Materials and Methods

This work focuses on the fMRI data pre-processing and group level analysis required to investigate the functional connectivity. Accordingly, fMRI data and pre-processing approaches are presented.

A. Participants

Seventy-seven subjects (age range: 9-18 years, M/F: 49/28), 39 Typical Readers – TR and 38 subjects with Developmental Dyslexia – DD) volunteered in the study and were recruited from a project about the genetic basis of DD [7]. The two groups show significant differences in terms of age, gender distribution, QI and DSM-IV-Inattention (DSM-IV-I) trait as Table I reports.

B. Experimental procedure and fMRI task design

MRI data were collected on a 3T Philips Achieva dStream scanner with a 32-channel head coil. Visual stimuli were

delivered through a VisuaStim digital device for fMRI (Resonance Technology Inc., Northridge, CA, USA). The MRI protocol included the use of an anatomical T1-weighted (T1W) 3D Turbo Field Echo sequence as a subject morphological reference of MRI data, and the fMRI data acquired with T2*-weighted Gradient Echo planar sequences. Children were administered with two visual tasks, i.e., Sinusoidal Gratings (SG) and Coherent Motion (CM), with the aim of eliciting the dorsal stream pathway (both SG and CM) and the attention network (CM) [8].

TABLE I: DATASET STATISTICS

	Children with DD (n=39)	*Typical Readers (n=38)*	χ^2	*df*	*p*
Gender (Female/Male)	19/20	9/29	4.19	1	0.041
	Mean (SD)	*Mean (SD)*	*t-Test*	*df*	*p*
Age	12.69 (1.64)	14.29 (1.67)	-4.23	75	$<10^{-4}$
IQ, Block Design†	13.18 (3.28)	11.82 (2.25)	2.12	75	0.037
DSM-IV-I‡	48.21 (7.6)	60.47 (11.4)	-5.57	75	$<10^{-4}$

†Block design subtests of the WISC-II [12]. ‡The DSM-IV-Inattention

C. MRI data common pre-processing

The fMRI data were preprocessed using FreeSurfer (https://surfer.nmr.mgh.harvard.edu/) and the FsFast toolkit. Briefly, functional images were motion corrected, slice-timing corrected, resampled on the "fsaverage" template, a standard space representation implemented in the FreeSurfer software package, using the subject T1W image as an intermediate step, smoothed with a 3 mm FWHM Gaussian kernel and intensity normalized. The HCP-MMP1 atlas was used to divide each hemisphere into 180 cortical regions, which can be grouped into 22 macro-regions. Moreover, we considered 18 regions of the deep grey matter.

D. Subject level general linear models

We analysed the fMRI data with two approaches based on General Linear Models (GLMs), the first one preserves the task-related information, so we named it as "Task condition", and the other one seeks to remove the task-related component from the data, so we named it as "Pseudo-resting condition".

Task condition: GLM analysis conducted without removing task induced signal changes. Thus, regressors of the subject level GLM of task-fMRI BOLD time-series included six motion parameters estimated during realignment, first five principal components of cerebrospinal fluid (CSF), first five principal components of white matter (WM) and the global signal mean. This way, residual fMRI signals preserve the contribution due to the neural activity linked to the visual stimuli.

Pseudo-resting condition: GLM analysis performed with task predictors. The subject level GLM of task-fMRI BOLD time-series included task predictors as additional regressors to create a "pseudo-resting" condition by regressing out the BOLD signal associated with task execution and saving the unwhitened residuals of the signal. Boxcar functions of tasks were convolved with canonical Haemodynamic Response Function (HRF) implemented in SPM and regressed out from data. Multiple task-regression models were used in this analysis differing in terms of the number of derivatives used in the GLM's HRF by which time series were convolved to get the neural response.

E. Functional Connectivity estimation

Connectomes were portrayed by means of ROI-wise Pearson correlation of the entire signal time-series of the experiment (i.e., across all conditions of the experiment), resulting in a 378x378 symmetric FC matrix for each subject. Since BOLD signals are influenced by a number of non-neural processes, the disposal of spurious connections is a crucial step in neuroimaging connectivity analysis, and thresholding is a popular procedure to sparse the connectivity matrices [9] even though there is no gold standard algorithm to select the optimal threshold [10]. Therefore, experiments were conducted with several sparsification thresholds *th*. Specifically, for each thresholding level top N ($N=th*N_{tot}$) connections were preserved in each subject's connectome, zeroing all the others. Moreover, connections equal to zero in more than half of the subjects were removed to avoid the impact of multiple removed connections from the group level analysis.

F. Evaluation of "pseudo-resting" condition

Multiple classification experiments were performed on the GLM-processed data (HRF derivatives in the GLM and sparsification) with the aim to predict the original administered task (i.e., SG or CM) from the derived connectomes.

Classifiers were tested with their default settings (i.e., SVM, Logistic Regression, Decision Tree, Random Forest, K-NN, Gaussian Naive Bayes, simple Multi-Layer Perceptron) with a repeated Cross-Validation (CV) to evaluate the removal of task-related information in the "pseudo-resting" connectomes.

G. Impact of GLM-processing of connectomes in a clinical context

We fixed the sparsity level to 50% and the number of derivatives to zero for task regression, and performed a classification experiment with the aim of investigating the impact of task regression in the characterization of DD and TR. Group classification was performed for all conditions, i.e., in both SG and CM task and in both "task" and "pseudo-resting" conditions, using a SVM classifier (C=1, linear kernel) with a 6-folding CV approach. Significance of classification was tested with a 1000-permutations test and pair-wise differences in the performances of the 4 classification experiments were tested with a two-tailed homoscedastic t-test.

In each fold of each experiment, the relevant connections to be used as features in the classification were selected by a Mann-Whitney test ($p<0.001$). Accuracy, AUC (Area Under the Curve) and relevant connections were saved to dig in the discriminative process. Connections selected in at least 5 folds out of 6 were identified as stable and discriminative, and compared between the 4 SVM experiments (i.e., task SG, task CM, "pseudo-resting" SG and "pseudo-resting" CM). All connections were grouped by the belonging macro-ROIs as defined in the HCP-MMP1 atlas to get an overview of the areas devoted to the discrimination of DD and TR.

III. RESULTS

A. Evaluation of "pseudo-resting" condition

In fig. 1 are summarized the results of the task classification experiments. Each boxplot reports the distribution of the classification AUCs of the classification experiments for each condition. It illustrates how task regression reduces the task-related content from the fMRI signal, even though the stimulus can still be inferred from the derived connectomes independently of pre-processing (i.e., "task" or "pseudo-resting").

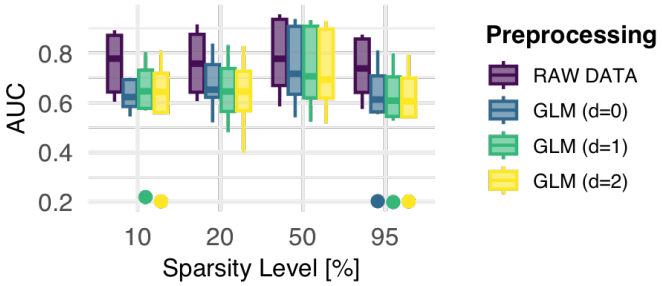

Fig. 1: Task discrimination (SG Vs CM) performances from connectome matrices among the different pre-processing techniques: applying different GLM derivatives (i.e., no derivatives – RAW DATA, 0 derivative – GLM (d=0), 1 derivative – GLM (d=1), or 2 derivatives – GLM (d=2)) and levels of graphs' sparsity (i.e., 10%, 20%, 50%, 95%).

B. Impact of GLM-processing of connectomes in a clinical context

Table II reports the Cross-Validated metrics of the 4 SVM experiments and suggests that classification of connectomes between DD and TR is significantly successful in both "task" and "pseudo-resting" conditions ($p<0.001$ in all experiments).

TABLE II: BEHAVIOURAL TRAIT CLASSIFICATION PERFORMANCES

Condition	*Accuracy mean (%)*	*AUC mean (%)*
Task Gratings	77 ± 11	82 ± 17
Pseudo Gratings	77 ± 13	83 ± 7
Task Coherent	72 ± 8	83 ± 5
Pseudo Coherent	79 ± 11	87 ± 11

Behavioral trait (DD Vs TR) classification performances from connectome matrices. Experiments were performed using both "task" and "pseudo-resting" (d=0) derived connectomes with a 50% sparsity level.

The performances of classification showed no significant differences when pair-wise tested with a two-tailed t-test (Table III reports pairwise *p*-values of accuracy and AUC in the upper and lower triangle, respectively).

TABLE III: TWO-TAILED T-TEST OF CLASSIFICATION PERFORMANCES

ACC / *AUC*	*Task gratings*	*Pseudo gratings*	*Task coherent*	*Pseudo coherent*
Task gratings	x	1	0.37	0.69
Pseudo gratings	0.92	x	0.43	0.71
Task coherent	0.37	0.43	x	0.18
Pseudo coherent	0.57	0.47	0.44	x

We investigated the impact of GLM-processing ("task" Vs "pseudo-resting") and the type of task (SG Vs CM) in the discriminative process. We quantified the overlap in the relevant connections selected by the classification experiments and reported the results in terms of overlap percentages in fig. 2. Very few connections are commonly selected by the classifiers working on SG and CM, either in "task" and "pseudo-resting" (*intra-processing* and *inter-task*), while >60% of the connections are commonly selected when comparing "task" and "pseudo-resting" conditions in both SG and CM (*intra-task* and *inter-processing*).

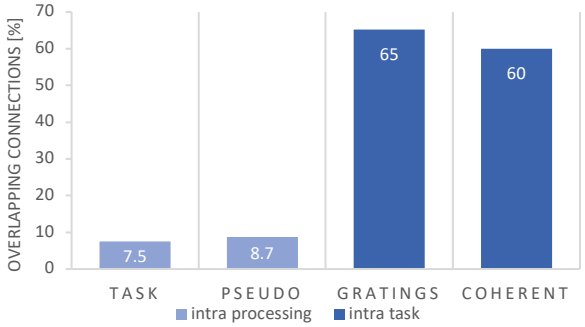

Fig. 2: Analysis of the ration of the overlap among connections chosen by the classifier in the group classification experiments (i.e., DD Vs TR). *Intra-processing* analysis explores the overlap between SG and CM with the same GLM-processing, while *intra-task* analysis highlights the overlap between the different GLM-processing on the same task.

From a macro-ROI point of view, Table IV shows the percentages of the most involved macro-ROIs defined by the HCP-MMP1 template in the 4 experiments. Results are more similar when comparing intra-task analyses than when comparing similar pipelines applied on different task, suggesting that a task related content is present in the derived connectomes independently of the processing pipeline.

IV. DISCUSSION AND CONCLUSIONS

In this work, processing of task fMRI data was analyzed to explore the contribution of the task information in connectomics.

The first aim of this study is the evaluation of the "pseudo-resting" condition got by regression of the BOLD signal in the fMRI data, i.e., to test whether "pseudo-resting" state connectivity can be inferred and investigated from task-fMRI data. The successful discrimination of the task in "pseudo-resting" conditions for all the tested conditions (fig. 1) indicates that connectomes preserve task information even after GLM regression, suggesting that a task-free "pseudo-resting" state cannot be inferred from task fMRI data, even if it can be inspected to study the context associated with DD not explicitly linked to the task-driven stimuli.

The second goal of this work explores the way GLM-processing in generating "pseudo-resting" condition affects subsequent analysis upon behavioral traits, seeking the optimal way to process fMRI data in the exploration of the clinical context. From fig. 2 we can deduce that discriminative connections mainly depend on the type of task, which drives the way the classifier discriminates between DD and TR, as

SG and CM share only few connections in both task and "pseudo" conditions. On the other hand, the greater intra-task and inter-processing coherence (i.e., a higher number of shared connections) shown in both SG and CM suggest that signal GLM-processing does not significantly influence the way the classification rules are inferred in the training, leading to similar evaluation of significant features. To verify this, we examined the macro-ROI analysis of table IV looking for DD-related networks highlighted by the classification of this behavioural trait. Overall, the most engaged macro-ROIs in the discrimination are known to be involved in DD, whereas differences between SG and CM are linked to the networks the two tasks are meant to elicit – dorsal and ventral visual paths in both SG and CM and attention network in CM. Yet, there is still a great deal of confusion and controversy regarding the processing of task-based connectivity in fMRI analyses. In some cases, this has led researchers to report two versions of their results, one version with task regression and another without task regression [11].

TABLE IV: MACRO-ROIS ANALYSIS OF RELEVANT CONNECTIONS

REGION NAME	*Task gratings*	*Pseudo gratings*	*Task coherent*	*Pseudo coherent*
Primary Visual Cortex	0	0	0	0
Early Visual Cortex	0	0	1.7	1.6

***Abstract*—Sleep-disordered breathing (SDB) are recognised as significant risk factors for the development of major diseases and, even in their mildest forms, have a strong impact on a person's quality of life and general well-being. The prevalence of SDB is much greater than one is generally led to believe; there are many people who suffer from them without ever having received a diagnosis, because the symptoms, although debilitating, are often difficult to attribute, especially in cases where they present in a milder form. This, coupled with the fact that polysomnographies are complex examinations to perform, makes it even more difficult to directly identify the sufferer.**

It is therefore of interest the development of techniques for studying the acquired signals. Among those, we focused on the relation between breath and peripheral pulse. The frequencies in the breathing range were extracted from photoplethysmographic (PPG) signals using Empirical Mode decomposition, and the temporal relation between the two parameters is described by means of their relative phase shift, normalized with respect to the breathing period. Preliminary results indicate that some of the analyzed pairs exhibit a stabilization of the relative time-shift at deeper sleep stages.

***Keywords*—PPG, Sleep analysis, phase synchronization**

I. Introduction

SDB is considered a relatively common condition, reported to be 2% in the female population and 4% in the male population, whose main manifestation is Sleep Apnea Syndrome (SAS). From a clinical point of view, in adults, SAS is defined as frequent stops of respiratory activity lasting at least 10 seconds during sleep and it can be divided into three categories: Obstructive Sleep Apnea (OSA) is the most common and is due to partial or complete obstruction of the upper airway, Central Sleep Apnea (CSA) which has a lower incidence and is due to lack of respiratory effort despite the presence of an open airway, and finally, mixed sleep apnea (MSA) which is the combination of the previous two [1]. Sleep studies are difficult, costly, and troublesome for those who undergo them; for a successful outcome of the examination, in the most comprehensive cases of polysomnography, subjects must spend a night wearing a wide range of sensors and monitoring systems that may hinder peaceful sleep. This leads to severe limitations in the clinical application of such studies and in the interpretation of the results, due to the lack of certainty that the recorded sleep disturbances are actually physiological and not induced by the measuring devices that the subject needs to wear; therefore, a less invasive and simple, but equally effective, examination could allow for a wider spread of such studies, possibly conducted completely autonomously by the subject himself through a wearable device and, consequently, a more widespread identification of people affected by these disorders. For this reason, many recent studies have focused on attempting to develop new, minimally invasive but highly effective polysomnographic procedures [2], [3]; most of these have focused on using the raw PPG signal because of the ease with which it can be implemented in a wearable and compact sensing system. In this study we sought to identify possible relationships between the raw PPG signals, acquired with red and infrared light, and a number of other respiratory signals acquired during polysomnographic examinations of subjects with sleep apnea, looking for a possible correlation between sleep state-induced changes in the respiratory component of peripheral pulsations and the other signals.

A. Effects of breathing on circulation

It is known that respiration has a definite influence on circulation; although the reasons why this happens are not always clear or confirmed, the underlying mechanisms are. In particular, breathing influences circulation in two ways. First, it has a direct effect on heart rate variability through a nervous mechanism known as respiratory sinus arrhythmia (RSA), whereby, as a result of receptor extension in the lungs, inhibitory signals sent to cardiac vagal neurons (CVNs) exert inhibitory control over heart rate: so that during inspiration the heart rate increases and vice versa; second, it influences left ventricular output with a series of opposing effects. On the one hand, breathing increases venous return due to the expansion of the chest, which generates radial traction on the organs within it causing a reduction in pressure in the right atrium by a few mmHg and increasing flow from the periphery; in addition, lowering the diaphragm compresses the intra-abdominal veins slightly increasing venous return. In contrast to this, the radial traction exerted by the thorax during expansion also distends the vessels outside the lungs, increasing their capacity, with the effect of generating an accumulation of blood in the extra-alveolar vessels within the thorax; conversely, the alveolar vessels are compressed when the alveoli expand and fill with air, thus increasing the resistance downstream of the

right atrium and reducing the blood supply to the left side of the heart. Furthermore, as a consequence of right ventricular expansion, a shift in the intraventricular septum causes a reduction in left ventricular compliance and, consequently, a reduction in stroke volume [4]. The overall effect of these opposing mechanisms is a reduction in systolic blood pressure during inspiration (approximately 5 mmHg in healthy adults). Since the induced changes in stroke volume during inspiration are reflected both in central [5] and in peripheral perfusion [6], they can be recorded with a photoplethysmograph and later extracted from the overall signal.

II. Materials and Methods

The study used retrospective data collected from 11 male and female subjects who underwent an overnight polysomnographic examination from which the analyzed signals were recorded, according with the planned therapeutic procedure. All participants were informed on the purpose of the study and its experimental procedures before obtaining their written informed consent and the enrolment in the study. All the data were collected and processed anonymously in accordance with privacy regulations and the guidelines of the Declaration of Helsinki of the World Medical Association.

A. Data collection

Polysomnographies were conducted in a controlled clinical environment for the duration of one full night (approximately 8 hours) during which the following signals were recorded:

- Photoplethysmogram, obtained by means of a self-made device using a light in the red zone (Red) with a wavelength of $640\,\mathrm{nm}$ and one in the infrared band (Ir) with a wavelength of 9 $40\,\mathrm{nm}$; both signals were sampled at a frequency of $300\,\mathrm{Hz}$. The combination of these signals provides also the saturation curve.
- Abdomen (Abd) and thorax (Thx) respiratory movements recorded by means of two different plethysmogram belts placed around the abdomen and around the chest respectively.
- Nasal flow (Flw) obtained with a nasal cannula connected to a pressure transducer (range $\pm 5\,\mathrm{mbar}$). This is a qualitative signal whose shape follows respiration: during inspiration the pressure in the cannula decreases, during exhalation the pressure in the cannula increases. We observed a strong non linearity of the relation between pressure and flow. In order to improve the linearity of the relationship between pressure changes and flow changes, we empirically processed the measured signal by square root transformation.
- Data representing the sleep events obtained as a result of the polysomnographic examination were used: each 30-second block of the examination was associated with a sleep stage following the general criterion that divides sleep stages into five main classes: wake (W), REM (R), non-REM light sleep 1 (N1), non-REM light sleep 2 (N2) and non-REM deep sleep (N3).

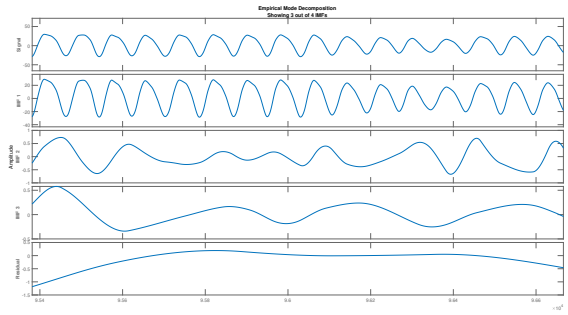

Fig. 1: Empirical mode decomposition of the infrared signal; the undecomposed signal is the one shown at the top, then the first 3 intrinsic mode functions are presented in order; the last section is the decomposition residuals.

The polysomnographic session also records several other signals, in addition to the ones listed above. For the sake of brevity, we will not list them here as they are unnecessary for the purposes of this study.

B. Data analysis

Given the small number of subjects, we tuned our system by using data corresponding to a single subject. The remaining 10 subject constitutes the test set for validating the outcome of the system.

In a preliminary step, all data tracks were synchronized, as their start and stop times were not perfectly aligned. The procedure identifies the latest starting time (t_s) and the earliest ending time (t_e); then each signal was clipped to the interval $[t_s, t_e]$. Also, all signal where resampled at a sampling rate of $300\,\mathrm{Hz}$. Next, a 7th-order IIR low-pass filter with a stop-band frequency of $f = 10$ Hz was applied to each signal to eliminate all higher-frequency noise, then down-sampling to 30 Hz to work with fewer samples. Finally, a 6th-order band-pass filter between 0.15 and 1.5 Hz isolates the respiratory frequencies, that vary approximately from 1 to 6 seconds per breath, and the heartbeat (Fig 1, top row).

Once the signals had been cleaned of noise, it was necessary to extract only the breathing-related components from Red and Ir signals. A recent approach proposed in 2011 by Madhav et al. [7] for extracting the breathing signal from PPG is Empirical Mode Decomposition (EMD), a time-frequency data analysis that has proven effective in extracting signals from data generated by non-linear, non-stationary noisy processes such as breathing and heartbeat.

Briefly, the Empirical Mode Decomposition is obtained by an iterative algorithm that decomposes the signal $s_0(t)$ into a finite number of components called Intrinsic Mode Functions (IMF); during each iteration i, first the local maxima and minima of the signal $s_{i-1}(t)$ are identified, then the respective interpolated signals are estimated obtaining the upper $U_i(t)$ and lower $L_i(t)$ envelopes, then the IMF $e_i(t)$ is calculated as the mean envelope:

$$e_i(t) = \frac{U_i(t) + L_(t)}{2}$$

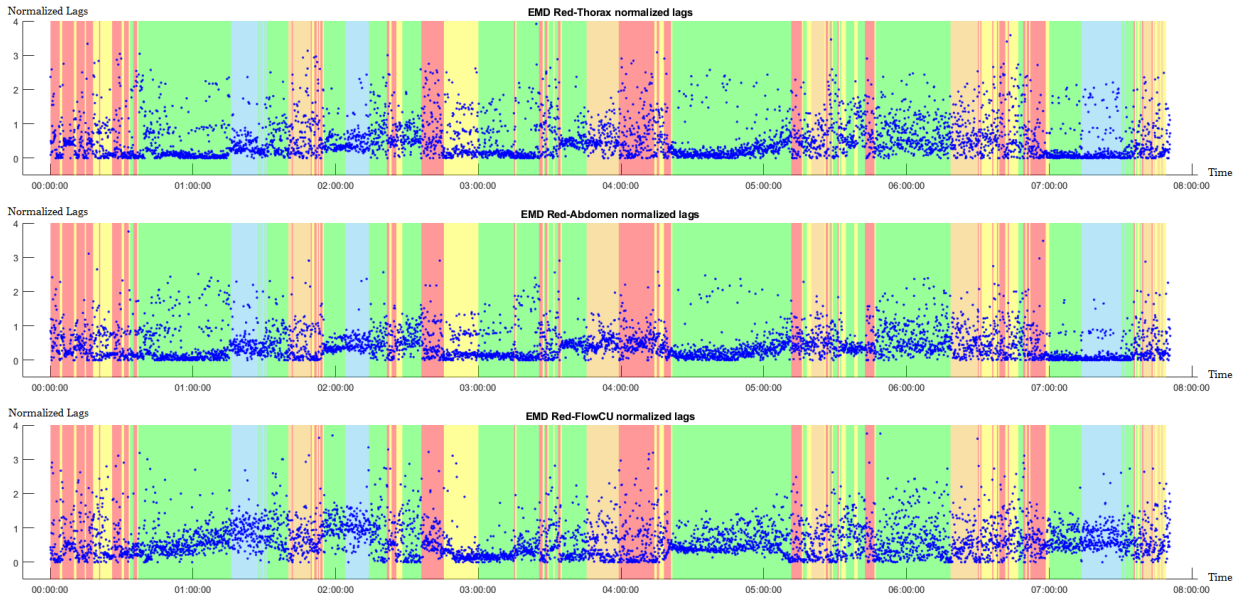

Fig. 2: Red normalized lags; Color indicate the sleep phase: red, W phase; orange, REM phase, yellow, N1; green, N2, and blue, N3

Finally, the residual signal $s_i(t)$ is obtained as the difference between $s_{i-1}(t)$ and $e_i(t)$, and a new iteration is performed. The algorithm can be stopped after an arbitrary number of iterations, in which case it provides an equal number of IMF, or it stops when the original signal remains nearly unaltered. An example of an EMD result is shown in Fig. 1.

In this study, respiration-related IMFs were identified by means of a power spectrum analysis, i.e. those whose main frequency components fell within the typical respiration range (0.2-0.6 Hz), which, typically, are those obtained from the second iteration ($e_2(t)$).

A cross-correlation analysis was conducted from the obtained IMFs. The cross-correlation is the measure of similarity of the periodicity of two signals which is expressed as a number between -1 e 1 (1 being the same periodicity and the same phase, - 1 the same periodicity and a 180° shift; in addition, the cross-correlation function allows the identification of the number of samples, referred to as lags, of which one signal must be shifted relative to the other in order to have the maximum periodicity similarity: it is, therefore, an index of the phase shift between the two signals. However, for cross-correlation to yield meaningful results, the analysed signals must be stationary, and neither the peripheral pulsation nor the respiratory signals are. For this reason, we considered only intervals of approximately two breaths, where both the PPG and respiratory signals could be considered reasonably stationary. Thus, we split both signals in 5-second signal windows (150 samples), and analyzed the cross-correlation in each window. Moreover, to increase resolution and accuracy, we introduced an overlap of ± 15 samples (± 0.5 seconds in the timeline) between adjacent windows.

In this procedure, each window is associated with the correlation values and the time lags between each of the respiratory IMFs extracted from both PPG signals (Red, Ir) and all respiratory signals (Abd, Thx, Flw), in the corresponding sleep phase (W, R, N1, N2 or N3). That is, for a set of possible combinations of feature pairs, Lags and correlation values were extracted; these pairs are: Red-Thx, Ir-Thx, Red-Abd, Ir-Abd, Red-Flw, Ir-Flw, Thx-Abd, Thx-Flw, Abd-Flw, Red-Ir. In order to compare the lags of the different windows into which the signals were divided, lags normalized to the period of the individual window were calculated: for each window, the positions of the peaks were identified and the period of the signal was evaluated as the difference of the position of two adjacent peaks, then the lag corresponding to the window was normalized divided by the period of the same window. Thus, we obtained a set of normalized lag, representing the phase shift in each 5-second time window for each considered signal pair. Those lags were finally grouped accordingly with the corresponding sleep phase, and their distribution was analyzed.

III. Results

Normalized lags results were collected in graphs that indicated with a blue dot each lag associated with a 5-second window within the whole-night sleep recording; sleep stages were highlighted with a color system that associated W phase with red, REM phase with orange, N1 with yellow, N2 with green, and N3 with blue. Graphs of normalized lags between the Red signal and the Thx, Abd, and Flw signals, respectively, were shown in Fig. 2.

A visual inspection of the lag histogram indicates the distribution is highly skewed, with most samples grouped together, but with a relatively large population of outliers, probably related to issues in the estimation procedure, in presence of signal artefacts (mainly, movement of the subject). For this reason, resorted to perform a preliminary analysis based on median and interquartile range. Visual inspection suggests also that the dispersion of the values tends to decrease

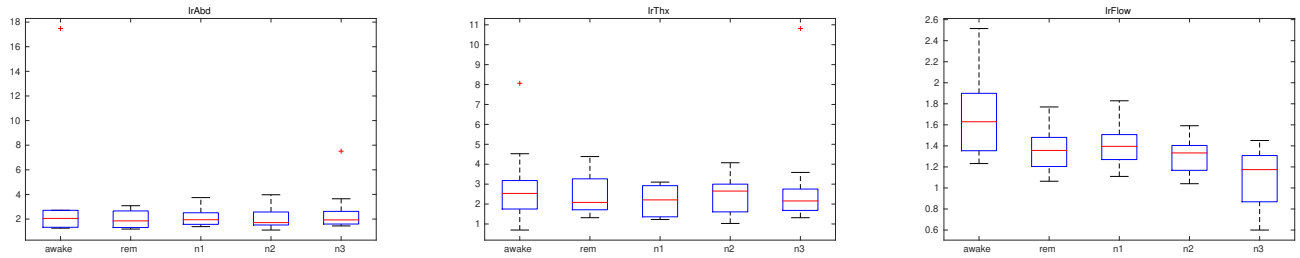

Fig. 3: Infrared interquartile and median ratios for sleep stage

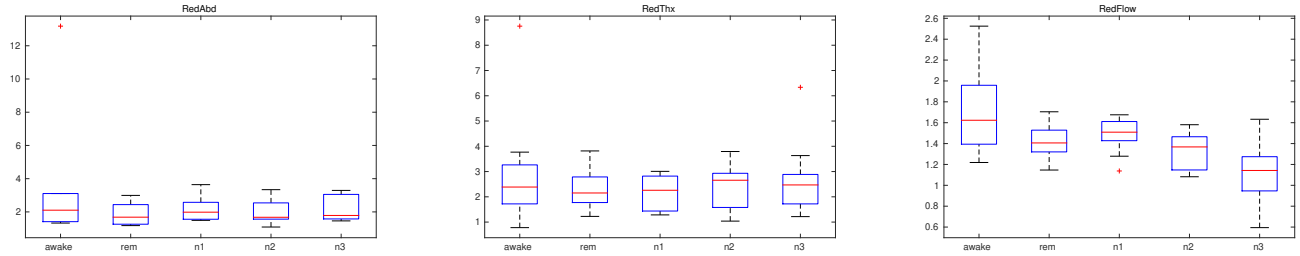

Fig. 4: Red interquartile and median ratios for sleep stage

with the increase of depth of sleep; therefore we decided to study this aspect by evaluating the ratio between interquartile range and median, for each parameter pair and for each sleep stage; the results have been reported in the form of box plots in Fig. 3 and Fig. 4 for both Red and Ir signal with Thx, Abd and Flw signal respectively.

IV. Discussion

Preliminary results do not seem to show a strong relation between PPG signals and the other signals. This could depend on many factors for which a multiparametric analysis seems necessary; for instance, we already observed a variability of the perfusion depending on the measurement site [8], as well as the feasibility of using a signal modelling technique for extracting a more robust representation of the PPG signal [9], [10].

However, an interesting aspect emerges from the box-plot analysis: it can be seen that while the ratio of interquartile to median normalized lags of both the Red signal with Abd and Thx and the Ir signal with Abd and Thx tends to remain constant for all sleep stages, that with the Flw signal tends to vary; in particular, the mean and dispersion decreases for deeper stages of sleep, suggesting an increased synchronization between those signal pairs. One interpretation of this phenomenon is that these are the effects of obstructive apnea, whereby during the obstructive event there are still chest and abdominal respiratory efforts that affect peripheral perfusion, but airflow in the nose is delayed or blocked, and this pattern is amplified in parallel with the transition from deep sleep stages toward awakening. The final result is, therefore, that perfusion signals remain synchronized with chest and abdominal movement signals throughout the awakening process whereas the same behavior does not occur with flow. One possible verification of this interpretation is to assess whether the same pattern arises in a healthy subject.

***Abstract*—Structural connectivity (SC) matrix of brain tumours is usually quantified by number of streamlines (NOS) of tracts connecting regions of interest. Several are the limitations linked to this weight. This study aims to investigate the impact of different connectome metrics by evaluating the white matter abnormalities. We found that diffusion microstructure parameters provide higher and spatially different alterations with respect to NOS. With this fact, we can enrich the NOS-based connectivity integrating diffusion microstructure properties.**

***Keywords*—glioma; structural connectivity; number of streamlines; diffusion microstructure.**

I. Introduction

Diffusion magnetic resonance imaging (dMRI) is one of the best in vivo technique able to non-invasively investigate white matter (WM) axonal fibers. Specifically, dMRI tractography, also called fiber-tracking, indicates the use of algorithms applied to delineate WM pathways in the brain [1].

The dMRI results can be used to calculate the structural connectivity (SC), defined as the quantification of the white matter tracts physically interconnecting the different brain regions [2]. Specifically, SC can be quantified as number of streamlines (NOS) connecting each pair of regions, like a proportional estimate to the total cross-sectional area of WM bundles connecting those areas [3]. Even if it is not without any problems [4], this is the commonly used metric. SC matrix can be also represented as the mean of some diffusion microstructure measures. For instance, SC can be obtained, for each connected regions pair, by averaging the Fractional Anisotropy (FA) microstructural values measured along their axonal fibers. Eventually, the two just described modalities can be joint, weighting the SC matrix characterized by NOS with diffusion microstructure metrics.

It is worth mentioning that SC [5] has become an useful tool to non-invasively infer abnormalities of brain structural connectivity in pathology [6]. As a matter of fact, SC has been applied to assess the tumours' impact on patient's whole brain structural network [7].

Therefore, the aim of this research was to investigate the impact of SC metrics derived from microstructure diffusion parameters with respect to NOS, in a multimodal assessment of the connectome abnormalities in gliomas.

II. Material and Methods

A. Dataset

Forty-six patients (60.2±14.3 years, 20 F) affected by de novo glioma at different positions (lesion hemisphere: 23 left hemisphere, 15 right hemisphere, 8 bilateral) and grades (I-IV) were included in the research between July 2017 and February 2021 at the Neurologic Clinic in Padua University Hospital. All procedures were in accordance with the ethical standards of the institutional research committee and with the 1964 Helsinki declaration plus later amendments. All participants provided written and informed consent in accordance with the local University Hospital Institutional Review Board (No. 2771P prot:0065859/12).

An expert neuroradiologist, with more than five years of experience, supplied the lesion mask delineating the entire lesion area and distinguishing two lesion tissue types: tumour and oedema. Lesion masks were used for pre-processing steps and advanced analyses.

Positron emission tomography (PET) and magnetic resonance imaging (MRI) images were acquired with a 3T Siemens Biograph mMR-PET/MR scanner, equipped with a 16-channels head-neck coil. Specifically, diffusion data analyzed for this study were collected according to the optimized Neurite Orientation Dispersion and Density Imaging (NODDI) diffusion protocol [8] (TR/TE 5355ms/104ms; 2x2x2mm): 100 diffusion images with 10 images at b=0 s/mm^2, 30 images at b-value=710 s/mm^2 and 60 at b-value=2855 s/mm^2. Each diffusion direction was acquired in two reversed phase encoding directions, i.e., anterior-posterior and posterior-anterior.

B. Diffusion processing and Tractogram generation

Diffusion data standard pre-processing was performed with FSL [9] and MRtrix3 [10] software. Co-registration steps were conducted with Advanced Normalization Tools (ANTs [11] v. 2.0.1) software. Tractography generation and SC computation were implemented with MRtrix3 [10] software. Further statistical analyses were examined with in-house MATLAB scripts (MATLAB 2022b, The MathWorks, Inc., Natick, MA, USA).

For each patient, WM tractogram was reconstructed applying the iFOD2 tracking algorithm [12], fixing the gray/white matter interface as seeding area, setting a default cut-off of 0.1 and generating 100 million of streamlines. The Anatomically Constrained Tractography [13] framework was applied during tracking: lesion area was excluded from the application of anatomical priors. Eventually, the final number of tractography streamlines was filtered to 10 million, by pruning off unreliable streamlines via the spherical-deconvolution informed filtering of tractogram (SIFT) [14] framework. Furthermore, Neurite Orientation Dispersion and Density Imaging (NODDI) [8], Diffusion Tensor Imaging (DTI) [15] and Diffusion Kurtosis Imaging (DKI) [16] models

were fitted on dMRI pre-processed data to estimate microstructure maps of the next eight microstructure parameters: intracellular volume fraction, isotropic volume fraction, orientation distribution fraction (NODDI model), FA, mean diffusivity (MD) and mean kurtosis (DKI model), FA and MD (DTI model). NODDI and DKI models were fitted on the dataset applying off-the-shelf toolboxes publicly available ([17] NODDI and [18] DKI). DTI models were fitted with *dtifit* command of FSL software [9]. All microstructure maps were checked for outliers: if voxels' values were outside the respective known literature range, voxels' outlier values were substituted by their new values, obtained from the application of a spatial median filter on the selected microstructure map.

C. SC matrices creation

For each patient, Schaefer [19] functional atlas (200 parcels, 17 Networks), joint with subcortical parcels of Automated anatomical (AAL3) atlas (Thalamus, Caudate, Putamen, Pallidum, Hippocampus) [20], were overlayed to the whole brain tractogram to then define the SC matrix (each parcel corresponds to a node). Each entry of the matrix represented the strength of the connection between each pair of nodes. Connectome matrices were quantified according to two different metrics of connectivity: *Number of Streamlines* (SC_{NOS}) and *Mean Microstructure* Parameter (SC_{MICRO}). A functional atlas was chosen given that this study is part of a project aiming to integrate functional, structural and PET connectivity for brain network analysis.

D. SC abnormalities definition

Structurally altered links were generally identified applying a non-parametrical statistic.

Concerning SC_{NOS}, for each subject, a $SC_{NOS\text{-}cleaned}$ was created. Specifically, the pseudo-healthy entries of the matrix were preserved if two conditions hold: 1) for each link, the parcels regions at the endpoints of the tract needed to feature an overlapping with the lesion for less than 5% of the total volume of the parcel, and 2) streamlines connecting such endpoints were required to not cross the lesion. Moreover, one-streamline entries of SC matrix were discarded from the analyses. Thus, a draft pseudo-healthy matrix was obtained computing the median among the patients. Then, the pseudo-healthy $SC_{NOS\text{-}MED}$ was obtained sparsifying the intra and inter hemispheres links with respectively 80% and 85% thresholds, by considering their different range of reconstructed track density. Eventually, an additional mask was overlayed to analyze only those tracts set as unaffected for more than five patients.

About SC_{MICRO}, for each patient, the SC_{MICRO} was masked by its $SC_{NOS\text{-}cleaned}$, to then compute the median among the patients and to obtain a draft pseudo-healthy SC_{MICRO}. At last, the pseudo-healthy $SC_{MICRO\text{-}MED}$ was derived masking the draft pseudo-healthy SC_{MICRO} with the pseudo-healthy $SC_{NOS\text{-}MED}$.

Thus, for a generic SC_{NOSi}, a link (j,k) was generally labelled as altered comparing the SC_{NOS} of each subject with its $SC_{NOS\text{-}MED}$ reference by the median absolute deviation $SC_{NOS\text{-}MAD}$, according to the following condition:

$$SC_i(j,k) < SC_{MED}(j,k) - 3 \cdot SC_{MAD}(j,k) \quad (1)$$

This constraint was imposed since a glioma can cause a displacement, infiltration, or disruption of the white matter fibers, thus potentially causing a decrease in the NOS of the potentially affected links [21].

Besides, a SC_{MICROi} link (j,k) was generally labelled as altered comparing the SC_{MICRO} of each subject with its $SC_{MICRO\text{-}MED}$ reference by the median absolute deviation $SC_{MICRO\text{-}MAD}$, according to the next conditions:

$$SC_i(j,k) < SC_{MED}(j,k) - 4 \cdot SC_{MAD}(j,k) \quad (2)$$
$$SC_i(j,k) > SC_{MED}(j,k) + 4 \cdot SC_{MAD}(j,k) \quad (3)$$

The threshold, equal to 4, was set to be more conservative on the links alterations definition. The double condition was applied because a white matter tract can present a deviation from the healthy behavior in both directions.

E. Degree of disconnections

Once the individual SC alteration matrix was defined, a measure of alteration was defined for each Cortical Schaefer and Subcortical AAL3 parcel (matrix nodes). At first, for each node, the normalized number of affected connections was computed dividing the number of affected links starting from that node by the reliable number of tracts seeding from the same node and derived by the pseudo-healthy SC_{MED}. Thus, given N nodes, the degree of disconnections, computed summing the number of altered links connecting each node with the other N-1, was derived to assess the impact of the metric of connectivity on the definition of the altered links. The Network degree of disconnections was derived summing the degree of disconnections of each node within a network with respect to other networks. Furthermore, the Global degree of disconnections was quantified summing the total amount of affected links for a patient.

III. Results

Collinearity of the eight types of SC_{MICRO}, derived from the inclusion of different signal models, was reduced based on the high correlation values, computed among the patients, between SC_{MICRO} of FA (1 +/- 0.002) and MD (0.99 +/- 0.004) of DTI and DKI models. For each patient, the links with an overlap of minimum 4 SC_{MICRO} affections were detected and labelled in the SC_{4MICRO} alteration matrix. Figure 1a) and 1b) show the Mean and Standard Deviation (SD) Correlations values among the different SCs types.

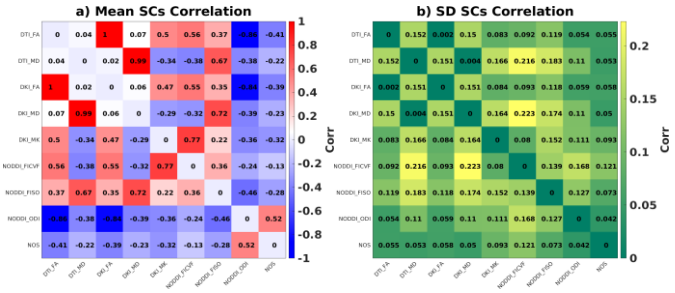

Fig. 1: On the left, fig. a) displays mean correlation values of different types of SCs among the patients. On the right, fig. b) displays SD values of different types of SCs among the patients.

A. Degree of disconnections

Figure 2a represents the Network degree of disconnections of SC_{NOS}, derived for each patient. Observing the figure, patients are characterized by a higher SC_{NOS} Network degree of disconnections derived for intra-hemisphere Cortical-

Cortical links homolateral to the lesion. Indeed, Network degree of disconnections derived for inter-hemisphere Cortical-Cortical links is sparser. A similar but less evident behavior can be observed for SC_{NOS} Network degree of disconnections of intra and inter hemisphere Cortical-Subcortical links. Looking at fourth row of Figure 2a, patients with a bilateral lesion show a behavior like patients with a right lesion.

Figure 2b refers to SC_{4MICRO} Network degree of disconnections. It is worth noting that intra-hemisphere Cortical-Cortical links homolateral to the lesion feature a high Network degree of disconnections. On the contrary, intra-hemisphere Cortical-Cortical links contralateral to the lesion rarely present an overlap of abnormalities detected from more than 4 SC_{MICRO} matrices. Indeed, SC_{4MICRO} distinguishes a low

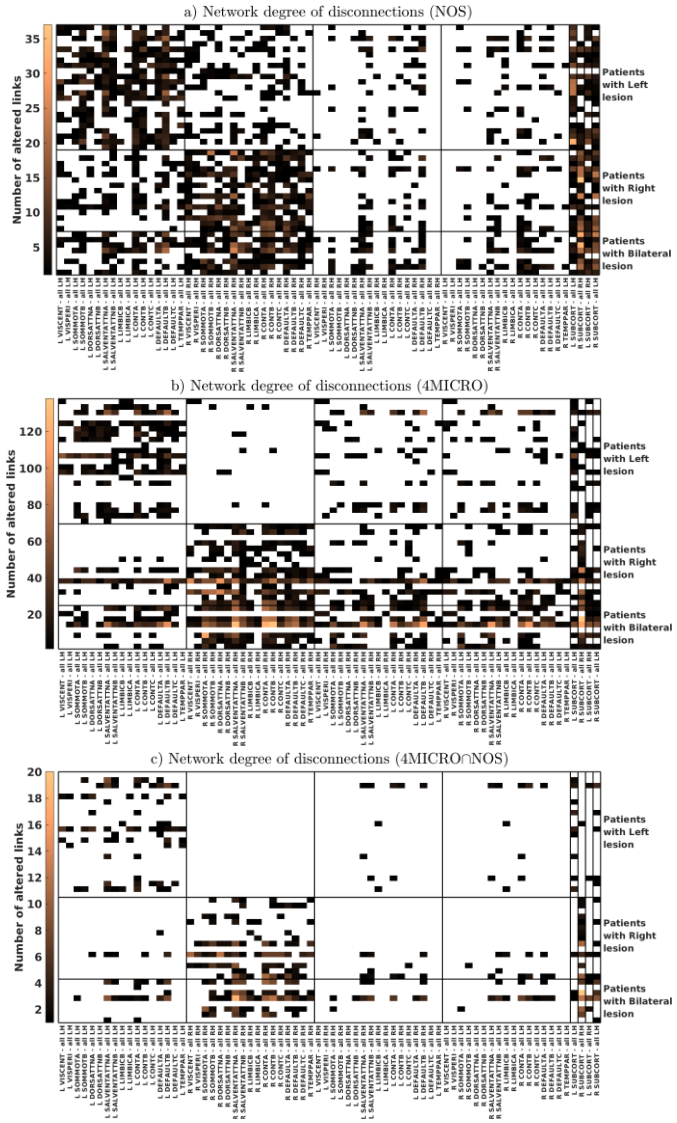

Fig. 2: Each subfigure refers to the Network degree of disconnections derived from SC_{NOS}, SC_{4MICRO} and $SC_{4MICRO} \cap SC_{NOS}$. For each subfigure, from the left: altered intra left hemisphere Cortical-Cortical links, altered intra right hemisphere Cortical-Cortical links, altered inter left-right hemisphere Cortical-Cortical links, altered inter right-left hemisphere Cortical-Cortical links, altered intra left hemisphere Subcortical-Cortical links, altered intra right hemisphere Subcortical-Cortical links, altered inter left-right hemisphere Subcortical-Cortical links, altered inter right-left hemisphere Subcortical-Cortical links. Patients are grouped across the rows by the lesion hemisphere position (from the top, lesion on the left or right hemisphere, bilateral lesion).

Network degree of disconnections for the inter-hemisphere cortical-cortical links. Considering Cortical-Subcortical Network degree of disconnections, both SC_{4MICRO} intra and inter connections present abnormalities. Again, looking at the bottom row of Figure 2b, patients with a bilateral lesion show a behavior like patients with a right lesion.

In Figure 2c the overlap of $SC_{4MICRO} \cap SC_{NOS}$ altered links is reported. It can be noted that intra-hemisphere cortical-cortical and cortical-subcortical connections of the hemisphere homolateral to the lesion, present a low overlap of disconnections. This overlap is almost null for intra-hemisphere cortical-cortical and cortical-subcortical connections contralateral to the tumor. Finally, affected inter-hemisphere Cortical-Cortical links are low and quite symmetric.

Figure 3 represents the above-described behavior for a representative patient with a lesion in the right hemisphere: most of the affected links are intra-right hemisphere. The WM abnormalities quantified by SC_{NOS} and SC_{4MICRO} are spatially distributed in different way. A low overlap of altered connections can be appreciated.

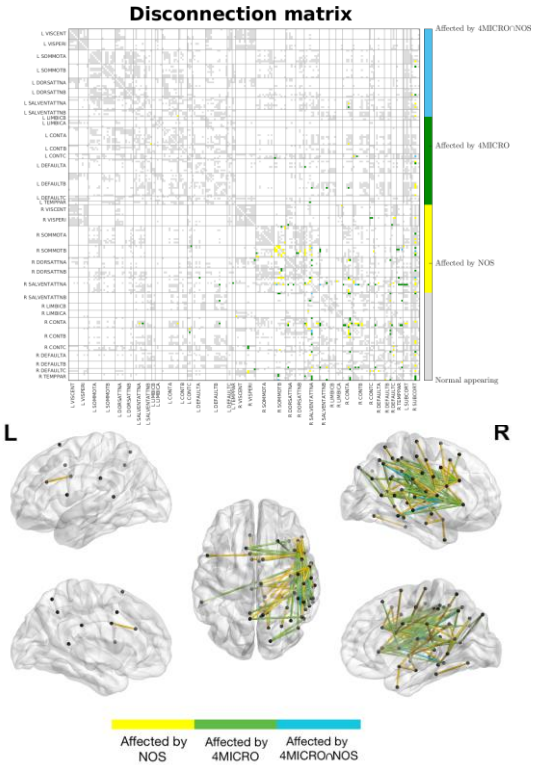

Fig. 3: On the top: Disconnection matrix for a representative patient with a right lesion. Links are grouped according to the Schaefer Cortical 17 Networks Parcellations joint with the AAL3 Subcortical parcels (Thalamus, Caudate, Putamen, Pallidum, Hippocampus), Left and Right hemispheres. Gray/white links represent reliable/unreliable connections according to the pseudo-healthy reference matrix. In yellow there are links affected by SC_{NOS}, in green there are links affected by SC_{4MICRO}, in light blue there are links affected by the intersection $SC_{4MICRO} \cap SC_{NOS}$. On the bottom: Ball and Stick representation of the disconnection matrix (only Schaefer Cortical Parcels). In black there are parcels that present altered connections. According to the matrix color bar, in yellow there are links affected by SC_{NOS}, in green there are links affected by SC_{4MICRO}, in light blue there are links affected by the intersection $SC_{4MICRO} \cap SC_{NOS}$.

Finally, the interest was about the number of WM abnormalities within the different lesion tissue types. Specifically, for each link alteration, it is possible to label it as crossing tumor, oedema, or normal appearing tissue. These distinctions highlight the impact of different brain tissues on the structural connectivity alterations. The distribution of the normalized number of affected links for the different SC types

is reported in Figure 4, grouping the patients according to the lesion position. Looking at the figure, it is evident that, for each type of SC metric and lesion position, the higher number of alterations is within the tumoral area. Concerning SC_{NOS}, the following lower normalized number of affected connections is within the normal appearing tissue. Finally, the lowest number of alterations is within the edematous area. Regarding SC_{4MICRO}, a low number of alterations is within the edematous area, while the least is within the healthy tissue. This could indicate a major impact of oedema on diffusion microstructure with respect to NOS.

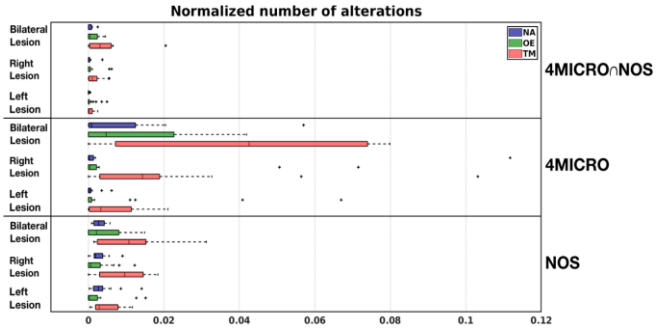

Fig. 4: Boxplots of distribution of normalized number of alterations within the different tissue types. For each lesion position hemisphere, each boxplot refers to the tissue type crossed by the altered links. Like in legend, in blue there is normalized number of altered links crossing normal appearing tissue, in green there is normalized number of altered links crossing edematous tissue, in red there is normalized number of altered links crossing tumoral tissue. Boxplots are also grouped according to the SC matrix type. From the top, for each block, there are boxplots derived for $SC_{4MICRO} \cap SC_{NOS}$, SC_{4MICRO} and SC_{NOS}. For visualization reason, an outlier value of 0.26 was cut by the image (SC_{4MICRO}, Bilateral Lesion, normalized number of altered links crossing tumoral tissue).

Eventually, comparing the distribution of normalized number of alterations between the different SC matrix type, SC_{4MICRO} generally shows a higher normalized number of alterations with respect to SC_{NOS}, thus indicating that microstructure alterations are more frequent than NOS alterations. Regarding the $SC_{4MICRO} \cap SC_{NOS}$, Figure 4 shows that the overlap is low, as already seen in Figures 2 and 3.

The last result concerns the Pearson correlation, among the patients, between the Global degree of disconnections and the tumoral/lesion volume. Considering SC_{NOS}, r values are equal to 0.65/0.81 (pval<0.05), while looking at SC_{4MICRO}, these values are equal to 0.33/0.38 (pval<0.05). The different r values suggest that, while SC_{NOS} seems to capture more the disrupted (by the glioma) structural fiber pathways, SC_{MICRO} depicts the overall neural fiber integrity related to the heterogeneity of tumor-infiltrating immune cells. It is worth observing that for both metrics, oedema plays a role in WM abnormalities.

IV. Conclusion

In this study we showed that the two different weight matrices of connectivity, SC_{NOS} and SC_{MICRO}, present a significant different spatial impact on the detection of the white matter alterations. These differences have the potential to provide complementary information of connections abnormalities. Furthermore, also given the impact of oedema on SC_{4MICRO} alterations, we can enrich the NOS-based connectivity integrating diffusion microstructure proprieties. This enrichment, when performing SC studies on glioma pathology, allows to empower our ability in the measures of alteration of glioma brain organization. Future studies could focus on the relationship between SC_{NOS} matrices enriched by the microstructure and other imaging modalities, given the multimodal acquisitions.

Millimeter-Waves Imaging for Breast Cancer Detection: Development of Analytical Models for Scattering Matrices Computation

S. Di Meo[1], G. Bertuzzi[1], G. Matrone[1], G. Magenes[1] and M. Pasian[1]
[1] *Department of Electrical, Computer and Biomedical Engineering, University of Pavia, Pavia, Italy*

***Abstract*—This contribution is divided in two parts. In the first part, we present the work done at the Microwave Laboratory and the Laboratory of Bioengineering of the University of Pavia on the design of a millimeter-wave imaging system for breast cancer detection. In the second part, we present the analytical model we have developed for the numerical simulation of multi-static radar configurations against both simple scenarios, in which one or more targets share the same medium as the antenna array, and more complex configurations, in which the targets lie in a medium other than the antennas and skin is present at the interface. Normalized radar images, reconstructed with the Delay-And-Sum (DAS) algorithm, show the robustness of the model in all scenarios considered. The models proposed in this work, although based on illustrative assumptions, make it possible to overcome the bottleneck provided by the enormous computational and temporal demands of full-wave simulations, thus offering the possibility of generating in real time the desired number of configurations on which to test, for example, skin removal algorithms and/or train the neural networks for artificial intelligence purposes (aimed, as an example, to classify suspicious regions).**

***Keywords*—Breast cancer detection, millimeter-wave imaging, numerical models, scattering matrix.**

I. Introduction

BREAST cancer is one of the most diagnosed type of cancer among women in industrialized countries. Fundamental in the fight against the disease is early detection. There are many imaging techniques currently available for the diagnosis of breast cancer. The most widely used are mammography (also used in screening programs), ultrasound, and breast MRI. However, the limitations associated with each of these techniques, such as the use of ionizing radiation in mammography, the strong dependence of the outcome of the ultrasound examination on the physician's skill, as well as the high cost of MRI, are pushing toward the study of complementary or supplementary imaging techniques for this purpose.

Among the most studied imaging techniques are microwave imaging systems, which represent a safe and low-cost option. Such systems are based on the significant dielectric contrast, i.e., the different response to exposure to electromagnetic fields, between healthy and neoplastic tissues, which becomes particularly pronounced when neoplasms are located in healthy tissues with a high percentage of adipose content [1].

In recent years, several microwave imaging systems have been proposed by different research groups around the world, some of them even reached the pre-clinical stage, either using the radar (for detection of the dielectric anomaly in the domain of investigation only) or tomographic (for reconstruction of the dielectric profile) approach [2]-[4].

However, approximately all of these imaging systems make use of relatively low frequencies and relatively narrow bandwidths, on the order of a few GHz, and for this reason, although they are capable of reaching targets several centimeters below the skin and can offer reasonable resolutions in dense breasts, they tend to lose resolution in presence of particularly fatty tissues. The high values of complex dielectric permittivity characterizing high-density healthy tissues (hence little adipose), compensate for the wavelengths in the medium, thus offering an effective wavelength of a few millimeters while using frequencies in the lower microwave region. Conversely, in presence of particularly adipose tissues, which are characterized by low values of dielectric permittivity, this compensation is lacking, so that the wavelength in the medium is approximately similar to that in air and therefore cannot detect sub-centimeter lesions.

To address this problem, at the University of Pavia, we have been working on an imaging system in the millimeter (mm)-wave regime for the early detection of breast cancer in particularly fat breasts (which are currently the target of X-ray mammography).

We have worked on several design steps over these years, from dielectric characterization of *ex-vivo* breast tissues, both healthy and neoplastic, up to 50 GHz [5]-[7], to the numerical feasibility study [8], to the realization of tissue-mimicking breast phantoms [9], to the experimental proof-of-concept of the imaging system [10]. These steps are presented in the following section.

In addition, in the direction of making our phantoms more and more realistic and our imaging tests more and more robust, we are currently working on the production of skin phantoms, as well as on the development of algorithms for the removal of the artifact associated with it. However, in order to test artifact removal algorithms on perfectly controlled scenarios and given the enormous computational demands of full-wave simulators (which sometimes limits simulations to unrealistic scenarios), we have developed an analytical-numerical model for reconstructing scattering matrices related to single- and multi-layer configurations. In particular, starting from the radar equation [11], we analyzed both the case where both antennas and one or more targets lie in the same medium, and the case where antennas are in the air and targets are in a different medium, including also the interface representing the skin. This last topic is the focus of the present paper.

The article is divided in this way. In Section II, the main

design steps of the mm-wave imaging system are presented. In Section III, the analytical models implemented for computing synthetic scattering matrices, with punctiform targets and not, in both single- and multi-layer cases are presented and discussed. Finally, some conclusions are derived.

II. State-of-the-Art of mm-Wave Imaging System for Breast Cancer Detection

A. STEP 1: Dielectric characterization of human breast ex-vivo tissues

Exact knowledge of tissues dielectric properties across the bandwidth of interest is a cornerstone for the design of all biomedical microwave and millimeter-wave applications. For this reason, in 2014 and 2016, we performed two experimental campaigns to characterize the dielectric properties of *ex-vivo* breast tissues, healthy and neoplastic, in collaboration with the European Institute of Oncology in Milan, Italy. In this way, we characterized in the 0.5-50 GHz frequency range the dielectric properties of more than 300 *ex-vivo* healthy and cancerous breast samples from about 100 women aged 14-89 years.

The results of these two experimental campaigns showed a significant dielectric contrast in the whole investigated bandwidth between healthy and malignant tissues [5]-[7].

B. STEP 2: Feasibility study of mm-wave imaging system

Based on the significant dielectric contrast between healthy and neoplastic tissues, we performed a numerical and simulative feasibility study of the mm-wave imaging system both in a linear and conformal configuration. In particular, through link-budget evaluation in different scenarios (i.e., different breast types), we evaluated aspects such as the optimal number of antennas in the array maximizing the signal-to-noise ratio, the maximum detectable depth of the lesion, as well as the achievable resolution for this type of system [8].

C. STEP 3: Tissue-mimicking breast phantoms

The realization of tissue-mimicking phantoms is an important step in the experimental testing, in a controlled but realistic environment, of any system for biomedical applications. For this reason, in [9], we developed recipes capable of mimicking the dielectric properties of all breast tissues, both healthy and neoplastic. Compared with previously published works [12]-[13], our recipes make use of only low-cost, safe and easily handled components. Furthermore, as with *ex-vivo* breast tissues, for the first time, we have characterized their properties up to 50 GHz.

In addition, we have produced two types of complete phantoms, conformal and planar, with a dielectric inclusion mimicking the dielectric properties of tumor tissues embedded in a phantom mimicking the dielectric properties of healthy adipose tissues. For reasons of space, please refer to the reference articles for more details and figures.

D. STEP 4: Experimental test of the mm-wave imaging system against breast phantoms

Testing of the millimeter-wave imaging prototype was carried out at the Microwave Laboratory of the University of Pavia [10]. The setup used for the imaging tests includes: two double-ridge waveguides (PNR180) with mono-modal frequency bandwidth [18-40] GHz, mounted on four linear actuators (Zaber technology) to enable a synthetic array and connected to a PNA Network Analyzer (Keysight E8361C) for signal acquisition. Both the actuators and the network analyzer are connected to a computer for both the movement of the antennas in the desired positions and the scattering parameters acquisition through proper Matlab routines. All measurements were done in air, without a coupling medium.

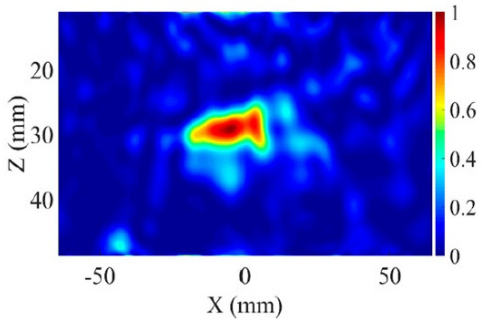

Fig. 1 Radar imaging result against experimental scenario, picture modified from [10].

The complete matrix including all combinations of transmitting and receiving antennas was created in post-processing and calibrated before using as input into the Delay-And-Sum algorithm, used for radar image reconstruction. An experimental image on phantom is shown in Figure 1 [10], showing a target 3 cm within the phantom.

III. Analytical Model for Scattering Matrix Calculation in Scenarios With/Without Interface

A. Work motivation

In the numerical study of the system presented in Section II.B, we first used Matlab for the implementation of the link-budget equations and system parameters, and then we used Ansys HFSS software for evaluation in the full-wave environment of a selected number of the scenarios.

Full-wave simulations are a very useful tool in the study of a new microwave system or device, since it describes the behavior of the propagating wave, as well as, in a noise-free environment, all the interactions between the different structures encountered by the electromagnetic wave in propagation. However, simulation times and computational demands tend to increase exponentially in the presence of biological tissues (due to their dielectric characteristics), to the point of making it practically impossible to model an anatomically realistic scenario for many practical cases.

To overcome this limitation, and to have a tool capable of providing in real-time scattering matrices corresponding to complex scenarios we implemented a numerical model starting from the radar equation [11]. In these models, one or more targets can be in a uniform medium, or in scenarios in which the antenna array is in air (or in a coupling medium) and one or more targets are embedded in a medium with dielectric properties similar to different types of healthy tissue, under a skin layer. The model was developed in Matlab (R2015a).

As an example of the model capabilities, a synthetized system based on a multi-static radar architecture, consisting of 28 elements, placed in the xz plane in linear configuration,

with symmetry with respect to the z axis and distance d between phase centers equal to λ/2 in the antenna medium at 30 GHz, was analysed. The frequency range investigated is 26.5–40 GHz, which is the mono-modal frequency bandwidth of the WR28, used in our full-wave simulations.

B. Case 1: Antenna array, punctiform target – same medium

In the first modeled configuration, the antennas and the target (one or more) lie in the same medium.

The scattering parameters corresponding to this configuration were derived starting from the radar equation, which is valid in far-field (in our case is an exemplifying assumption). In particular, to switch from powers to fields and to take into account that the scattering parameters are complex numbers, we arbitrarily added the phase terms. Therefore, the implemented equation is:

$$\sqrt{\frac{P_r}{P_t}} = \sqrt{\frac{GA_{eff}\sigma}{(4\pi)^2(R_t)^2(R_r)^2 e^{\alpha R_t} e^{\alpha R_r}}}\, e^{-j\beta R_t} e^{-j\beta R_r} \quad (1)$$

where P_r is the received power, P_t is the transmitted power, G is the gain and A_{eff} is the effective area of the antenna, σ is the radar cross section of the target, α is the attenuation constant, β is the phase constant, R_t is the path from the transmitting antenna to the target and R_r is the path from the target to the receiving antenna.

A sketch of the analysed configuration in this case is shown in Figure 2. The scattering matrix thus calculated was used as input into the image reconstruction algorithm, Delay-And-Sum, and Figure 3 shows the result. In this case, as an example, the target and antennas are both in air. Taking into account the many approximations that were necessary in modeling the scenarios, all images are normalized.

C. Case 2: Antenna array and punctiform target in different media

In the second modeled scenario, the antennas are in the air,

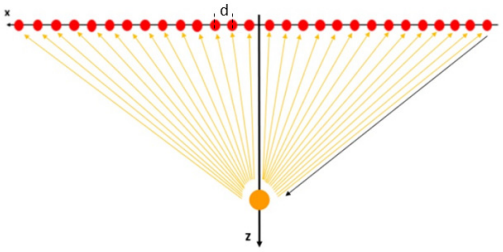

Fig. 2: Sketch of the analysed configuration in Case 1, where the red dots indicate the position of the antennas, separated by a distance d, the yellow dot the position of the target, and the yellow and black lines exemplify the propagation paths.

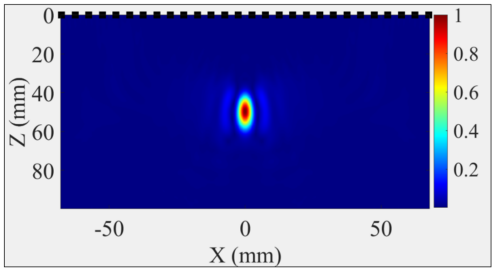

Fig. 3: Normalized DAS image for Case 1, in which both the target and the antenna array are in air. Black dots indicate the position of the antennas.

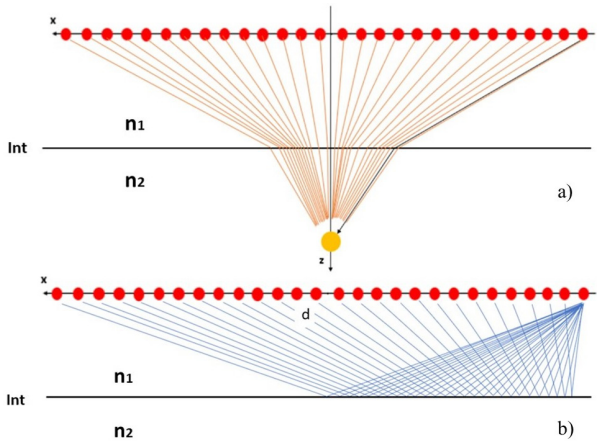

Fig. 4 Sketch of the analysed configuration in Case 2 showing the different contributions to the scattering matrix; a) target; b) skin. the red dots indicate the position of the antennas, separated by a distance d, the yellow dot the position of the target, and the yellow, black, and blue lines exemplify the propagation paths. The refractive index of the upper and lower medium is n_1 and n_2, respectively, while Int indicates the position of the interface.

while the target (one or more) is immersed in a second medium, separated by an interface representing the skin.

In this configuration, the signal received by the antennas is a function not only of the backscatter from the target, but also of the separation interface between the two media (Figure 4). In the real case, there are also the multiple reflections between the air-skin interface and the target, as well as between multiple targets and interfaces; however, in our modeling this contribution was not added for simplicity, without losing the validity (exemplifying assumption).

In this configuration, unlike the previous case, the path of the wave undergoes the presence of the second medium, so the calculation of the outward and return paths to and from the target needs to include Snell's law. Specifically, the paths are calculated by considering the following set of equations, with the nomenclature as per Figure 5:

$$\begin{cases} L1 = \sqrt{(x_{antenna\#} - x)^2 + d_{ant_{int}}{}^2} \\ L2 = \sqrt{(x - x_{target})^2 + d_{int_{tar}}{}^2} \\ \theta_1 = \cos^{-1}\left(d_{ant_{int}}/L1\right) \\ \theta_2 = \sin^{-1}\left((n_1/n_2)\sin(\theta_1)\right) \\ L2 = d_{int_{tar}}/\cos(\theta_2) \end{cases} \quad (2)$$

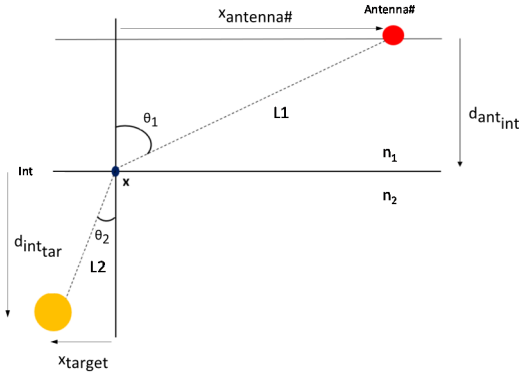

Fig. 5 Schematic drawing for path computation corresponding to one antenna by means of Snell's law.

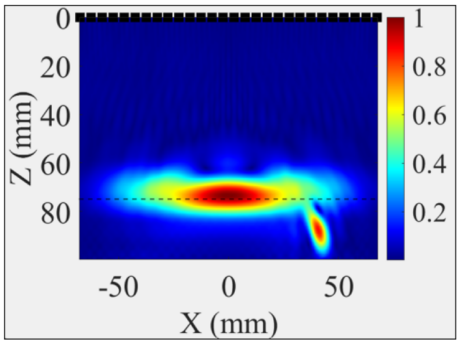

Fig. 6: Normalized DAS image for Case 2, in which the antenna array is in air, while the target in an adipose layer. Black dots indicate the position of the antennas, the black dashed line indicate the interface between air (from z=0 to z= 75 mm) and the adipose layer (from z=75 mm to z= 100 mm).

Downstream of the calculation of the round-trip path to and from the target, equation (1) was used to calculate the scattering matrix corresponding to the target.

The interface, on the other hand, was modeled as a delay matrix with an amplitude dependent on the dielectric characteristics of the skin, using the following equation:

$$S = \Gamma(\lambda^4) e^{-j2\pi f\tau} / {R_t}^2 {R_r}^2 \qquad (3)$$

Where Γ is the reflection coefficient used to model the reflection from the skin, λ is the wavelength, f is the frequency, R_t is the path from the transmitting antenna to the target, R_r is the path from the target to the receiving antenna, and τ is the corresponding round-trip time.

Then, this was added to the target contribution to create the complete matrix (exemplifying assumption). The full scattering matrix was used as input into the Delay-And-Sum beamforming algorithm. The propagation speed used in the image reconstruction in this second scenario was calculated as a weighted average over the two paths through the two media. In the configuration corresponding to Figure 6, the antennas are in air, while the target is immersed in a non-dispersive layer of fat with dielectric properties equal to ε' = 3 and ε " = 0.3 [6]. In this image, both the interface and the target are clearly seen.

D. Case 3: Non-punctiform targets in single and multiple layers

Finally, we tried to reconstruct the scattering matrix related to non-punctiform targets, both in absence and in presence of the interface. Specifically, multiple targets were modeled as a succession of punctiform targets, and the corresponding scattering matrices were summed. Again, for simplicity, we did not model the mutual interaction between targets (exemplifying assumption). To test the robustness of our models against targets at arbitrary positions in the domain of investigation, we modeled the logo of the Microwave Laboratory of the University of Pavia, which in some ways represents a relatively complex target. In Figure 7, its radar image in air is shown.

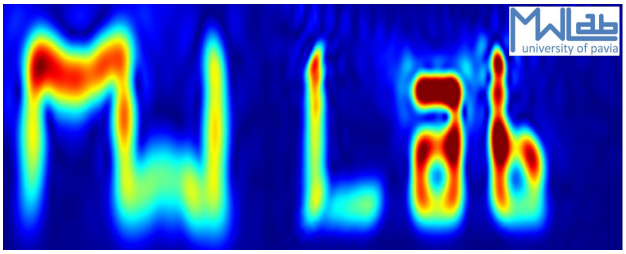

Fig. 7: DAS image of the modeled logo of the Microwave Laboratory of the University of Pavia in air.

IV. Conclusion

In this paper, some of the main results obtained in recent years by the Microwave Laboratory and the Bioengineering Laboratory of the University of Pavia about the study of a new mm-wave imaging system for breast cancer detection have been presented. In addition, we presented for the first time the numerical models we developed to overcome the limitations of full-wave simulations. In this way, even if with some tolerable exemplifying assumptions, it is possible to compute very quickly the scattering matrix corresponding to somehow complex synthetic scenarios, possibly useful not only for the tuning of skin-reflection removal algorithms, but also for the training of artificial neural networks to be used for artificial intelligence purposes, in which it becomes carrier to have a huge amount of data, albeit approximated.

Ultimately, the results obtained show the robustness of the models. This is the starting point for implementing also the mutual interaction between different structures.

***Abstract*—A person's mobility can be examined to learn vital details about their health.Non-contact technology can be used for this investigation with the aim of ensuring freedom of movement of the subject and realistic analysis of movement. Automotive mmWaves radars, while made for different uses, are a powerful low-cost technology for detecting human movement without physical contact, which can introduce fascinating implications as an aid to health monitoring at home or at work. This paper shows how to process the data recorded by commercial radars to extract simple spatio-temporal parameters of people's walking. The processing algorithms provides the cadence, step length and step duration with a good approximation of the true gait parameters.**

***Keywords*—e-health, human gait, mmWave radar.**

I. INTRODUCTION

Under the broad umbrella of *e-health* [1], contactless monitoring of vital parameters aims at becoming a viable substitute for traditional methods, which often employ cumbersome and inconvenient sensors on the human body. On the other hand the advantage of non-contact methods is precisely to provide an unobtrusive measurement of different subjects' conditions.

The human gait provides useful information about a person's health status and its applications are numerous, such as clinical gait characterization for pathological disorders, automated person detection for security purposes, and even biometric identification [2]. Among the different contactless technologies, radars have attracted the attention of the scientific community thanks to their precision and versatility applied to the medical field. Examples include the remote monitoring of heart rate and respiratory frequency [3], the measurement of people's velocity and gait style [4] and the identification of different parts of the human body [5]. Furthermore, Continuous Wave (CW) radar are applied to acquire general gait parameters, as the speed of the torso, the step duration and the step asymmetry [6], or even more precisely the linear velocity of the single joint by making the subject walk on a treadmill and thus removing the main Doppler component given by the torso velocity [7]. In this paper we employ an automotive frequency Modulated Continuous Wave (FMCW) radar with the aim of extracting cadence, step length and step duration from the normal gait of one subject. We exploit radar bi-dimensional maps, which are related to range (distance) or Doppler signal (velocity) across time. Different algorithms are compared for the extraction of micro-Doppler signature envelopes which are related to the movement of limbs. The results are compared to the same parameters extracted from a motion capture system representing the gold standard. By adding the range information, our approach allows to directly compute the step lengths, differently from the CW radars used in the literature [6], [7], which allow only Doppler-time information to be extracted and thus to calculate the step length indirectly, using the estimated average velocity and step duration.

II. EXPERIMENTAL SETUP

The radar here employed is the Texas Instruments AWR 1642 [8] shown in Figure 1. It works in the frequency range between 77 and 81 GHz in FMCW mode, transmitting a chirp signal with a frequency that is linearly modulated in time. The chirps are sampled at a sampling frequency of 10 MHz for a total of 512 samples per chirps and the total time occupied by a single chirp is set to 0.16 ms. The chirps are grouped into 128 to form a frame lasting a 'periodicity' of 25 ms. Thus, the total chirp time is 81.92% of the periodicity to give the device time for the processing of the the chirp signals. 400 frames are collected, with a total acquisition time of 10 s. The slope is set up to 60.012e12 Hz/s, leading to a bandwidth of 3.6 GHz. The choice of the mentioned radar parameters is the same of [4], where the same radar was comprehensively tested for gait pattern analysis and classification.

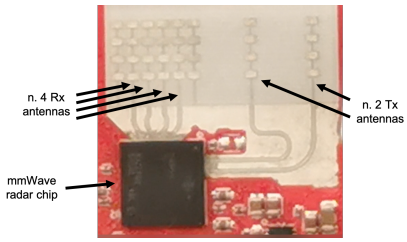

Fig. 1: mmWave radar component with antennas.

During the experimental tests, one subject was asked to walk on a straight path in a radial direction with respect to the radar for three trials, including both a motion towards the radar and a motion away from the radar. The reason we choose a radial walking direction is because the radial velocity components are the ones that produces the best frequency response. A diagonal or even perpendicular walk with respect to the radial direction of the radar will produce a decreased Doppler signal, because a smaller portion of the velocity of the limbs and torso is in the radial direction to the radar [9]. The three trials correspond to three slightly different experimental setups:

1) in trial 1 (T1) the subject starts at about 5 meters from the radar and walks towards the radar and then back;
2) in trial 2 (T2), the subject starts near to the radar, walks away for about 4 meters and came back;
3) in trial 3 (T3), the subject repeats the instructions given in trial 2 but with the hands in the pockets.

The rationale behind the choice of the first two experimental setup is given by the greater attenuation of the signal received by the radar as the subject is far away from the radar, therefore in the first trial we are going to see the subject and its steps with increased clarity as it proceed towards the radar, whereas the opposite is true for the second trial. In the third trial, we decided to remove the movement of the upper limbs, which contribute to the micro-Doppler signature extracted from the radar to understand if this is a way to increase the accuracy of the parameters extraction. The background environment in absence of subjects is also analysed in the same way with both range-time and Doppler-time maps. As a ground truth, two retro-reflective markers are placed on both feet at the position of the prominence of the calcaneus and the first metatarsal head (toe). The BTS Bioengineering motion capture system, composed of eight optoelectrical motion cameras, is employed to extract the position of both the markers at a frequency of 250 Hz. The markers define a three-dimensional position in x being the medio-lateral direction, y being the vertical direction and z being the anterior-posterior direction, corresponding to the radial direction to the radar. The vertical trajectory of the calcaneus is used to extract the heel strike event, corresponding to the start of a normal gait. Once the heel strike time points are defined it is possible to derive the steps duration, steps length and cadence of the subject exploiting the anterior-posterior trajectory of the marker positions (see Fig. 2). We examined a total of 13 steps for the first, 11 steps for the second and 12 steps for the third trial. We computed the cadence for each trial as the number of steps divided by the considered time period.

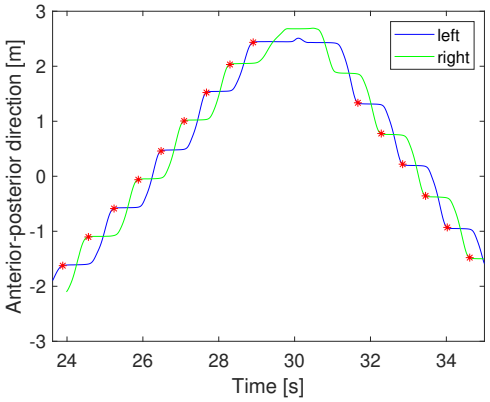

Fig. 2: Movement of both calcanei along the anterior-posterior direction (radial direction to the radar) extracted with the BTS; the red asteriks represent the heel strike time points events. The zero value corresponds to the center of the system of reference considered by the BTS.

III. Radar Data Signal Processing

A. Range-time map and Doppler-time map extraction

The data coming from four receiving antennas are summed together to improve the signal-to-noise ratio. The obtained signal is than reshaped into a three-dimensional configuration following in order the 512 samples, which represents the fast time, then the 128 chirps, representing the slow time, and the 400 frames. For each time frame, a raw matrix of dimension 512x128 is obtained, on which a two-dimensional Fast-Fourier Transform (FFT) is applied to extract the range-Doppler information. The result is a cube of data representing range, Doppler and time information. This cube is then compressed summing the values along the Doppler dimension to obtain a bi-dimensional range-time map (see Fig. 3). In addition, a Doppler-time map is extracted exploiting repeated spectrograms. The original mono-dimensional data extracted from the radar is reshaped into a 512 x 51200 bi-dimensional map. We first apply a FFT along the columns to extract range information and then along the rows a Short Time Fourier Transform, applied to Hamming windows of 128 samples with no overlap between them. The dimension of the obtained spectrograms is 128x400. The resulting 512 spectrograms, one for each range value, are summed to form a bi-dimensional description of Doppler-time evolution of dimension 128x400.

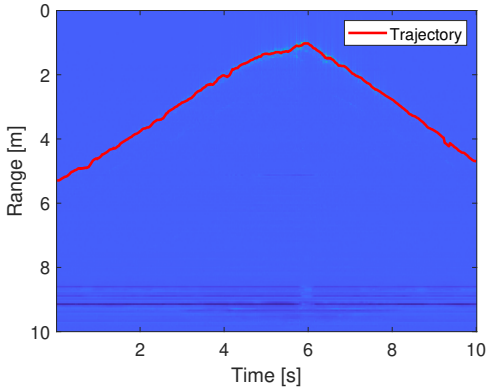

Fig. 3: Range-time map extracted from the first acquisition with the radar.

B. Extraction of torso Doppler envelope

The Doppler-time map is used to extract the torso Doppler envelope and the micro-Doppler envelope, dependent on the torso movement and on the limb movement, respectively. The torso Doppler envelope is extracted by computing the maximum Doppler intensity for each time frame. Then, we convert the torso Doppler values to velocity and the obtained torso velocity envelope was cleaned by removing from the signal derivative spikes values higher than 2g and maintaining the values below, which describe 99.21% of the possible accelerations values at the tested speed, always below 2 m/s [10]. The removed values from the torso velocity were then linearly interpolated using the remaining ones.

Given the torso velocity envelope, we extract the cadence, measured as number of steps per minute, with:

- The application of the FFT on the envelope to extract the higher harmonic, interpreted as the number of steps per seconds, then multiplied by 60 to obtain the cadence.
- The application of a second order butterworth bandpass filter with cutoff frequencies at 0.5 Hz and 2 Hz and the evaluation of the local minima of the torso Doppler envelope, from which the time points of individual steps were extracted. In this case the cadence is calculated as number of steps divided by total step duration.

In addition, the maximum intensity values are extracted from the range-time map to form a range profile curve. The time points corresponding to each step are then transferred to the range-time curve where the corresponding range are computed to extract the step length. We compute the median values and interquartile ranges of the absolute difference of step duration and length with respect to the ground truth. The choice of the median values is justified by the small number of steps analysed and to exclude possible outliers.

C. Extraction of micro-Doppler envelope

The extraction of the micro-Doppler Envelope (microDE) starts with a the application of a threshold to produce a binary map in the Doppler-time. The threshold is chosen according to five different methods:

- The mean Doppler intensity for each time point.
- The 1/100 of the maximum Doppler intensity for each time point [6].
- A two-dimensional Cell-Averaging Constant False Alarm Rate adaptive thresholding technique. A training size of 50 cells and a guard cells size of 10 was used to compute the adaptive threshold.
- A threshold based on the first deviation of the power histogram of the Doppler-time corresponding to the subject with respect to the background.

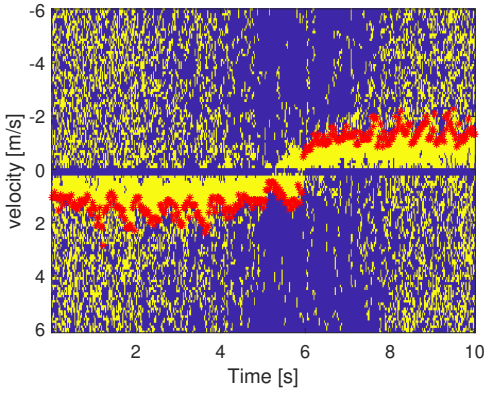

Fig. 4: Example of binary map extracted with a threshold equal to one hundredth of the max intensity of each row. The red asterisks represent the chosen envelope points.

The application of the mentioned threshold enables to create a noisy binary map which is first cleaned by removing the groups of less than two contiguous pixels with value 1 surrounded with background values equal to 0. The MicroDE

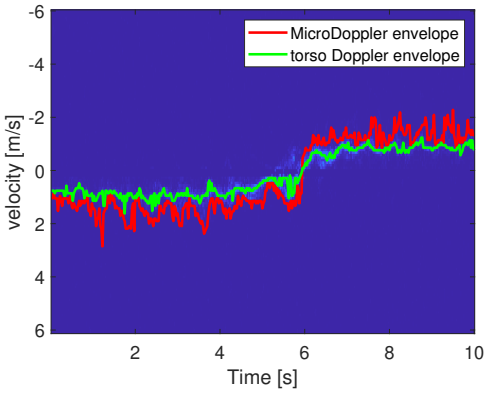

Fig. 5: Velocity-time map with the extracted torso doppler and micro Doppler envelope using the binary map in Figure 4.

is extracted by taking the first variation from 1 to 0 after the torso Doppler value in the positive direction for positive velocity and in the negative direction for negative velocities in each time point of the binary map as can be seen from figure 4 and 5. We apply the same processing on the microDE as explained for the torso Doppler envelope to extract cadence, step duration and length and compare the results with the ground truth.

IV. RESULTS

We now report the results obtained for the different gait parameters considering all the methods discussed in Section III. In the rest of this section, we consider the following notation to indicate the type of extraction process: GT = ground truth from markers; A = torso Doppler envelope; B = microDE from mean Doppler; C = microDE from fraction of the max Doppler; D = microDE from 2D-CFAR; E = microDE from power threshold. The computed cadence for the three trials is 97.9, 105.2 and 110.6, respectively. The results obtained for step length and step duration are compared to the ground truth extracted in a movement lab reporting median absolute error and interquartile ranges in Tables II, III and IV. The results about cadence are reported in Table I, where the numbers in the first column indicate the cadence extraction from one of the two local maxima (1) or first harmonic (2). Each row of the table show the difference (bias) of the cadence extracted from the respective method when compared to the ground truth. Considering all trials, the median absolute error of step length always remains in the centimeter range for method D and E, which is comparable to state-of-art methods for estimating the step length under indoor walking conditions using wearable sensors [11]–[13]. Method A has a median absolute error in the decimeter range for trials 1 and 2 while method B and C have the same magnitude of error for the step length estimation in trial 2. All methods perform well for the step duration estimation, but method B and C are affected by trial configuration 2. Compared with the other methods, D and E seem to be more robust against changes in experimental settings, probably because the thresholds are set according to the noise level of the background environment. Trials 2 and

3 produce the largest difference in cadence from the ground truth, as can be seen in Table I. The major cadence biases for trials 2 and 3 may be caused by the subject's choice of path, as explained in Section II. The reason why the robustness of methods D and E toward the test configuration is not valid for cadence estimation could be due to the observation time limited to 10s. Future approaches should increase the number of steps observed and the time window to report cadence with an higher reliability. A limitation of the proposed method can also be noticed in the last column of Tables II, III, IV, where the number of measured steps is always less than the actual number of steps performed by the subject with the exception of method B and E of Table III. This is probably due to the increasing attenuation of the received signal when the subject is far away from the radar, leading to a loss in the total measured steps.

TABLE I: Bias of each method when comparing the cadence (steps/min) to the BTS.

Method	*cadence T1*	*cadence T2*	*cadence T3*
A1	0.9	-4.0	-7.2
A2	-0.3	9.1	-7.4
B1	-1.1	-2.1	-11.6
B2	-0.1	-5.0	7.0
C1	-0.7	-11.8	-3.0

V. CONCLUSION

In this paper, we studied the contactless extraction of typical parameters from the normal gait of a subject using a commercially available radar sensor. After extracting Doppler-time and range-time maps from raw radar data, the torso Doppler envelope and the micro-Doppler envelopes were derived to obtain the cadence, the step duration and the step length. The proposed methods have proven their effectiveness against the chosen ground truth, with low median absolute errors for step length and step duration and low biases for the cadence. We then demonstrated the feasibility of this contactless structure for the extraction of simple spatio-temporal gait parameters. Future works will include the application of this technique to larger groups of individuals to better validate the results and developing methods to better discriminate the motion of individual joints in order to extract their velocity curve.
